Methylation.—All attempts to methylate the ester resulted in the formation of a strongly acid substance, which remained in the alkaline aqueous solution obtained on working up the product in the usual way; mineral acids precipitated a solid, melting at 135° after purification, giving an intense green colour with alcoholic ferric chloride, and having all the other properties of ethyl 2:6-dicyano-1 : 1 : 5-trimethyl- Δ^2 : Δ^4 -cyclohexadien-3-ol-6-carboxylate (Gardner and Haworth, *loc. cit.*) (Found: N = 11.44. Calc., N = 10.77 per cent.).

The same compound was formed when the cyano-ester was added

to an excess of alcoholic sodium ethoxide. The reaction appeared to be almost instantaneous and on pouring the mixture into water no oil was precipitated; on acidifying the solution with mineral acid, the compound m. p. 135° separated as an oil which soon solidified.

Ethyl α -Cyano- $\beta\beta$ -diethylacrylate.

A mixture of diethyl ketone (84 grams), ethyl cyanoacetate (113 grams), and piperidine (1 c.c.) was digested on the steam-bath for forty-eight hours. The mixture was dissolved in ether, washed with dilute hydrochloric acid, then with water, dried, and the ether removed with the aid of a column. The residue was distilled under reduced pressure, giving 25 grams of an oil boiling above $140^{\circ}/35$ mm.; this on redistillation gave 9.5 grams boiling at 127 — $132^{\circ}/30$ mm. and 8 grams at 132 — $140^{\circ}/30$ mm.; more of the latter was obtained by redistilling the lower fractions. The highest fraction consisted of almost pure ethyl α -cyano- $\beta\beta$ -diethylacrylate and had d_4^{25} 0.99690, n_D^{25} 1.46649, and $[R_L]_D$ 50.37 (Found: N = 8.21. $C_{10}H_{15}O_2N$ requires N = 7.74 per cent.).

The low fractions obtained in this preparation consist of unchanged starting materials and can be used again.

The condensation can also be carried out using acetic anhydride and zinc chloride as condensing agents, but this method presents no advantages over that described above. A specimen of the ester obtained in this way had d_4^{25} 0.994105, n_D^{25} 1.46699, and $[R_L]_D$ 50.56 (calc. 49.27).

The ester condensed readily with ethyl cyanoacetate and alcoholic ammonia, and an almost quantitative yield of the ω -imide of $\alpha\alpha'$ -dicyano- $\beta\beta$ -diethylglutaric acid was obtained, the compound melting at 202° (Guareschi, *loc. cit.*); it was identified by direct comparison with a genuine specimen.

In conclusion, our thanks are due to Professor J. F. Thorpe, F.R.S., for his kind interest in the progress of this investigation.

CCLXXIX.—The Low Temperature Activation of Hydrogen.

By ALLAN ERNEST MITCHELL and ABRAHAM LINCOLN MARSHALL.

IN connexion with this work it is, in the first instance, opportune to give some account of the work carried out by Dr. S. Judd Lewis at the suggestion of Mr. Colin E. Campbell in 1918—1919, a note of which (privately communicated to the authors) is appended:

"From consideration of several catalytic phenomena, in particular the low temperature reduction by hydrogen of copper oxide associated with a small percentage of palladium (Campbell, *Amer. Chem. Journ.*, 1899, 17), Mr. Colin Campbell concluded that there must be an ultra-molecular effect, and arranged with Dr. Judd Lewis for a course of experiments, which were carried out in two stages.

"The first series consisted in applying hydrogen to the reduction of copper oxide placed just below and out of contact with a thin sheet of palladium. A comparison of the temperatures at which reduction took place under those conditions with those necessary in the control experiments carried out in the absence of palladium, showed a marked effect due to the vicinity of that metal.

"It was an interesting feature of these experiments that the copper oxide nearest to the source of hydrogen was completely reduced, down to the bottom of the boat, as far as (as observed in the last three experiments) 5 cm. from the palladium asbestos, whatever the position of the boat, while there was no reduction whatever throughout the rest of the boat, either on the surface or in the body of the copper oxide. Dr. Lewis is of opinion that this effect would repay investigation.

"In the second series of experiments, palladium asbestos was employed. Hydrogen was passed over copper oxide by way of a tube in which the asbestos was placed at a distance of 3 cm. from the oxide. The following (Table I) shows the results obtained under these conditions.

TABLE I.

Expt. No.	Temper- ature. B. = blank. E. = expt.	Rate of flow of H ₂ . Bubbles per minute.	Duration of expt. (mins.).	Grams of copper oxide taken.	Loss in weight of copper oxide by reduction.

"It was found that the active hydrogen reduced oleic acid (as olive oil) but did not reduce indigo solution and lost its power at a moderate distance from the palladium."

At the suggestion of Professor Donnan, Anderson (T., 1922, 121, 1153) carried out some work in which he found that apparently pure, dry hydrogen, when passed over platinised asbestos, acquired abnormal properties enabling it to react with other substances, such as cupric oxide, at much lower temperatures than when no platinum was present. He also found that this abnormal hydrogen was unstable, the effect only being obtained within a distance of 5 cm. from the platinum. A critical examination of his methods of hydrogen purification left considerable doubt as to its purity, and therefore it was thought necessary to repeat some of the work, taking extreme precautions with the manipulation.

EXPERIMENTAL.

Accordingly, an apparatus (Fig. 1) was constructed which made it possible to use absolutely pure hydrogen. The gas from various sources, but principally either from the commercial cylinder supply or from the electrolysis of purified baryta solution, was passed through a tube carrying a small electric furnace. This tube contained a platinum-palladium diffusion tube sealed directly into the reaction tube. The temperature of the furnace was maintained at about 800°, and the external hydrogen pressure at 2–3 atmospheres, when it was found that the gas readily passed through the palladium and was thus purified by direct diffusion into the apparatus. The whole apparatus could be closed from the air, the ground joints *A* and *B* being lubricated with pasty phosphoric acid and mercury-sealed. The silica boats containing the samples were provided with sealed-in iron cores and were capable of being moved by a magnet during the course of an experiment without the apparatus being opened. The moisture indicator consisted of two platinum wires sealed into *B*, their inside ends being joined by a bead of anhydrous calcium chloride. Of the outer ends, one was insulated while the other made contact with the mercury of the seal. This arrangement was connected in series with a sensitive galvanometer and a 4-volt battery, so that any change in surface conductivity due to hydration of the calcium chloride would be shown by a deflection of the galvanometer. The reaction tube was about 60 cm. long, the length of the part indicated within the oil-bath being 25 cm. The outlet tube passed through a spiral cooled in liquid air, which served to remove any moisture possibly diffusing back, and to condense any mercury vapour or heavy hydrocarbon vapour possibly diffusing, during the evacuation, from the outlet tap, *C*, which was lubricated by rubber tap grease, previously heated at 200° under diminished pressure for several hours. The portion of the tube outside the oil-bath carried an electric

furnace capable of giving temperatures up to 300° , so that if necessary the boats could be withdrawn from the portion within the oil-bath and heated to that temperature.

It was decided to follow Anderson, and employ the temperature of reduction of cupric oxide as a test for the activity of the hydrogen.

The platinised asbestos used was prepared according to Lunge ("Technical Gas Analysis") and was placed in its silica boat in a glass tube heated at 200° . Air was swept out by passing dry nitrogen; hydrogen was then admitted and passed for thirty minutes. This was removed by passing more nitrogen, and then oxygen was passed for the same time. This process was repeated six times, the boat allowed to cool, and then transferred quickly to the reaction tube through *A*.

The cupric oxide was precipitated from a boiling solution of copper sulphate by addition of alkali, washed free from salts by boiling water, and dried. It is well known that the reactivity of cupric oxide depends on its previous treatment. In all the experiments described, therefore, with the exception of the first three, the samples were prepared in the following manner. The silica boat, containing the sample, and the platinised asbestos were heated in the same tube at 200° . Oxygen was swept out with

nitrogen and the substance alternately reduced and oxidised in the same manner as the platinum, each process occupying an hour and being repeated six times. The oxide was finally cooled and transferred to the reaction tube through *A*.

The sensitivity of the moisture indicator was tested from time to time by passing in air saturated with water vapour from 85–90 per cent. sulphuric acid at 20°, and was found to be sensitive at once to this amount of moisture, the partial pressure of which is of the order of 0.15–0.10 mm. (Landolt-Börnstein, "Tabellen").

The apparatus was exhausted by means of a Völmer pump and the vacuum maintained over a period of twenty-four hours (the pressure, therefore, could not be measured by means of a McLeod gauge of 100 c.c. capacity), the platinised asbestos and cupric oxide being in the outer portion of the tube and maintained at 300°. After twenty-four hours, the cupric oxide was moved up until it was immediately below and at a distance of about 5 cm. from the indicator. The diffusion tube was then heated, and hydrogen admitted and allowed to escape at *C* under atmospheric pressure. The temperature of the oil-bath was raised slowly until a deflection of the galvanometer indicated the formation of water by the reduction of the oxide. The hydrogen was then stopped, the calcium chloride dried by means of a small heating coil, *F*, and the apparatus again evacuated for twelve hours. The platinised asbestos was then moved up into close proximity to the oxide and the experiment conducted as before. In all cases, unless otherwise specifically stated, the rate of flow of the gas stream was 35 c.c./minute.

A series of such determinations were made with the following results, the term "control" being applied to experiments in which the platinised asbestos was in the outer portion of the tube :

Reduction Temperature.

Control	135°	125°	140°	118°	115°	118°	116°
Pt. adjacent	135.5° *	124.5° *	139° *	117.5°	115°	117°	117°

* These samples were prepared by reduction at haphazard temperatures.

Experiments were then made in the same manner using cylinder hydrogen, which contained 0.2 per cent. of oxygen and no measurable amount of carbon monoxide. The gas was dried by passage through about 14 inches of phosphoric oxide and a liquid air-cooled coil to remove possible grease or volatile phosphorus compounds.

The following results were obtained :

Reduction Temperature.

Control	118°	117°	117°	116°	116°
Pt. adjacent	82°	83°	82°	82.6°	89°

The hydrogen was found to be activated in all cases, and by moving the platinum progressively further from the oxide, it was found that no activation could be detected if the distance were greater than 5.5 cm., at which extreme range the reduction temperature rose to 84° and beyond which all were of the order of 117°.

These results lead us to suppose that the activation was due to the presence of oxygen, and therefore experiments were made in which small quantities of pure oxygen were mixed with pure hydrogen. A side tube with a ground joint was introduced at *E*. The joint was lubricated with pasty phosphoric acid and mercury-sealed, and the tube contained a known weight of purified potassium permanganate. Pure oxygen was then generated by carefully and regularly warming the permanganate, the liquid air-cooled tap serving to remove any moisture. Then, the rate of flow of the gas stream, the time of the experiment, and the loss of weight of the permanganate being known, the percentage of oxygen added was determined. In such a series the results were :

Reduction Temperature.

% Oxygen.	Control.	Pt. adjacent.	Activity range (cm.).
0.21	118°	83°	5.5
0.15	118	82.5	5.0
0.12	117	83	5.0
0.08	117	83	5.5
0.05	116	83.5	5.5
0.02	118	83	5.0

Owing to difficulty in maintaining a steady evolution of oxygen, it was found impossible to work with quantities less than 0.02 per cent. by this method. In all these cases the range of activity was again about 5.5 cm.

Pease and Taylor (*J. Amer. Chem. Soc.*, 1921, **43**, 2197) claim :

(1) That the reduction of copper oxide by hydrogen is autocatalytic, depending on the formation of copper nuclei in the copper oxide surfaces, and that reduction takes place only at these interfaces.

(2) That the presence of oxygen is anticatalytic to the reduction of the oxide.

This second view supports the observations of Bone and Wheeler (*Phil. Trans.*, 1906, **206**, [A], 1).

It was thought in the first instance that, if the first point raised by Pease and Taylor were of consequence, once the copper oxide were slightly reduced, further reduction in the absence of platinum might be catalytic and could possibly take place at a lower temperature. In all the experiments described, however, check controls were made after the reduction with platinum present, and in every

case they agreed closely with the original controls. To test this idea further, experiments were made in which two separate samples of oxide were prepared under identical conditions. One was used for the control experiment, the other being placed meanwhile in a vacuum desiccator. The control having been made, the oxide was removed and the second sample placed in its stead, and the experiment repeated with the platinum adjacent. In these experiments, dried cylinder hydrogen (containing 0.2 per cent. of oxygen) was used and the following results were obtained :

Reduction Temperatures.

Control (sample 1)	117°	116°	118°	117.5°
Pt. adjacent (sample 2)	83°	82°	83°	82°

Thus it would seem that the lowering of reduction temperature in presence of platinum is not influenced by the presence or absence of copper-copper oxide interfaces in so far as they can be decreased by alternation of reduction and oxidation in the preparation of the sample.

In order to investigate the possible formation of water due to the combustion of hydrogen on the platinum surface, experiments were made with platinised asbestos alone, occupying the place of the copper oxide. Cylinder hydrogen was dried by phosphoric oxide and passage through the liquid air-cooled trap. The temperature of the bath was raised slowly to 80° and maintained at 80—85° for two and a half hours, and was then again raised slowly to 110° and kept at 110—120° for a further two and a half hours, due allowance thus being made for possible adsorption on the walls of the tube. At neither temperature was water indicated. Analysis of the issuing gas showed it to be deficient in oxygen, the amount of which could not be estimated accurately.

The experiment was repeated at 80—85°, the gas stream being passed for six hours. The platinised asbestos was then withdrawn to the outer portion of the tube, and heated at 300°, a stream of dry nitrogen being passed in place of the hydrogen. The presence of water in the nitrogen stream could then be detected by the indicator. On repeating the experiment at 80—85°, it was found that the hydrogen stream had to be passed for at least twelve hours before the moisture indicator was affected. The effect was a cumulative one in that the conductivity of the calcium chloride increased very slowly, a definite deflection of the galvanometer being obtained only after twelve hours. At 110—120°, the same effect was produced in eight to nine hours.

The whole series of experiments was repeated, (1) the amount of platinised asbestos and of cupric oxide being varied between

0.5 gram and 1.5 grams, (2) the rate of flow of the hydrogen and of the mixtures being varied between 10 and 100 c.c./minute.

The results obtained confirmed those of the earlier experiments, except that with rates of flow of 75–100 c.c./minute the reduction temperatures with platinum adjacent varied over a range of 84–90°, and the range of activity decreased to about 2 cm.

Experiments in which plugs of glass-wool and purified phosphoric oxide were introduced between the platinised asbestos and the copper oxide indicated that for a certain period, ranging between fifteen and sixty minutes, the activity was destroyed, but after that period the results were the same as before.

Discussion.

Regarding the activation of hydrogen by these methods, the results of Anderson are confirmed. It is clear, however, that the activation is not a property of pure hydrogen, but can be attributed to the presence of traces of oxygen, amounts as low as, and perhaps lower than, 0.02 per cent. being sufficient to produce it. It is probable that, although Anderson took precautions to remove oxygen, some was left, although the amount should have been less than 0.02 per cent.

We have shown that some combustion of the hydrogen does take place on the platinum at 80–85°, and also at 110–120°, but that the water formed, or at least most of it, is retained on the surface. The effect is cumulative and a considerable period must elapse before the surface becomes sufficiently saturated to allow of enough water passing on to affect the indicator, upon which the effect is again cumulative, the conductivity increasing very slowly and not rapidly as in the case of copper oxide reduction.

If the pressure measurements of Anderson be considered, it would seem that the active hydrogen is not the triatomic gas of Usher (T., 1910, **97**, 400), Lind (*J. Amer. Chem. Soc.*, 1919, **40**, 454), Collie and Patterson (P., 1913, **41**, 545), Chattock and Tyndall (*Phil. Mag.*, 1908, [vi], **16**, 24), and Wendt (*J. Amer. Chem. Soc.*, 1920, **42**, 930).

Bone and Wheeler (*Trans. Faraday Soc.*, 1922, **51**, 659) explain the activation of gases on surfaces as due to ionisation on desorption.

Venkataramaiah and Swamy (*Proc. Sci. Ass. Maharajah's College, Vizianagram*, Dec., 1922, p. 23; *Chem. Abstracts*, 1923, **17**, 1908) have shown that hydrogen is activated by diffusion through platinum or palladium at 400–500°, and that the gas produced is probably ionised, since it discharges a gold-leaf electroscope.

Working with hydrogen alone, Wendt and Landauer (*J. Amer. Chem. Soc.*, 1922, **44**, 610) have shown that formation of triatomic

hydrogen is effected by contact with a heated platinum wire. Venkataramaiah (*J. Amer. Chem. Soc.*, 1923, **42**, 930) has described the activation of hydrogen by the combustion of hydrogen and oxygen on hot platinum surfaces, and claims that in the reaction the gases are ionised and triatomic hydrogen results. All the experiments in which the production of triatomic hydrogen is claimed were carried out at high temperatures, or, as in the cases of Usher and Lind, by α -particle bombardment; whilst in the present work it is certain that the temperature in general never rises above 120°. At these temperatures it does not seem likely that increase in electron emission or ionisation should be sufficient to impart to the gas its greater activity. Also since the introduction of plugs of glass-wool and phosphoric oxide have been shown to have no effect on the activation other than that of retarding it, the possibility of reduction by hydrogen atoms or ions is precluded, since they will not survive such treatment. A possible explanation of the activation therefore presents itself in the formation of triatomic hydrogen either by ionisation by desorption, or by the local high temperatures which must result from the small amounts of combustion. It must be remembered that the amount of triatomic hydrogen produced under these conditions must be very small, and it is not surprising that Anderson's pressure measurements did not indicate any molecular rearrangement.

From comparison with other experimental work, we can only come to the conclusion that the activity is due to the formation of small amounts of triatomic hydrogen, and that the apparent differences in its behaviour as compared with that of the substance produced by Wendt and others are due more to differences of concentration than of constitution; this view, however, does not preclude the possible occurrence of a different modification of triatomic hydrogen. The energy hypothesis, as offered by Anderson, does not seem necessary to explain the observed phenomena.

Summary.

- (1) Low temperature activation of pure hydrogen by contact with platinised asbestos does not occur.
- (2) It has been shown that traces of oxygen down to 0.02 per cent. will promote the activation, and that there is combustion of some of the hydrogen during the process.
- (3) The active hydrogen produced under these conditions is unstable—only persisting for a distance of 5 cm. from the activating surface, thus confirming the results of Anderson and Judd Lewis. The activity is apparently independent of the amount of platinum, but varies slightly with the time of contact.

(4) It is thought that the activity is due to the production of triatomic hydrogen in very small quantities, promoted by ionisation induced by the local high temperature of the combustion.

In conclusion, the authors thank Professor F. G. Donnan, at whose suggestion this investigation was made, for his advice and helpful criticism, and Dr. Judd Lewis and Mr. Colin Campbell for communicating their results.

CCLXXX.—*The Hydroferrocyanides and Hydroferricyanides of the Organic Bases. Part II.*

By WILLIAM MURDOCH CUMMING.

In continuation of work already described (T., 1922, **121**, 1287), several new hydroferrocyanides have been prepared; their properties conform with the results already obtained. Attempts to prepare hydroferrocyanides of ethylenediamine, pyrrole, carbazole, and 3-aminocarbazole have been unsuccessful. The salts were all precipitated in acid solution.

Unless stated otherwise, the formulæ of the following salts are of the type $(\text{Base})_2\text{H}_4\text{Fe}(\text{CN})_6 \cdot 2\text{H}_2\text{O}$.

Piperidine Hydroferrocyanide.—Yellowish-white, rhombic crystals, soluble in hot water, the solution being decomposed on continued boiling; decomposed by acetyl chloride in the cold. The salt becomes bright yellow, then orange on heating; it turns bright green on standing, the base being given off (Found: Fe = 13·10; N = 26·40. Calc., Fe = 13·27; N = 26·54 per cent.). The salt examined crystallographically by Hiortdahl (*Jahresbericht*, 1886, **1**, 512) consisted of yellow, triclinic prisms, $(\text{C}_5\text{H}_{11}\text{N})_4\text{H}_4\text{Fe}(\text{CN})_6 \cdot 3\text{H}_2\text{O}$, but no indication was given of the method of preparation.

Piperazine Hydroferrocyanide, $\text{C}_4\text{H}_{10}\text{N}_2\text{H}_4\text{Fe}(\text{CN})_6 \cdot \text{H}_2\text{O}$.—Green, rhombohedral crystals slightly soluble in water, a yellowish-green precipitate being thrown down from the solution on boiling; not decomposed by boiling acetic anhydride. The salt changes to bright yellow on heating and is stable (Found: Fe = 17·44; N = 35·03. Calc., Fe = 17·50; N = 35·00 per cent.).

1. *Menthylamine Hydroferrocyanide*, $\text{C}_{10}\text{H}_{21}\text{N}_2\text{H}_4\text{Fe}(\text{CN})_6 \cdot 3\text{H}_2\text{O}$.—White, rhombohedral crystals with bluish tinge; precipitated only by saturated sodium ferrocyanide solution; fairly soluble in water and soluble in excess of sodium ferrocyanide solution, both solu-

tions being decomposed on boiling. The salt turns blue on standing (Found : Fe = 13.06; N = 23.11. Calc., Fe = 13.17; N = 23.06 per cent.). The salt loses its water of crystallisation on keeping for twenty-four hours in a desiccator over concentrated sulphuric acid (Found : Fe = 14.97. Calc., Fe = 15.09 per cent.).

Methyldiphenylamine Hydroferrocyanide,

—The base is soluble in concentrated hydrochloric acid, but is precipitated on dilution. When saturated sodium ferrocyanide solution is added to the solution, a hydroferrocyanide as well as the base is precipitated; the base is removed by washing with absolute alcohol. White square plates, decomposed by hot water, the base being liberated as an oil; soluble in hot absolute alcohol, no decomposition taking place on boiling. Like the free base, it gives a violet coloration, turning blue then black on heating, with concentrated sulphuric acid. The salt gives off water on heating and turns green on keeping (Found : Fe = 10.54; N = 18.55. Calc., Fe = 10.66; N = 18.66 per cent.).

Tetramethyldiaminodiphenylmethane Hydroferrocyanide,

—White prisms, slightly soluble in water, from which it crystallises in green prisms; the solution decomposes on continued boiling. The salt turns green on keeping (Found : Fe = 11.01. Calc., Fe = 11.06 per cent.).

Hexamethylenetetramine Hydroferrocyanide,

—Green, rhombic prisms, fairly soluble in cold, readily soluble in hot water, from which it crystallises in greenish-yellow needles; the solution on continued boiling deposits a bright green precipitate, the usual decomposition not taking place. The salt turns bright yellow on heating, much water being given off; it is stable on keeping (Found : Fe = 8.96. Calc., Fe = 9.00 per cent.). The greenish-yellow needles formed on crystallisation from hot water contain $8\text{H}_2\text{O}$, and have similar properties (Found : Fe = 8.74. Calc., Fe = 8.75 per cent.).

Dimethylaminoazobenzene Hydroferrocyanide.—Dark red plates, slightly soluble in water and soluble in absolute alcohol, giving red solutions which are not decomposed on continued boiling and are turned yellow by alkalis. The salt gives off red vapours, then yellow, when heated, but is stable on standing (Found : Fe = 7.97. Calc., Fe = 7.97 per cent.).

Monomethyl-p-aminophenol Hydroferrocyanide,

—White, diamond-shaped prisms with a blue tinge are gradually

precipitated by saturated ferrocyanide solution. The green solution in hot water becomes brownish-yellow and is decolorised by alkali. The salt becomes lemon-green, giving off water, when heated, and blue on keeping (Found: Fe = 10.83, 10.90. Calc., Fe = 10.85 per cent.).

Hydroferrocyanides of Basic Dyestuffs.—Insoluble salts form when saturated ferrocyanide solution is added to acid solutions of the basic dyestuffs. These compounds should prove useful for isolating such dyestuffs. Most of these salts, owing to their insolubility, have badly-defined crystalline structure, some being practically amorphous. They give off highly coloured vapours when heated, have in general the same colour as the dyestuffs from which they are prepared, and are generally stable. Owing to the difficulty of preparing some of the dyestuffs in a pure form, definite formulæ could not be assigned to all the hydroferrocyanides. The dyestuffs examined were Bismarck brown, auramine, chrysoidine Y, magenta, malachite-green, methyl-violet, proflavine, and acriflavine.

Bismarck-brown Hydroferrocyanide,

—Reddish-brown plates, giving off heavy orange vapours when heated; almost insoluble in water (Found: Fe = 9.60. Calc., Fe = 9.65 per cent.).

Chrysoidine Y (Diaminoazobenzene) Hydroferrocyanide,

—Dark red needles, giving off heavy orange vapours when heated; slightly soluble in hot water to give an orange-coloured solution which is not decomposed on boiling. Slightly soluble in boiling absolute alcohol (Found: Fe = 6.03. Calc., Fe = 6.06 per cent.).

Auramine Hydroferrocyanide, $\text{C}_{17}\text{H}_{21}\text{N}_3, \text{H}_4\text{Fe}(\text{CN})_6, \frac{1}{2}\text{H}_2\text{O}$.—Buff-coloured plates which turn bright red when heated, white fumes being evolved. Slightly soluble in boiling water, giving a green solution which is only slightly decomposed on continued boiling; slightly soluble in boiling absolute alcohol, giving a yellow solution. The salt becomes green when kept (Found: Fe = 11.33. Calc., Fe = 11.38 per cent.).

The conclusion drawn from the foregoing results is that an aromatic organic substance which is truly basic will form a hydroferrocyanide and, conversely, an aromatic compound which will form a hydroferrocyanide is truly basic. In the case of the following compounds, the introduction of an alkyl group increases the basicity to such an extent that a hydroferrocyanide is formed in acid solution, a result which seems contrary to the generally accepted view; *o*-anisidine, methyl-*p*-aminophenol, methyldiphenylamine, and dimethylaminoazobenzene form definite salts, whilst the

corresponding non-methyl-substituted compounds do not. The formation of salts in the case of the first two compounds shows that the basicity is increased whether the methyl group is substituted in the hydroxyl or in the amino-group.

The purity of an aromatic base may be determined by an estimation of the iron in the hydroferrocyanide, except in the case where isomerides are present which form hydroferrocyanides of identical composition, for example, the phenylenediamines. In the same way, such an estimation could be used for identifying certain bases; for example, quinoline and isoquinoline hydroferrocyanides contain 11.59 and 11.81 per cent. of iron, respectively.

Hydroferrocyanides Precipitated in Alcoholic Solution.—In pursuance of the work of Eisenberg (*Annalen*, 1880, 205, 265), hydroferrocyanides were formed by adding a cold saturated solution of hydroferrocyanic acid to a cold solution of the base in absolute alcohol. In some cases the salts were precipitated at once, in others only after standing. In the former cases, more and more dilute solutions of the bases were used until the precipitates were of definite crystalline structure when examined under the microscope; the salts were then washed with absolute alcohol and with ether and dried by suction.

Their properties are similar to those of the salts already described. They are not decomposed by cold concentrated sulphuric acid, but dissolve on heating, the sulphate of the base being precipitated on cooling. In the case of para-substituted bases, colorations were obtained with cold concentrated nitric acid except in the case of *p*-bromo- and *p*-nitroso-dimethylaniline. The salts have generally the same crystalline structure and are more soluble in water than the corresponding salts precipitated in acid solution, and the solutions in water are only slightly decomposed on continued boiling; in many cases, the free base is liberated by hot water. They are highly coloured, but are not so stable as the corresponding salts precipitated in acid solution.

The analysis of these salts was carried out as before. Many of the salts correspond to the general formula $(\text{Base})_4, \text{H}_4\text{Fe}(\text{CN})_6$, as found by Eisenberg (*loc. cit.*) for the aniline salt. Another series of salts was obtained in which the general formula was $(\text{Base})_2, \text{H}_4\text{Fe}(\text{CN})_6$. In several cases alcohol of crystallisation was present. Except where the bases were volatile, this could usually be identified by the iodoform and the ethyl acetate reactions.

Hydroferrocyanides of certain hydrazo-compounds have been prepared; salts of such compounds have hitherto not been described. From what has been said before, these compounds must be basic, and the author believes that this basicity is produced by intra

molecular change (compare this vol., p. 2470). The combination between base and acid is loose, for treatment with ether removes a part of the base.

The influence of acidic groups was also studied in this case, with the same results as before. When an acidic group was present no hydroferrocyanide was precipitated in alcoholic solution. So the same rule with regard to basicity also applies to this class of hydroferrocyanides. The only compound so far examined which gives a hydroferrocyanide in alcoholic solution but not in acid or neutral solution is diphenylamine, and the hydroferrocyanide is only precipitated from a saturated solution of the base.

The formulæ, etc., of the compounds prepared are given in the following table. Where nothing appears in the third column, the crystalline structure and properties are similar to those of the corresponding salt precipitated in acid solution. For convenience, the symbols *A*, *B*, and *C* are used for base, $\text{H}_4\text{Fe}(\text{CN})_6$, and $\text{C}_2\text{H}_6\text{O}$, respectively, while solubility in water and in alcohol is denoted by *s* and *ss*, respectively.

			(N = 23.15 N = 23.10)	

The pyridine salt is extremely hygroscopic and the percentage of iron varied from 13.82 to 13.64 during a few hours, so that a definite composition could not be determined (for $x = 3/4$, Fe = 13.71 per cent.). The salt is more soluble than the quinoline

compound in alcohol. The methyl-diphenylamine and diphenylamine salts are the only ones soluble in absolute alcohol and no decomposition takes place on boiling. The aqueous solution of the *p*-nitrosodimethylaniline salt is not decomposed on boiling.

Hydroferrocyanides of Hydrazo-compounds.—A saturated solution of hydroferrocyanic acid in absolute alcohol was added to a like solution of the hydrazo-compound in the cold. The salt that was precipitated on keeping was washed with absolute alcohol and dried by suction. The hydrazo-compound was completely precipitated as its salt in this way. These salts are insoluble in water or in boiling absolute alcohol; they are decomposed by boiling water. The hydrazo-compound is liberated by the action of alkali. The salts are decomposed by boiling acetic anhydride but not by boiling acetyl chloride. On standing, they turn blue, hydrocyanic acid being evolved. Ether partly dissolves the base in the cold.

Hydrazobenzene hydroferrocyanide, $C_6H_5 \cdot NH_2 \cdot N \cdot C_6H_5 \cdot H_4Fe(CN)_6$, forms white, lustrous plates (Found: Fe = 14.07; N = 27.04. Calc., Fe = 14.00; N = 28.00 per cent.). *o*-*Hydrazotoluene hydroferrocyanide*, $C_6H_4Me \cdot NH_2 \cdot N \cdot C_6H_4Me \cdot 2H_4Fe(CN)_6$, forms white, lustrous plates with a green tinge (Found: Fe = 17.39. Calc., Fe = 17.39 per cent.).

Hydroferrocyanides Precipitated in Neutral Solution.—In the earlier paper, it was pointed out that *p*-toluidine does not form a hydroferrocyanide in acid solution, a property which was utilised in the separation of *o*- and *p*-toluidines. When, however, ferrocyanide solution was added to a saturated solution of *p*-toluidine hydrochloride a definite salt was formed. This reaction has been extended to other hydrochlorides and a new series of salts obtained of the general formula $(Base)_3 \cdot H_4Fe(CN)_6 \cdot xH_2O$. These salts have the same properties as those already described. In some cases the base was dissolved in concentrated or dilute hydrochloric acid until the solution was neutral to congo-red and saturated at the ordinary temperature, and a saturated or dilute sodium ferrocyanide solution was added as required.

Pyridine and isoquinoline form double salts with sodium ferrocyanide which are very soluble in water.

The formulæ, etc., of these salts are given in the following table, *C* in this case representing one molecule of water of crystallisation.

Pyridine and isoquinoline Sodium Ferrocyanides.—When concentrated hydrochloric acid was added to pyridine or isoquinoline in such amount as to leave excess of the base, and the cooled solution treated with saturated sodium ferrocyanide solution, a colour change to orange took place and crystals then separated.

These crystals fused when heated, giving off the base, and on ignition left a residue (about 70 per cent.) containing sodium and iron. In the case of pyridine two salts were isolated. The salts are very soluble in water and insoluble in absolute alcohol, and become slightly green when kept. The cyanogen in these cases was readily estimated by Williams's method (*J. Soc. Chem. Ind.*, 1912, **31**, 468; see T., 1922, **121**, 1292).

Pyridine sodium ferrocyanide, $(C_5H_5N)_2 \cdot Na_4Fe(CN)_6$, forms white, lustrous plates (Found: CN = 33-86. Calc., CN = 33-76 per cent.). Another crop of crystals of the same composition was obtained by adding saturated ferrocyanide solution to the mother-liquor. The crystals obtained by evaporation of the mother-liquor without the addition of ferrocyanide gave no pyridine when heated; they consisted of square, yellow plates and appeared to have the composition represented by the formula $Na_4Fe(CN)_6 \cdot 7H_2O$ (Found: CN = 36-06. Calc., CN = 36-27 per cent.). When a little caustic soda was added to a solution of the white plates in water, long, yellow needles separated. This substance gave off the base and water when heated, and appeared to be a monohydrate of the original salt (Found: CN = 32-11. Calc., CN = 32-50 per cent.).

isoQuinoline sodium ferrocyanide, $(C_9H_7N)_3 \cdot 2Na_4Fe(CN)_6 \cdot H_2O$, forms white, lustrous plates (Found: CN = 30-69. Calc., CN = 30-85 per cent.).

Quinoline hydroferrocyanide, $(C_9H_7N)_3 \cdot H_4Fe(CN)_6 \cdot 1\frac{1}{2}H_2O$, prepared in the same way as pyridine sodium ferrocyanide, forms deep red, rhombic crystals which become yellow, then green, when heated. The salt is insoluble in cold, but soluble in hot water; when boiled, the solution gives an orange precipitate without the usual decomposition. The salt is stable (Found: Fe = 8-86; N = 20-15. Calc., Fe = 8-88; N = 20-00 per cent.).

Separations.—Isolation of Pure Diphenylamine from the Commercial Product. To a dilute absolute alcoholic solution of the

commercial product, which usually contains a considerable proportion of aniline, is added a saturated solution of hydroferrocyanic acid in absolute alcohol. The aniline salt, which is immediately precipitated, is removed and washed with a little absolute alcohol. The diphenylamine is obtained from the filtrate, after concentration, by treatment with caustic soda.

Separation of Quinoline from isoQuinoline.—To the mixture is added concentrated hydrochloric acid in sufficient quantity to leave excess of the bases present. Saturated sodium ferrocyanide solution is added; after some time, a mixture is precipitated consisting of the red crystals of the normal neutral hydroferrocyanide of quinoline along with the white plates of isoquinoline sodium ferrocyanide. This mixture is filtered off and washed with absolute alcohol. The residue is treated with water, when the isoquinoline salt passes into solution, leaving the insoluble quinoline compound. The bases are then liberated in the usual way. This separation coupled with that already given in the earlier paper (*loc. cit.*, p. 1298) effects a separation of quinoline and isoquinoline from mixtures containing pyridine and its homologues such as are present in the higher-boiling bases obtained from coal tar.

The author wishes again to thank Professor F. J. Wilson for his kind interest in this work.

CCLXXXI.—*Reduction of Nitronaphthalenes. Part I.* *Reduction of α -Nitronaphthalene.*

By WILLIAM MURDOCH CUMMING and JAMES KING STEEL.

THE work was undertaken in order, if possible, to reduce α -nitronaphthalene to the hydrazo-compound and to convert this into naphthidine. Reduction in alkaline solution having proved unsuccessful, a neutral reducing agent was employed. The most satisfactory agent was zinc dust and ammonium chloride at a temperature of 70°. Below this temperature, according to D.R.-P. 84,138, α -naphthylhydroxylamine, and above it α -naphthylamine, is formed. The azoxy-, azo-, and hydrazo-compounds were obtained by this means, the requisite quantity of zinc being used in each case.

Two modifications of the azoxy-compound were isolated in

yellow plates and red, rhombic crystals, both melting at 127° . The yellow modification is phototropic, being converted into the red modification on exposure to bright sunlight for a few minutes or to ultra-violet light. Very sharp prints were obtained by exposing paper, moistened with a very dilute alcoholic solution of the yellow modification, to sunlight behind a photographic negative. This colour change was noticed by Wacker (*Annalen*, 1901, **317**, 375), and is also referred to by Baudisch and Furst (*Ber.*, 1912, **45**, 3426), who explain it as being due to the conversion of α '-azoxy-naphthalene into α -naphthaleneazo- α -naphthol on exposure to light.

The view of the present authors is that the change from the yellow to the red modification is represented by a change of structure from $O \begin{smallmatrix} \diagup NR \\ \diagdown NR \end{smallmatrix}$ to $O:NR:NR$. Isomerides, $O:NR:NR'$ and $O:NR':NR$, of the second type have already been isolated by Angeli and others (*Atti R. Accad. Lincei*, 1915, [v], **22**, i, 201, 282; *Gazzetta*, 1916, **46**, ii, 67), and two modifications of azoxybenzene and azoxytoluene by Reissart (*Ber.*, 1909, **42**, 1364).

The authors also suggest that the two forms of the hydrazo-compound isolated by them represent isomerides of a similar type, namely, $NHR:NHR$ and $NR:NH_2R$. The existence of these isomerides seems to afford additional evidence in favour of the formulæ assigned to the two modifications of the azoxy-compounds, which would respectively produce them on reduction.

EXPERIMENTAL.

Alkaline Reduction.—The α -nitronaphthalene, crystallised ten times from alcohol, melted at 58.5° (Beilstein and Kuhlberg, *Annalen*, 1873, **169**, 81, give m. p. 58.5° ; Mills, *Proc. Roy. Soc.*, 1881, **31**, 205, gives m. p. 56° ; and Schiff, *Annalen*, 1884, **223**, 247, gives m. p. 61.5°). Reduction with sodium amalgam in alcoholic solution failed to give any satisfactory results. When a large excess of amalgam was employed, the solution became very dark, there was a tendency to tarring, and a brown deposit resembling that obtained by Jaworsky (*Jahresbericht.*, 1864, 532) was formed in small quantity. Sodium hydroxide and zinc dust also failed as reducing agent. On carrying out the experiment under reflux at 70 – 75° with 5 per cent. aqueous sodium hydroxide and an equal volume of alcohol, a small quantity of a brown, amorphous compound was deposited after standing. This had no definite melting point and was extremely difficult to free from zinc (compare Wacker, *loc. cit.*). Sodium hydroxide appears to hinder reduction to the azoxy.

compound and tends to produce tar and naphthylamine. The more important results are summarised in the following table :

% NaOH in aqueous soln.	Solvent.	Temp.	Products.
20	No solvent	105°	Tar, $C_{10}H_7NH_2$, and a little $C_{10}H_7NO_2$.
20	Benzene	80	Tar, $C_{10}H_7NH_2$; no $C_{10}H_7NO_2$ detected.
5	No solvent	100	$C_{10}H_7NO_2$, tar (little reduction).
5	Alcohol	70—75	$C_{10}H_7NO_2$, brown deposit; no tar.
7.5	Alcohol	70—75	$C_{10}H_7NO_2$, brown deposit, tar.

In general, with concentrations of sodium hydroxide higher than 5 per cent. and at temperatures exceeding 75°, the products of reduction are α -naphthylamine and tar, whilst at lower temperatures and concentrations little reduction occurs.

Neutral Reduction.— *$\alpha\alpha'$ -Azoxynaphthalene.* Attempts to carry out the reduction according to Wacker's directions (*loc. cit.*) were not successful, as on addition of water to the filtrate tarring always took place. Azoxynaphthalene was finally isolated in the following manner: Twenty grams of α -nitronaphthalene, 175 c.c. of 90 per cent. alcohol, 50 c.c. of water, and 40 grams of ammonium chloride were heated together on the water-bath at 70°, the nitronaphthalene going completely into solution, but some of the ammonium chloride remaining undissolved. To this solution 28 grams of zinc dust were added at such a rate that the temperature was maintained at 70—75°; above 75°, tarring took place and below 70° a part of the nitronaphthalene was precipitated. The solution, which gradually changed from yellow to red, was filtered hot, the residue extracted with boiling 90 per cent. alcohol, and the combined extract and filtrate cooled. The yellow, crystalline precipitate was removed and the filtrate concentrated under diminished pressure, a further deposit being obtained. When kept for more than twelve hours or if heated, the filtrate became dark in colour and decomposition took place. The crystalline product was extracted with warm water to remove ammonium chloride and then several times with alcohol; white, slightly efflorescent needles of a zinc compound remained, which was insoluble in water, but dissolved readily in dilute hydrochloric acid [Found: Zn = 54.14; Cl = 11.75; NH_4 = 5.95. $2NH_4Cl, 5Zn(OH)_2$ requires Zn = 54.88; Cl = 11.66; NH_4 = 5.65 per cent.]. Bertrand (*Compt. rend.* 1892, 115, 940), in an investigation on the zincates of the alkaline earths, obtained a compound which he believed had the above composition. He, however, gave no details of preparation or analysis.

The product obtained from the alcoholic extracts was recrystallised from alcohol and the yellow crystals deposited on cooling

melted at 127° and displayed the characteristic reactions of $\alpha\alpha'$ -azoxynaphthalene (Found: N = 9.33. Calc., N = 9.39 per cent.).

On slow crystallisation of an alcoholic solution, red, rhombic crystals, m. p. 127° , were obtained together with those of the yellow variety. The red crystals readily grew in the solution and were easily separated from the yellow by mechanical means. They were also obtained by evaporation of a solution of the yellow variety in chloroform. The yellow crystals gradually became red on exposure to bright sunlight or to the rays from a mercury vapour lamp. This change took place more quickly in alcoholic solution, the light yellow solution becoming deep red.

$\alpha\alpha'$ -Azonaphthalene.— α -Nitronaphthalene was reduced to the azoxy-compound as described above and 7 grams of zinc dust were then added to the mixture, the temperature being maintained at 70 – 75° . In this case, as in the preceding, the heat evolved was considerably greater towards the end of the reaction, necessitating slower addition of the zinc; in all about forty-five minutes were required for the reduction. After filtration at 50° and treatment of the residue in small portions with dilute hydrochloric acid to remove α -naphthylamine and zinc oxide, red, rhombic crystals together with a small quantity of the azoxy-compound and a few colourless plates remained. Extraction with 90 per cent. alcohol and repeated crystallisation from the same solvent and finally from absolute alcohol yielded red crystals, m. p. 186° , of azonaphthalene (Neitski and Goll, *Ber.*, 1885, **18**, 297, 3252). A current of air passing through an alcoholic solution of the substance sufficed to oxidise it to the azoxy-compound.

The filtrate from the reduction product after treatment with dilute hydrochloric acid yielded α -naphthylamine on addition of sodium hydroxide. In the case of azonaphthalene only one crystalline formation was observed; the colour was red, not blue as stated by Neitski and Goll (*loc. cit.*).

$\alpha\alpha'$ -Hydrazonaphthalene.—The preparation previously described was repeated and a further quantity of alcohol was added when the solution had attained its maximum redness in order to dissolve completely the azonaphthalene, part of which had been thrown out of solution. After the addition of 45 grams of zinc the solution became colourless. On exposure to air, it reddened very quickly; rapid filtration was therefore necessary. The filtrate having been decolorised by addition of a little zinc, about two-thirds of the alcohol was evaporated under reduced pressure, and the white mass of ammonium chloride, zinc oxide, and hydrazonaphthalene dried as quickly as possible and treated with absolute alcohol, in which

hydrazonaphthalene is fairly stable; the addition, however, of a small quantity of water readily brought about oxidation on exposure to air. $\alpha\alpha'$ -Hydrazonaphthalene was finally obtained in colourless needles, m. p. 274° (Found: N = 9.76. $C_{20}H_{16}N_2$ requires N = 9.79 per cent.); a few diamond-shaped plates always occurred mixed with the needles. A current of air passed through a dilute alcoholic solution of the hydrazo-compound oxidised it to the azoxy-compound, but when part of the alcohol was removed from more concentrated solution under reduced pressure azonaphthalene was deposited. The hydrazo-compound was treated with dilute hydrochloric acid at 70° ; addition of concentrated hydrochloric acid caused no separation, but sodium hydroxide precipitated a white compound, which, recrystallised from alcohol, formed colourless needles, m. p. 273° , corresponding to the dinaphthylene of Neitski and Goll (m. p. 273°). With oxidising agents a solution of the hydrochloride gave a brown coloration. On diazotisation and coupling with R salt, a red dyestuff was obtained.

Naphthidine.—This compound was obtained by reducing azoxy-naphthalene in glacial acetic acid solution by means of stannous chloride in hydrochloric acid; under similar conditions, α -nitronaphthalene is not reduced. Reduction readily took place and no α -naphthylamine was detected. The white compound precipitated on addition of concentrated hydrochloric acid was washed with dilute hydrochloric acid and its aqueous solution treated with sodium hydroxide; the base crystallised from alcohol in silvery plates, m. p. 198° . The solution of the hydrochloride gave a carmine coloration with oxidising agents. On diazotisation and coupling with R salt, a dye was obtained the aqueous solution of which was reddish-violet with a blue fluorescence.

After reduction of α -nitronaphthalene to the hydrazo-compound the reduction mixture was filtered quickly and dilute sulphuric acid added to the filtrate, when a crystalline compound was immediately thrown down. This was recrystallised several times from alcohol, from which it separated in colourless, silky needles, melting at 216° and giving the characteristic reactions of a secondary amine. It was the dinaphthyleneimine obtained by Neitski and Goll after boiling naphthidine for some time with dilute hydrochloric acid (Found: N = 5.16. Calc., N = 5.24 per cent.). It readily gave a benzoyl derivative, colourless plates, m. p. 119° . Its formation is represented by the following scheme; the sulphate of the base was not obtained.

Constitution of the Two Forms of Azoxynaphthalene.—Photographs of the absorption spectra of a $N/3000$ -solution of the yellow modification in alcohol were taken, the solution was then exposed to sunlight for about one hour until it attained its maximum redness, and photographs were again taken (Fig. 1); the graphs show that the compounds are not dimorphous. Conversion from the red into the yellow modification took place on dissolving the former in hot alcohol and rapidly cooling the solution. Only one type of compound is possible in the case of $\alpha\alpha'$ -azonaphthalene and only one crystalline form was obtained.

FIG. 1.

The possibility of a similar change in structure occurring in the case of hydrazonaphthalene was investigated. The filtrate from the reduction mixture was saturated with sulphur dioxide and allowed to crystallise under reduced pressure, when the hydrazo-compound was precipitated in diamond-shaped plates mixed with a few needles. The needles were found to be the more stable form; crystallisation from absolute alcohol partly converted the plates into needles. The needles were converted into plates by treating saturated alcoholic solution at 70° with sulphur dioxide and allowing it to crystallise slowly; 0.54 gram of sulphur dioxide in 100 c.c. of solution was required to bring about complete conversion.

The plates melt at 271° and the needles at 274° ; a mixture of the two melted at 269.5° .

When a saturated solution of hydroferrocyanic acid in absolute alcohol was added to a similar solution of hydrazonaphthalene and the solution concentrated under reduced pressure, a salt was obtained in colourless plates [Found: Fe = 13.85. $(C_{20}H_{16}N_2)_2 \cdot 3H_4Fe(CN)_6$ requires Fe = 13.82 per cent.]. The salt was unstable and had the properties of such salts already described by Cumming (compare this vol., p. 2461).

This result does not conflict with the view already stated with regard to the conversion of the hydrazo-compound into the base. By the action of a dilute acid the first change shown in the following scheme occurs. On increasing the strength of the acid or raising the temperature, the semidine change takes place, and is followed by the benzidine transformation; the imine $\begin{smallmatrix} R \\ | \\ R \end{smallmatrix} > NH$ is formed finally by the loss of ammonia:

Summary.

1. $\alpha\alpha'$ -Hydrazonaphthalene can be formed by the direct reduction of α -nitronaphthalene in neutral solution.
2. The azoxy- and hydrazo-compounds exist in two isomeric forms of the constitutions suggested, the one form being readily converted into the other.
3. Naphthidine, dinaphthylene, and an imine are formed by treating the hydrazo-compound with strong acids.

[Received, June 18th, 1923.]

CCLXXXII.—Chlorination of Benzoyl Chloride. Part II.

By EDWARD HOPE and GEORGE CLIFFORD RILEY.

IN the previous communication (T., 1922, **121**, 2510), we described the investigation of the nature and proportions of the products obtained when benzoyl chloride was chlorinated in the presence of anhydrous ferric chloride to a stage corresponding to the introduction of one atom of chlorine into the molecule.

The present paper deals with the products, in particular the

dichloro-compounds, obtained when the reaction is carried a stage further.

The chlorination was carried out at 35° in a similar manner and apparatus to that already described, but was continued until the increase in weight had attained a value 1.6 times that corresponding with the substitution of one atom of chlorine for hydrogen. The estimation of the individual compounds in the product was again carried out by repeated fractional distillation of the mixture under reduced pressure, collection of definite fractions, hydrolysis of these separately to the corresponding acid mixtures, and estimation of the composition of the latter.

In the case of the monochloro-fractions, this was accomplished by the method previously described, and the proportions of the isomerides were found to be very similar to those in the monochlorinated mixture, namely, meta-, 79.3 per cent.; ortho-, 20 per cent.; para-, 0.7 per cent. Compared with the previous figures, these are an increase of 5.5 per cent. in the case of the ortho-, and a decrease of 4.2 and 1.3 per cent. respectively in those of the meta- and para-compounds. A possible explanation of the difference is that the meta- and para-compounds may more readily undergo further chlorination than the ortho-.

The analysis also showed that, under the conditions described, none of the original benzoyl chloride was left unchanged, 54 per cent. of it was converted into monochlorobenzoyl chlorides, and 37 per cent. was isolated as a very definite fraction boiling at 120—122°/12 mm., consisting of dichlorobenzoyl chlorides. A considerable amount of tarry matter was formed, weighing, when freed from iron, 7.5 per cent. of the original benzoyl chloride.

The acid mixture from the hydrolysis of the dichloro-fraction was shown to contain 2:5-dichlorobenzoic acid as main constituent, and its approximate proportion in the mixture, 70 per cent., was estimated by means of a melting-point curve subsequently determined for mixtures of 2:5- and 2:3-dichlorobenzoic acids. By converting the mixture into its barium salts, and fractionally crystallising these from water, the very sparingly soluble barium salt of 3:4-dichlorobenzoic acid (m. p. 205°) was isolated, in amount corresponding with a proportion of 6.7 per cent. of this acid in the original mixture, next the salt of the 2:5-acid (m. p. 154.4°), and finally fractions giving an acid product melting fairly sharply between 126° and 128°. This at first seemed to indicate a pure acid, but the conclusion was shown to be incorrect by the fact that the addition of a fairly small amount of the 2:5-acid raised the melting point. Recrystallisation of this product from water, 30 per cent. acetic acid, benzene, or light petroleum, and of the barium

salt from water or 95 per cent. alcohol, was not successful in separating an acid having a total melting point above 128° , or which was half melted below 122° .

On reviewing the literature, it was found that this corresponds with the results recorded by some of the earlier investigators of the mixture of dichlorobenzoic acids obtained from the dichlorotoluene fraction produced in the chlorination of toluene, and it accounts for much of the confusion existing in the identification of the products of this reaction, as it was always taken to be a single pure compound.

FIG. 1.

Solidification temperatures of mixtures of *m*-chlorobenzoic acid and 2;5-dichlorobenzoic acid.

Aronheim and Dietrich (*Ber.*, 1875, **8**, 1401), on fractionally crystallising the barium salts of the acid mixture from the above dichlorotoluene fraction, obtained acids melting at 201° and 122° . Schultz (*Annalen*, 1877, **187**, 260) similarly obtained acids of melting points 201° , 156° , and 126.5° and considered them to be pure compounds. Claus and Stavenhagen (*ibid.*, 1892, **269**, 224) suggested that the latter could not be pure, on the ground that its melting point did not agree with that of any one of the pure dichloroacids that had been obtained (for example, by Lellmann and Klotz, *ibid.*, 1885, **231**, 308), but Cohen and Dakin (*T.*, 1901, **79**, 1111) say that the melting point of this acid is "in fair agreement" with that

of the 2:6-acid they prepared of melting point 139–140°, and consequently assign to it this constitution.

A clue to the true nature of this product was obtained when the melting-point curve of mixtures of *m*-chlorobenzoic acid and 2:5-dichlorobenzoic acid was determined, for the purpose of comparing the effect of the latter with that of the *o*- or *p*-chlorobenzoic acid.

The interesting result of this determination was that the curve obtained indicated the existence of a molecular compound of one

FIG. 2.

Solidification temperatures of mixtures of 2:3-dichlorobenzoic acid and 2:5-dichlorobenzoic acid.

molecule of each acid (Fig. 1). By analogy, it was concluded that the above substance of melting point 128° was most probably a similar molecular compound between the 2:5- and another dichloro-acid, and consideration of the rules of substitution made it seem most likely that the latter would be the 2:3-acid. Accordingly the mixed melting-point curve of the 2:5- and 2:3-dichlorobenzoic acids was determined (Fig. 2). Although not quite of the form expected, this curve indicates the existence of a molecular compound, of probably two molecules of the 2:5-acid with one of the

2 : 3-, as the slope of the curve at 66 per cent. 2 : 5-acid is within the range of the experimental error, but it is possible that it contains a greater proportion of the 2 : 5-acid, the portion of the curve showing the lowering of the fusion point of the 2 : 5-acid masking that part of the curve that would decide this point. The curve also shows that over quite a large range (from 33.3 to 49 per cent. of the 2 : 3-acid) the upper fusion point of such mixtures lies between the temperatures 126° and 130°.

The products of m. p. 126—128° from the barium salt crystallisation were shown to be mainly identical with some mixture in this range, by taking a mixed melting point, the somewhat lower temperatures probably being caused by the presence of another dichloro-acid in very small quantity. It was not possible to say whether the fractional crystallisation really did or did not have an effect on the composition of the fractions, for as long as the composition remained between these limits it was not possible to distinguish by melting-point determinations.

The approximate composition of the 120—122° fraction was thus shown to be 70 per cent. of 2 : 5-, 23 per cent. of 2 : 3-, and 7 per cent. of 3 : 4-dichlorobenzoyl chloride.

The literature concerning the dichloro-acids obtained in the chlorination of benzoic acid, which seemed to be the most nearly related reaction with which to compare the above results, is very conflicting and unsatisfactory. Up to 1912, the only dichloro-acid definitely established as being produced in this reaction was the 3 : 4-acid, isolated by Beilstein and Kuhlberg (*Annalen*, 1869, **152**, 231) by means of its sparingly soluble barium salt. Claus and Pfeiffer (*Ber.*, 1872, **5**, 656; 1873, **6**, 721) and Claus and Thiel (*ibid.*, 1875, **8**, 948) overlooked this acid, but isolated an acid of melting point 156°, and later observers described acids melting at 150°, 153°, and 156°, certain observations of their properties (for example, by Claus and Bucher, *ibid.*, 1887, **20**, 1622) indicating that these acids were not identical. They have been variously described as being the 2 : 3-, 2 : 4-, or 2 : 5-dichloro-acid, but without any very convincing proof. Bornwater (*Rec. trav. chim.*, 1912, **31**, 221) identified the 3 : 4- and 2 : 5-acids in his product. He also revised the values for the melting points of the dichlorobenzoic acids, to which very varying values had been assigned, with the exception of the 2 : 3-acid. In the present work, this was redetermined, and found to have the value 168.3° (compare Cohen and Dakin, *T.*, 1901, **79**, 1128, who give the value 163°).

Much more definite and quantitative results are given by Holleman for the nitration of the monochlorobenzoic acids ("Die direkte Einführung von Substituenten in den Benzolkern," 1910, p. 245).

Thus, nitration at 0° of *o*-chlorobenzoic acid gives 84 per cent. of 2-chloro-5-nitro-acid and 16 per cent. of 2-chloro-3-nitro-acid, of *m*-chlorobenzoic acid gives 91.3 per cent. of 5-chloro-2-nitro-acid and 8.7 per cent. of 3-chloro-2-nitro-acid, and of *p*-chlorobenzoic acid gives the 4-chloro-3-nitro-acid. In this case, as with the chlorination of the chlorobenzoyl chlorides in the present investigation, the entering group seems to take up a position solely due to the orientating effect of the chlorine atom already present.

EXPERIMENTAL.

Chlorination of 301.2 grams of pure benzoyl chloride with the addition of 7.1 grams of anhydrous ferric chloride was carried out at 35° in an apparatus and manner similar to that described previously (T., 1922, 121, 2515). At the end of seven and a quarter hours the increase of weight was 125.4 grams, giving a total weight of 433.7 grams of the reaction mixture, a clear deep red solution.

Distillation of the Reaction Mixture.—285.5 Grams of the liquid were weighed out into a large Claisen distilling flask, and heated at 12 mm. pressure until on the point of distilling, reweighed, and then distilled at this pressure until the thermometer reading was 124°.

Loss of weight before distillation	.	3.5 grams.
Distillate collected between 105—115°	.	135.7 "
" " " 115—124°	.	117.7 "
Dark red residual liquid	.	27.3 "

The distillate was fractionally redistilled three times from one of the special flasks with a column of eight bulbs, giving the final fractions

98—102°	50.4 grams.	120—122°	106.7 grams.
102—106°	40.9 "	Further residue	12.9 "
106—120°	40.2 "	Total	251.1 "

Hydrolysis and Estimation of the Fractions.—Each fraction was hydrolysed with boiling distilled water as before, and the acid mixtures from the fractions up to 120° were analysed by the physical method already described (*loc. cit.*). In that from the 106—120° fraction, containing some dichloro-acids, the amounts of the *m*-chloro- and *o*-chloro-acids were estimated separately by addition of excess of the particular pure acid and a solidification-point determination in each case.

120—122° Fraction.

The acid mixture from this fraction had a solidification point of 134.3°, which was raised by the addition of a little 2 : 5-dichlorobenzoic acid, this indicating (from the curve for the 2 : 5- and 2 : 3-acids, Fig. 2) an approximate value of 70 per cent. of the 2 : 5-acid, on the assumption that the small percentage of acid present other than the 2 : 3-acid would have practically the same effect on the melting point as the latter acid itself. Repeated recrystallisation of this mixture from benzene isolated a pure specimen of the 2 : 5-acid, weighing a third of the original mixture.

Fractional Crystallisation of Barium Salts.—Thirty-two grams of the original mixture were boiled with 700 c.c. of water and a small excess of barium carbonate, and the hot solution was filtered from the undissolved barium carbonate. On cooling to 50°, a flocculent precipitate was deposited, which was filtered off and washed (1). After cooling to room temperature, a further amount separated, and was filtered off (2). The remaining solution was fractionally evaporated and crystallised. From a weighed portion of each fraction of the barium salts, the acids were liberated by solution in hot water and addition of excess of hydrochloric acid, and the acids well washed and dried, giving results as below (the values under "Acid" being calculated for the whole fraction) :

	C.c. of liquid.	Acid (grams).	M. p.	
(1)	700 at 50°	1.75	* (170)—197°	3:4-Acid. Approx. 93 per cent.
(2)	700 at 20°	0.4	(154)—189	3:4-Acid. Approx. 83 per cent.
(3)	460	13.0	(134)—149	} M. p. raised by addition of 2:5-acid.
(4)	220	6.2	(126)—130.8	
(5)	110	4.8	(115)—128.8	
(6)	Remainder	3.5	(123)—127.3	
		29.65		

* The figures in brackets denote temperatures at which the first signs of melting were apparent. The intermediate figures are the temperatures at which the mixture was half melted.

(1) and (2). Recrystallisation of these fractions from 30 per cent. acetic acid isolated a specimen of pure 3 : 4-dichlorobenzoic acid of m. p. 205°. The approximate percentage values are taken from analogy with the curve for the lowering of m. p. of *p*-chlorobenzoic acid, and calculation from these gives a value of 6.4 per cent. for the proportion of the 3 : 4-acid present in the original mixture. Another experiment gave the value 6.8 per cent.

(3). Recrystallisation of the barium salt from water finally gave the pure salt of the 2 : 5-acid.

(5) and (6). The barium salts were deposited in opaque, hemispherical masses, growing outwards from a centre point, on the sides

of the beaker. Fractional recrystallisation of the barium salts, or the free acids from various solvents, was unsuccessful in giving any appreciable further separation, values obtained being as follows:

		Acid, m. p.
Acids from 30 per cent. acetic acid . . .	first fraction	*(126)—127—128°
	last	„ (121)—124—125
„ from light petroleum	first	„ (125)—126·8—128·3
	last	„ 122·3—126·8
„ from benzene	first	„ (126)—127·3—127·8
	last	„ 124·3—125·8
Barium salt (4) from 95 per cent. alcohol	first	„ (128·3)—129·8—135·3
	last	„ 117—119

* The figures in brackets denote temperatures at which the first signs of melting were apparent. The intermediate figures are the temperatures at which the mixture was half melted.

The acid fractions of m. p. 127—128° were later shown to be composed of the 2:5- and 2:3-dichlorobenzoic acids, as a considerable addition of this fraction to a pure mixture of 66 per cent. of 2:5- and 34 per cent. of 2:3-dichlorobenzoic acid gave a mixture with an intermediate m. p. The exact composition of the fraction could not be deduced, as the melting points of such mixtures lie close together (127—130°) between the limits 51—66 per cent. of the 2:5-acid (see Fig. 2), and there might possibly be present a small amount of another isomeride or impurity which would have a slight effect on the m. p.

Tarry Matter.—A portion of the original reaction mixture was hydrolysed with boiling water in the usual way. The solid product was dissolved in sodium carbonate solution, and the insoluble mixture of ferric hydroxide and tarry matter filtered off. The latter was extracted with hot dilute hydrochloric acid, and the residue of tar dried at 100°. It had a weight corresponding with 7·5 per cent. of the original benzoyl chloride.

The residues above 122° weighed 40·2 grams. Deducting the equivalent weights of ferric chloride, 4·7 grams, and of tar, 14·5 grams, leaves a weight of 21 grams of liquid not investigated. This might possibly contain some small amount of dichloro-compounds, but from a consideration of the weights of the products was most likely to consist largely of more highly chlorinated compounds.

Summary of Analysis.

The original weight of benzoyl chloride equivalent to the weight of reaction mixture (285·5 grams, losing 3·5 grams in a vacuum) taken for distillation was 198·3 grams, and similarly the ferric chloride added was 4·7 grams.

The total increase in weight due to the introduction of chlorine was thus 79 grams, or 1·62 times the theoretical increase for the introduction of one atom of chlorine.

The weight of liquid undergoing continued fractional distillation was $285.5 - (3.5 + 27.3)$ grams = 254.7 grams, giving a final total weight of distillate of 251.1 grams.

Fraction.	Wt. (grams).	Proportion of acids per cent. after hydrolysis.			Original weights of chlorides (grams).		
		Monochloro- benzoic.	Dichloro- benzoic.		Monochloro- benzoyl.	Dichloro- benzoyl.	
		<i>m.</i>	<i>o.</i>	<i>p.</i>	<i>m.</i>	<i>o.</i>	<i>p.</i>

Multiplying by 254.7/251.1, to correct for dis-							
tillation loss							
					105.3	26.6	0.9
					132.8		

Thus the proportions of the original benzoyl chloride used in producing the final products were (approximated to the nearest 0.5 per cent.) 54.0 per cent. (to monochloro-compounds) and 37.0 per cent. (to dichloro-compounds).

The *m*-, *o*-, and *p*-monochloro-compounds were formed in the proportions 79.3% : 20.0% : 0.7% or 100 : 25.2 : 0.9.

The main dichloro-compound fraction contained 2 : 5-, 2 : 3-, and 3 : 4-dichlorobenzoyl chlorides in the approximate proportions 70% : 23% : 7%.

Preparation of 2 : 3- and 2 : 5-Dichlorobenzoic Acids.

Nitration of aceto-*o*-toluidide for the production of the 3-nitro-compound was carried out by Gabriel and Thieme's method (*Ber.*, 1919, **52**, 1080), which was found to give very much better results than that used by Cohen and Dakin (*T.*, 1901, **79**, 1127). The separation from the 5-nitro-compound was, however, considered to be better effected by distillation in steam from an acid solution, as the latter authors describe, and the subsequent stages of the synthesis were carried out according to their method, with the exception of the final oxidation of the 2 : 3-dichlorotoluene to the acid. This was effected in the usual manner with permanganate, giving a purer acid, free from nitro-compounds. One recrystallisation from 30 per cent. acetic acid, and then several from pure benzene finally gave pure 2 : 3-dichlorobenzoic acid with a melting or solidification point of 168.3° (corr.) (compare Cohen and Dakin, 163°, and Wynne and Greeves, 164°, *P.*, 1895, **11**, 151).

2 : 5-Dichlorobenzoic acid was prepared partly in an exactly similar manner from the 5-nitro-compound simultaneously pro-

duced in the above nitration, and isolated from the mother-liquor after the 3-nitro-compound had been distilled off in steam, and partly as Cohen and Dakin describe (*loc. cit.*, p. 1130), starting from the chlorination of aceto-*o*-toluidide by the method of Chattaway and Orton (T., 1900, 77, 790), but carrying out the final oxidation with permanganate. Recrystallisation as above gave the pure acid melting at 154.4° (corr.), the value given by Bornwater (*loc. cit.*).

Solidification-point curves for mixtures of these acids, and for mixtures of the 2 : 5-acid with *m*-chlorobenzoic acid were determined as described in the previous communication, using short-range Anschütz thermometers reading to 0.1°, and standardised under conditions as nearly as possible those prevailing when the determinations were actually carried out. The results were as given in Tables I and II.

TABLE I.

51.0	122.3	119.7			

TABLE II.

Solidification points of mixtures of 2 : 3-dichlorobenzoic acid and 2 : 5-dichlorobenzoic acid.

2 : 3-Acid per cent.	Initial solidification point.	2 : 3-Acid per cent.	Initial solidification point.	2 : 3-Acid per cent.	Initial solidification point.
0	154.4°	35.5	130.0°	50.0	131.0°
9.6	148.4	37.2	129.6	51.5	132.8
20.8	141.0	38.2	129.5	57.5	138.3
30.1	133.9	40.6	129.3	66.1	145.7
32.0	132.6	44.0	128.3	69.0	148.4
33.0	131.2	45.1	127.9	82.7	157.6
34.0	130.2	45.6	127.3	100.0	168.3
34.7	130.1	47.1	128.0		

In the case of mixtures of the 2 : 3- and 2 : 5-dichloro-acids, the rate of crystallisation was extremely slow, so that for an accurate determination of the solidification point the temperature of the outer bath was not allowed to fall more rapidly than 0.1° in one minute, especially with mixtures containing between 20 and 60

per cent. of the 2:3-acid. Eutectic temperatures could not be determined.

Summary.

When benzoyl chloride was chlorinated in presence of anhydrous ferric chloride until the increase in weight corresponded to 1.6 times the theoretical for the introduction of one atom of chlorine, 54 per cent. was converted into monochloro-compounds, and 37 per cent. into dichloro-compounds.

The monochlorobenzoyl chlorides were formed in the proportions: meta 79.3, ortho 20, and para 0.7 per cent.

The dichloro-fraction consisted of 70 per cent. of 2:5-dichlorobenzoyl chloride, 23 per cent. of 2:3-dichlorobenzoyl chloride, and 7 per cent. of 3:4-dichlorobenzoyl chloride.

The fusion point curves for mixtures of 2:5-dichlorobenzoic acid with *m*-chlorobenzoic acid and with 2:3-dichlorobenzoic acid respectively were determined, and showed evidence of the formation of molecular compounds.

One of us (G. C. R.) wishes to express his indebtedness for a grant from the Department of Scientific and Industrial Research.

CCLXXXIII.—*The Relative Stability of Open-chain Dibasic Acids containing Odd and Even Numbers of Carbon Atoms.*

By WILLIAM ARTHUR PERCIVAL CHALLENGOR and
JOCELYN FIELD THORPE.

It is a well-known fact that the acids of the oxalic acid series show an alternation in properties between the odd and even members. Thus the odd members have much lower melting points than the even members, and their solubility in water is also very much greater, although these differences tend to disappear higher up the series as shown in the tables below.

Melting points of the dibasic acids.

Even members.		Odd members.	
Oxalic	189.5 ⁷	Malonic	133 ²
Succinic	183	Glutaric	97.5
Adipic	153	Pimelic	105
Suberic	140	Azelaic	107
Sebacic	133	Nonanedicarboxylic	110
Decanedicarboxylic	126	Undecanedicarboxylic	113
Dodecanedicarboxylic	124		
Hexadecanedicarboxylic ...	118		

Solubility of the dibasic acids in water.

100 C.c. of the aqueous solution at 20° contain :—

Even members.	Grams.	Odd members.	Grams.
Oxalic	8.6	Malonic	73.5
Succinic	5.8	Glutaric	63.9
Adipic (15°)	1.4	Pimelic	5.0
Suberic	0.16	Azelaic	0.24
Sebacic	0.10		

Another property is the case with which the even members of the series are produced by the direct oxidation of suitable substances, whereas the yield of the odd members is very small, except under carefully regulated conditions, the substance being oxidised to the next lower even member. This is borne out by the following examples.

When *cyclohexanone* is oxidised with nitric acid or potassium permanganate, it gives an excellent yield of adipic acid (Wislicenus and Mayer, *Annalen*, 1893, **275**, 363; Rosenlew, *Ber.*, 1906, **39**, 2202), but when *cyclopentanone* is similarly treated it gives only a poor yield of glutaric acid, except under carefully regulated conditions (Ingold, T., 1921, **119**, 305; Wislicenus and Mayer, *loc. cit.*, 320), a large amount of succinic acid being produced.

Another example is the oxidation of dimethyldihydroresorcinol (I), which on direct oxidation with potassium permanganate gives *α*-dimethylsuccinic acid (II) (Vorländer and Gartner, A., 1899, i, 259), *ββ*-dimethylglutaric acid (III) 'only being obtained by oxidising dimethyldihydroresorcinol (I) with hypobromite solution, which first converts it into a bromo-derivative (IV) (Komppa, A., 1889, i, 574).

A further example is that given by the oxidation of ricinoleic acid (V) with nitric acid, which yields azelaic acid (VI) and suberic acid (VII) in about equal proportions (Baker and Ingold, this vol., p. 128; Dale, *Annalen*, 1864, **132**, 244), although theoretically only azelaic acid should be obtained.

Applying the recent theories of Lapworth (T., 1922, 121, 416) and Kermack and Robinson (*ibid.*, p. 427) on alternate positive and negative polarities to the above, it appears that the compounds with crossed polarities, that is, the even members, are more stable than those in which the positive and negative charges continue to the end of the chain of carbon atoms as shown below:

The charges tend to strengthen one another in azelaic acid, whereas in suberic acid they tend to neutralise one another, which probably means that azelaic acid is much more reactive than suberic acid and is thus more readily oxidised, giving an even member of the series, in this case suberic acid.

The above examples, although they manifestly point in the direction indicated by these views, suffer from a certain indirectness in their application. The experimental portion of this paper, however, contains a description of a series of examples which illustrate in a remarkable way the tendency of an even-carbon chain to lose 0, 2, 4, etc., atoms of carbon on oxidation, and of an odd-carbon chain to lose 1, 3, 5, etc., carbon atoms, the product in all cases belonging to the even series.

Azelaic acid was dibrominated in the α - and α' -positions, the dibromo-acid (VIII) thus obtained was treated with aqueous alkali, probably yielding the corresponding dihydroxy-acid (IX), and the solution oxidised directly with potassium permanganate solution. The solution, on evaporation, acidification, and extraction with ether, yielded a solid which proved to be adipic acid and not pimelic acid, which might have been expected on theoretical grounds.

It was then thought that pimelic acid would be obtained if monobromoazelaic acid were treated in a similar manner. Azelaic acid was therefore monobrominated and the monobromo-acid (X) treated with aqueous alkali, probably yielding the corresponding hydroxy-acid (XI), and the solution treated with potassium permanganate as in the case of the dibromo-compound. This on extraction with ether gave suberic acid as the sole oxidation product,

again showing the tendency to form the even members of the series.

Monobromoazelaic acid was then treated with 6*N*-methyl-alcoholic potassium hydroxide in an attempt to obtain the unsaturated acid, $\text{CO}_2\text{H} \cdot \text{CH} : \text{CH} \cdot (\text{CH}_2)_5 \cdot \text{CO}_2\text{H}$, which on oxidation might give pimelic acid, together with adipic and oxalic acids; but suberic acid was again obtained, and therefore it seems probable that a methoxy-derivative was formed instead of the unsaturated acid (compare monobromosuberic acid, which with alcoholic potassium hydroxide gives a mixture of the ethoxy- and hydroxy-compounds [Beilstein, "Organische Chemie," I, 681]).

EXPERIMENTAL.

Dibromination of Azelaic Acid: Formation of $\alpha\alpha'$ -Dibromoazelaic Acid and Ethyl $\alpha\alpha'$ -Dibromoazelaate.—Azelaic acid (200 grams) was treated with phosphorus pentachloride (500 grams), and 400 grams of dry bromine (125 c.c.) were added in several portions according to the rate of absorption. After heating on the steam-bath for twenty hours, the mixture was allowed to cool and part poured into water and the remainder into absolute alcohol.

$\alpha\alpha'$ -Dibromoazelaic Acid.—The aqueous portion was heated on the steam-bath for a short time and, when cold, the pale yellow, heavy oil, on standing in contact with the aqueous layer for several days, slowly crystallised. The aqueous layer was separated and the semi-solid residue filtered, yielding an oil and a solid, which, after crystallising from dilute acetic acid, melted at 125° and after recrystallising from water, at 140°. It crystallised from water, in which it was readily soluble in the hot, but almost insoluble in the cold, in small, glistening flakes (Found: Br = 46.12. $\text{C}_9\text{H}_{14}\text{O}_4\text{Br}_2$ requires Br = 46.20 per cent.). This acid has not previously been obtained in the solid state, Neuberg (*Biochem. Z.*, 1906, **1**, 282) having used the impure oily product in his experiments.

Ethyl $\alpha\alpha'$ -Dibromoazelaate.—The alcoholic portion, after being kept for three to four hours, was boiled for a few minutes, cooled, and poured into water, and the oil was extracted with ether, washed with water, sodium bicarbonate solution (which removed traces of acidic products), and finally with water. After drying over calcium chloride, the ether was distilled off and the residual oil distilled in a vacuum (b. p. 200–220°/12 mm.), yielding a colourless oil.

Treatment of Ethyl $\alpha\alpha'$ -Dibromoazelaate with Sodium Hydroxide and Oxidation of the Product thus obtained.—Ethyl $\alpha\alpha'$ -dibromoazelaate (20 grams) was boiled under reflux for ten to fifteen hours with 8 grams of sodium hydroxide, dissolved in 50 c.c. of water, until it had all dissolved. The cooled solution was filtered from a small amount of insoluble matter and treated slowly with a cold solution of 21 grams of potassium permanganate in 375 c.c. of water, the mixture being kept cold by the addition of ice. When all the permanganate had been reduced, the mixture was treated with sulphur dioxide and evaporated, acidified with sulphuric acid, and extracted with ether. The ethereal solution was dried over calcium chloride and evaporated, yielding a semi-solid. This was spread on a porous tile and the resulting solid recrystallised from water, when it melted at 149° , and was identified as adipic acid.

Monobromination of Azelaic Acid. Preparation of α -Monobromoazelaic Acid.—1. Azelaic acid (200 grams) was treated with phosphorus pentachloride (500 grams) in a Geissler flask. After the vigorous reaction had subsided, the mixture was heated on the steam-bath and bromine (192 grams = 60 c.c.) added in quantities determined by the rate of absorption. When all the bromine had disappeared, the product was cooled and poured into 500 c.c. of water and heated on the steam-bath for a short time. It was then allowed to cool, when it separated as a dark-coloured oil which did not solidify.

2. Azelaic acid (40 grams) was treated with phosphorus pentachloride (100 grams) and bromine (11 c.c.), added as above (1). The product was then allowed to cool and poured into 250 c.c. of absolute formic acid and heated on the steam-bath until the reaction was finished. Most of the formic acid was then evaporated off and the residue dissolved in ether and washed with water to remove phosphoric acid, etc., the ethereal solution dried over calcium chloride, and evaporated. The residual pale yellow oil, on keeping in a vacuum desiccator for a few weeks, deposited crystals (7 grams) of azelaic acid, which were filtered off. The residual oil did not solidify even on keeping for several months.

Treatment of α -Monobromoazelaic Acid with Sodium Hydroxide and Oxidation of the Product thus obtained.— α -Monobromoazelaic acid (26 grams), made by method 1, was heated under reflux with a solution of sodium hydroxide (14 grams) in 50 c.c. of water for six to seven hours. The mixture was allowed to cool, sodium bicarbonate added to reduce the alkalinity of the solution, followed by ice and a solution of 42 grams of potassium permanganate in 800 c.c. of water, slowly added, the mixture being kept cold by the addition of ice as the reaction proceeded. When all the potassium

permanganate had been decolorised, the mixture was treated with sulphur dioxide to remove manganese dioxide, and the clear solution evaporated on the steam-bath. The residue was acidified with hydrochloric acid and extracted with ether, the first two ether extracts being kept separately. The ethereal extracts were dried over calcium chloride and distilled, leaving a white solid in each case.

The solid obtained from the first two ether extracts melted at 74–80° and on repeated crystallisation from water melted at 106° and was proved to be identical with azelaic acid by the method of mixed melting point. This azelaic acid was some which had presumably escaped bromination.

The remainder of the ether extracts gave a solid melting at 68–76°, which, on repeated crystallisation from water, melted at 138° and was proved to be suberic acid by the method of mixed melting point. Yield 25–30 per cent.

α -Monobromoazelaic acid (25 grams), made by method II above, was treated with sodium hydroxide (16 grams) and subsequently with potassium permanganate (22 grams in 400 c.c. of water) as described above. The ether extracts of the acidified solution were dried over calcium chloride and evaporated (yield 10 grams). The oil thus obtained, on standing for a short time, deposited crystals which on recrystallising from water melted at 138° and were identified as suberic acid by the melting point of the mixture. Weight 4 grams (25 per cent.).

Treatment of Monobromoazelaic Acid with 6N-Methyl-alcoholic Potash and Oxidation of the Product thus obtained.—Monobromoazelaic acid (20 grams) was added in a thin stream to 100 c.c. of boiling 6N-methyl-alcoholic potash. When the reaction was finished, the mixture was diluted with water, evaporated to remove alcohol, acidified with hydrochloric acid, and extracted with ether. The oil obtained was dissolved in sodium bicarbonate solution and treated with a solution of 31.5 grams of potassium permanganate in 600 c.c. of water. When all the permanganate had been reduced, the solution was filtered, evaporated, and acidified with hydrochloric acid. It was then extracted with ether; on evaporation, the extract yielded about 2 grams of a solid which, on recrystallisation from water, melted at 138° and was identified with suberic acid (yield 16 per cent.).

The authors desire to express their thanks to the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the expenses of this investigation.

[Received, August 2nd, 1923.]

CCLXXXIV.—*Hydrolysis of $\beta\beta'$ -Dichlorodiethyl Sulphide and Action of Hydrogen Halides on Divinyl Sulphide.*

By SIDNEY HARTLEY BALES and STANLEY ARTHUR NICKELSON.

It has already been shown (T., 1922, **121**, 2137) that divinyl sulphide is one of the chief products of the hydrolysis of $\beta\beta'$ -dichlorodiethyl sulphide with 20 per cent. alcoholic potassium hydroxide. Confirmation has also been recorded (*loc. cit.*) of the observation of Helferich and Emmet Reid (*J. Amer. Chem. Soc.*, 1920, **42**, 1219) that hydrolysis with caustic alkali in 50 per cent. alcohol yields only a small quantity of a heavy oil, surmised by them to be a polymeride of divinyl sulphide.

Before investigating the nature of this heavy oil, we carried out a series of experiments on the influence of increasing concentration of water on the course of the hydrolysis. By distilling $\beta\beta'$ -dichlorodiethyl sulphide with 20 per cent. alcoholic potassium hydroxide without previous heating under reflux, the yield of light oil (divinyl sulphide) obtained on pouring the alcoholic distillate into water was increased to about 35 per cent. of the weight of $\beta\beta'$ -dichlorodiethyl sulphide taken, as against 26 per cent. previously reported. This method was therefore adopted in the following experiments.

Hydrolysis with alcoholic potassium hydroxide containing water causes the product gradually to increase in density as the proportion of water increases, until, when the alcohol contains 20 per cent. of water, the hydrolysis product has a density greater than that of water. The yield is almost constant up to this concentration of water, but with higher concentrations the yields are smaller and the product is denser.

Hydrolysis of $\beta\beta'$ -dichlorodiethyl sulphide with 20 per cent. potassium hydroxide in alcohol-water mixtures. ("Yield" denotes the percentage of the product of hydrolysis calculated on the weight of dichlorodiethyl sulphide taken.)

Water %.	Yield.	<i>d.</i>	Water %.	Yield.	<i>d.</i>
5	35	0.931	20	33.5	1.014
15	33.5	0.941	24	21.0	1.034
17	33.6	0.960	43	16.0	1.050

With alcoholic sodium ethoxide, the yield was 36 per cent.

When the product obtained by the hydrolysis of 100 grams of $\beta\beta'$ -dichlorodiethyl sulphide with 20 per cent. potassium hydroxide in 80/20 or 57/43 alcohol-water was heated, distillation com-

menced at 86° (b. p. of divinyl sulphide), about half the liquid had distilled at 115°, and most of the remainder came over at 150—155°. Carefully redistilled, 9 c.c. of a clear, colourless liquid, b. p. 152—154°, d_4^{20} 1.110, were obtained. This liquid, which contains chlorine and regenerates $\beta\beta'$ -dichlorodiethyl sulphide on treatment with phosphorus trichloride, is probably β -chloro- β' -hydroxydiethyl sulphide (Found: S = 22.70; Cl = 25.11. Calc., S = 22.77; Cl = 25.27 per cent.). It is converted into divinyl sulphide by boiling alcoholic potassium hydroxide, but on prolonged boiling decomposes with the production of acid fumes and the pungent objectionable odour associated with the additive compound of hydrogen chloride and divinyl sulphide (T., 1922, 121, 2138). It has vesicant properties, but its action is milder and more delayed than that of $\beta\beta'$ -dichlorodiethyl sulphide.

Since the above reaction was investigated and the presumed β -chloro- β' -hydroxydiethyl sulphide isolated, Peters and Walker (*Biochem. J.*, 1923, 17, 274) have drawn the conclusion, from a study of the rate of hydrolysis of $\beta\beta'$ -dichlorodiethyl sulphide, that the reaction occurs in two stages:

The isolation of the intermediate compound substantiates this conclusion.

The residue, after distillation of alcohol and divinyl sulphide from the product of the hydrolysis of $\beta\beta'$ -dichlorodiethyl sulphide with excess of 20 per cent. alcoholic potassium hydroxide and removal of potassium chloride by filtration, consists of a dark oil together with some aqueous liquid. The oil could be distilled only under diminished pressure, and even so no liquid of definite boiling point could be obtained; with the aid of a Dufton column (*J. Soc. Chem. Ind.*, 1919, 38, 45r), most of the liquid was distilled at 98—112°/13 mm., the yield being about 5 per cent. of the weight of dichlorodiethyl sulphide used. The distillate was a colourless, oily liquid with a pleasant ethereal odour; d_4^{20} 0.998. Although no definite compound has been isolated from it, there seems little doubt that a substance containing an ethoxy-group or groups is present, since the action of dry hydrogen bromide gave ethyl bromide and a small quantity of a highly vesicant liquid, distilling at 134°/17 mm. and freezing at 25° (approx.) ($\beta\beta'$ -dibromodiethyl sulphide?). It has not been possible to carry the investigation to completion, although it is hoped to do so at a later date, and meanwhile these observations are mentioned as being of possible interest in view of the statement by Helferich and Emmet Reid

(*loc. cit.*) that no ethoxy-derivative is formed by the action of sodium ethoxide on $\beta\beta'$ -dichlorodiethyl sulphide.*

Halogenated Ethyl Sulphides.—Divinyl sulphide reacts additively with two molecules of hydrogen chloride with the formation of $\alpha\alpha'$ -dichlorodiethyl sulphide (T., 1922, 121, 2138). Monohalogen derivatives may be formed similarly by the addition of hydrogen halide (1 mol.), thus giving rise to the possibility of preparing mixed halogenated ethyl sulphides.

The following compounds have been thus prepared. All have the objectionable odour attributed to the $\alpha\alpha'$ -dichloro-compound already described, and all are clear, colourless liquids which decompose on boiling at atmospheric pressure.

1. *α -Chloroethyl vinyl sulphide*, $\text{CH}_3\text{CH}\cdot\text{S}\cdot\text{CHCl}\cdot\text{CH}_3$, is prepared by addition of hydrogen chloride (1 mol.) to divinyl sulphide. It has b. p. $36^\circ/15$ mm., d_{15}^{20} 1.081 (Found: S = 25.90; Cl = 28.79, 28.91. $\text{C}_4\text{H}_7\text{ClS}$ requires S = 26.15; Cl = 28.93 per cent.).

2. *α -Bromoethyl vinyl sulphide*, $\text{CH}_3\text{CH}\cdot\text{S}\cdot\text{CHBr}\cdot\text{CH}_3$, prepared similarly, has b. p. $50.5^\circ/12$ mm., and d_{15}^{20} 1.413 (Found: S = 19.44; Br = 47.89. $\text{C}_4\text{H}_7\text{BrS}$ requires S = 19.22; Br = 47.84 per cent.). It darkens and decomposes on keeping.

3. *α -Chloro- α' -bromodiethyl sulphide*, $\text{CH}_3\text{CHCl}\cdot\text{S}\cdot\text{CHBr}\cdot\text{CH}_3$, prepared by the addition of hydrogen bromide (1 mol.) to (1) or of hydrogen chloride (1 mol.) to (2), has b. p. $78^\circ/15$ mm., and d_{15}^{20} 1.500 (Found: S = 15.91. $\text{C}_4\text{H}_8\text{ClBrS}$ requires S = 15.75 per cent.). It darkens and decomposes on keeping.

4. *$\alpha\alpha'$ -Dibromodiethyl sulphide*, $\text{CH}_3\text{CHBr}\cdot\text{S}\cdot\text{CHBr}\cdot\text{CH}_3$, prepared by the addition of hydrogen bromide (2 mols.) to divinyl sulphide, has b. p. $87^\circ/15$ mm. and d_{15}^{20} 1.742 (Found: S = 12.71; Br = 64.08. $\text{C}_4\text{H}_8\text{Br}_2\text{S}$ requires S = 12.93; Br = 64.50 per cent.). It decomposes with darkening on keeping.

When dry hydrogen iodide is passed into divinyl sulphide, ready absorption occurs as with the other hydrogen halides, but with considerable darkening. When an attempt was made to distil the product of addition of 2 mols. of hydrogen iodide under reduced pressure (15 mm.), rapid decomposition took place, finally with explosive violence.

On standing in stoppered vessels, all the above α -halogenated ethyl sulphides deposit small quantities of fine, white, silky, needle-like crystals round the stopper. Crystals similar in appearance and odour were obtained when $\alpha\alpha'$ -dichlorodiethyl sulphide was

* Since the above was written, Cashmore (this vol., p. 1740) has shown that both the sulfoxide and sulphone of $\beta\beta'$ -dichlorodiethyl sulphide yield diethoxy-compounds on treatment with sodium hydroxide in 95 per cent. ethyl-alcoholic solution.

treated with alcoholic alkali, with sodium phenoxide in alcoholic solution, or with ethylene chlorohydrin. In the last case, the crystals were identified as β -trithioacetaldehyde, m. p. 125° (compare Mann and Pope, this vol., p. 1181) (Found: S = 53.12. Calc., S = 53.35 per cent.).

It has been found necessary to interrupt this investigation, but it is hoped to return later to the consideration of other points of interest which have arisen during the work, including the action of halogens on divinyl sulphide.

The authors wish to express their thanks to the Director of Artillery for permission to publish these notes, and to the Director of Chemical Inspection, Mr. G. H. Perry, O.B.E., for his continued interest and encouragement.

CCLXXXV.—As-Methyldihydroarsindole.

By EUSTACE EBENEZER TURNER and FRANK WARD BURY.

SOME time ago (Burrows and Turner, T., 1921, **119**, 426), the arsenic analogue of *N*-methyltetrahydroquinoline was described. The present communication records the synthesis of As-methyldihydroarsindole, $\text{C}_6\text{H}_4\text{AsMe}(\text{CH}_2)_2$, the arsenic analogue of *N*-methyldihydroindole.

The synthesis of this substance from β -phenylethyl alcohol has presented considerable difficulty, and although the preliminary work is now complete, it has not been possible to examine the new arsine in any great quantity. Such examination will be described in a subsequent communication.

EXPERIMENTAL.

β -Bromoethylbenzene.—The β -phenylethyl alcohol used in this work was either the pure commercial material, or the product (b. p. 104°/21 mm.) obtained by the small-scale reduction of ethyl phenylacetate by means of sodium and alcohol. This reduction is less easily effected on the laboratory scale than that of ethyl β -phenylpropionate. The bromo-derivative was prepared by means of phosphorus tribromide* (compare Burrows and Turner, *loc. cit.*)

* Phosphorus tribromide is readily obtained in good yield if bromine is added to a suspension of red phosphorus in carbon tetrachloride at 0°.

and was obtained in good yield (b. p. $96^{\circ}/13$ mm. or $98^{\circ}/14$ mm.) (compare Rupe, *Annalen*, 1913, **395**, 87). The bromo-compound cannot be dried over calcium chloride; anhydrous sodium sulphate is to be recommended.

$\alpha\delta$ -Diphenylbutane.—The bromo-compound (28 grams) combined readily with magnesium (4.1 grams) in ethereal solution (60 c.c.), and the resulting product reacted vigorously with anhydrous cupric chloride (compare T., 1919, **115**, 559) to give a good yield of $\alpha\delta$ -diphenylbutane, having the melting point (52°) recorded in the literature. No unsaturated hydrocarbons were formed.

β -Phenylethyldimethylarsine.— β -Bromoethylbenzene (153 grams) and magnesium (25 grams, that is, a slight excess) were allowed to interact in presence of 350 c.c. of ether, the clear solution obtained was decanted and slowly treated, in an atmosphere of hydrogen, with 150 grams of dimethyliodoarsine. Vigorous interaction occurred, with the formation of two layers. After addition of ice and dilute hydrochloric acid, the ethereal layer was separated, the aqueous layer extracted with ether, and the combined extracts, after being dried over anhydrous sodium sulphate, freed from ether by distillation. The residual oily liquid was then distilled under diminished pressure in an atmosphere of hydrogen, when 132 grams (97 per cent. of that quantity theoretically obtainable from the dimethyliodoarsine used) of *β -phenylethyldimethylarsine*, b. p. $115^{\circ}/15$ mm. or $116^{\circ}/16$ mm., were obtained as a colourless liquid with a high refractive index and a more unpleasant odour than that of most arsines.

The arsine readily oxidises in the air, more particularly if it is heated. It forms a compound with dimethyliodoarsine, and for this reason an excess of Grignard reagent over dimethyliodoarsine was used. The compound was not examined, but is presumably analogous to that formed by γ -phenylpropyldimethylarsine.

The *methiodide* of *β -phenylethyldimethylarsine* was formed readily and crystallised from alcohol in slender, colourless prisms melting at 200° (Found: I = 36.0. $C_{11}H_{13}IAs$ requires I = 36.1 per cent.). The *ethiodide*, formed less readily, separated from alcohol in large, colourless prisms melting at 139° (Found: I = 34.8. $C_{12}H_{20}IAs$ requires I = 34.7 per cent.). These arsonium iodides combine with mercuric iodide in alcoholic solution to give pale yellow *mercuri-iodides*.

Conversion of β -Phenylethyldimethylarsine into β -Phenylethylmethylchloro- and -bromo-arsines.— *β -Phenylethyldimethylarsine* readily combined with bromine in carbon tetrachloride solution to give the *dibromide*, which separated in colourless prisms. The

dibromide decomposed, on heating at 180° , to give a mixture of dimethylbromoarsine, β -bromoethylbenzene, and β -phenylethylmethylbromoarsine. The last substance was not obtained pure and was found to be less suitable for the purpose of this work than the corresponding chloro-arsine, which was prepared in the following manner:

A solution of 100 grams of β -phenylethyldimethylarsine in its own volume of carbon tetrachloride was treated with dry chlorine until the yellow colour of the latter persisted—the stage corresponding to the formation of the *dichloride* (which, however, did not separate). The solvent was removed by distillation, and the residue heated in a metal-bath kept at 180° until no further evolution of methyl chloride occurred. The oil thus obtained, on distilling under diminished pressure, gave 39 grams of a mixture of dimethylchloroarsine and β -chloroethylbenzene and 48 grams of β -phenylethylmethylchloroarsine. The latter is a colourless liquid, b. p. $147^{\circ}/16$ mm. or $152^{\circ}/21$ mm., has a high refractive index, and is practically odourless, although its vapours possess sternutatory properties (Found: Cl = 14.7. $C_9H_{12}ClAs$ requires Cl = 15.4 per cent.).

The chloroarsine reacted readily with magnesium methyl iodide in ethereal solution to give β -phenylethyldimethylarsine, which was identified by conversion into the methiodide.

As-Methyldihydroarsindole.—A mixture of 10 grams of the preceding chloroarsine, 5 grams of anhydrous aluminium chloride, and 20 c.c. of carbon disulphide was gently warmed. Two layers formed almost immediately and hydrogen chloride was evolved. After the solvent had been gently boiling for two hours, the mixture was poured on to ice, dilute hydrochloric acid added, and the whole extracted with carbon tetrachloride. The dried extracts were evaporated and the residue was distilled under diminished pressure, when the major portion distilled at 115 – $125^{\circ}/20$ – 25 mm. On redistillation, *As-methyldihydroarsindole* was obtained as a colourless liquid boiling at 112 – $113^{\circ}/15$ mm., and possessing an odour similar to that of the arsinoline.

On one occasion, the experimental conditions being apparently the same, the chloroarsine was recovered practically unchanged, although hydrogen chloride was evolved freely. It is probable that the change

is reversible in presence of aluminium chloride. This point will be examined when larger quantities of material are available.

The arsindole readily forms a *methiodide*, which crystallises from alcohol in colourless prisms melting at 250° (Found: I = 37.8. $C_{10}H_{14}IAS$ requires I = 37.8 per cent.). The methiodide combines readily with mercuric iodide, in alcoholic solution, to give the *mercuri-iodide*, $C_{10}H_{14}As.HgI_2$, canary-yellow needles melting at 160–161° (with preliminary softening) (Found: Hg = 25.9. $C_{10}H_{14}I_3AsHg$ requires Hg = 25.4 per cent.). The *ethiodide* is formed less readily than the methiodide and crystallises from alcohol in colourless prisms, m. p. 162–163° (Found: I = 36.0. $C_{11}H_{16}IAS$ requires I = 36.3 per cent.).

Both these arsonium iodides appear to undergo intramolecular (reversible) change on heating in alcoholic solution. The hot solution is brown, the colour disappearing on cooling:

The *benzobromide* is produced rapidly from its constituents at water-bath temperatures and crystallises from alcohol in slender, colourless needles melting at 180° (Found: Br = 21.9. $C_{16}H_{18}BrAs$ requires Br = 21.9 per cent.). Owing to the deliquescent nature of the bromide, crystallisation was performed in a dry atmosphere. The investigation of this substance, containing an asymmetric arsenic atom, and also of the compounds of the oxide of the arsindole with optically active acids, is under contemplation.

Tri-β-phenylethylmethylarsonium Iodide,* $(CH_2Ph \cdot CH_2)_3MeAsI$.—This substance was obtained by allowing the Grignard reagent prepared from β-bromoethylbenzene to react with arsenic iodide. The product was a mixture of αδ-diphenylbutane and tri-β-phenylethylarsine, which could not be separated. Methyl iodide was therefore added and the product crystallised from alcohol, when a good separation of the hydrocarbon from the arsonium iodide was effected. The iodide forms colourless leaflets, melting at 112° (Found: I = 24.4. $C_{23}H_{30}IAS$ requires I = 23.9 per cent.).

Part of the expenses entailed were met by a grant from the Research Fund Committee of the Chemical Society, to whom the authors express their thanks.

CCLXXXVI.—*Selective Solvent Action by the Constituents of Aqueous Alcohol. Part II. The Effect of some Alcohol-soluble Semi-solutes.*

By ROBERT WRIGHT.

In a former paper (I., 1922, 121, 2251), the effects of the three solutes benzyl alcohol, glycerol, and sucrose on the partial vapour pressures of the constituents of aqueous alcohol were described. It was shown that when a 38 per cent. solution of alcohol in water was used, the effect of both sucrose and glycerol was to lower the partial vapour pressure of the water and raise that of the alcohol, whilst benzyl alcohol lowered the vapour pressures of both constituents of the solvent.

The term "semi-solute" was used to designate a substance soluble in only one constituent of the mixed solvent, whilst "amphi-solute" implied a substance soluble in each of the separate constituents. Of the three solutes used, benzyl alcohol is soluble in alcohol and insoluble in water, sucrose is soluble in water and insoluble in alcohol, whilst glycerol is completely miscible with both alcohol and water. Thus each solute belongs to a separate class, and as their effects on the partial vapour pressures of the mixed solvent did not admit of any simple explanation, the investigation was extended to a larger number of solutes. What may be called the normal effect of a solute on the mixed solvent would be that it should lower the vapour pressure of the solvent constituent in which it is soluble, and either have no effect on, or at most slightly raise, the vapour pressure of the constituent in which it is insoluble. This elevation of the vapour pressure of the solvent constituent in which the semi-solute is insoluble is due to the union between the semi-solute and the constituent in which it is soluble, thus leaving the solvent richer in the non-dissolving constituent, which has in consequence an increased vapour pressure. Of the three solutes dealt with in the last paper, sucrose alone gave the normal result, as it lowered the vapour pressure of the water and raised that of the alcohol; glycerol lowered only the aqueous vapour pressure and raised that of the alcohol, although it is soluble in both constituents, whilst benzyl alcohol was also abnormal in that it lowered both partial vapour pressures, although it is only soluble in the alcohol constituent.

In the present paper two points are examined: (a) the partial pressures of a series of aqueous alcohol solutions of varying composition and all containing 5 gram-molecules of glycerol per kilogram of mixed solvent were measured, and compared with the

partial pressures of the same series of solvents when no glycerol was present, (b) the effects produced by a considerable number of alcohol-soluble semi-solutes were examined, the aqueous alcohol used as solvent being an equimolecular mixture of the two constituents. In all cases the vapour pressures were determined at 20°.

The partial vapour pressures obtained for a series of aqueous alcohol mixtures when no solute was present are given in Table I, and those for solutions of 5*M*-glycerol in a similar series of solvents are in Table II. Graphs drawn from the results are also shown. It will be seen that whilst glycerol lowers the vapour pressure of

the water throughout the whole series of the solutions, it is only in the solutions rich in alcohol that the alcohol vapour pressure is lowered, the effect of the added glycerol in the case of the more dilute alcoholic solutions being to raise slightly the partial pressure of the alcohol. Thus the two partial pressure curves for the alcohol,

when no glycerol is present, and when glycerol has been added, intersect each other, although the exact point of intersection is somewhat doubtful. It would seem that although glycerol is completely miscible with both alcohol and water, yet it has a greater attraction for the latter solvent, since its action in the case of dilute alcoholic solutions can be explained only on the assumption that the glycerol molecules become hydrated and, as it were, render the solution richer in alcohol, and therefore with an increased alcohol vapour pressure. The reverse effect with strong alcoholic solutions was not observed, that is, such solutions did not show a higher water partial pressure in the presence of glycerol than in its absence.

FIG. 1.

Vapour pressure of aqueous alcohol at 20°.

- Curve A = Vapour pressure of alcohol.
 A' = Vapour pressure of alcohol with 5M-glycerol.
 W = Vapour pressure of water.
 W' = Vapour pressure of water with 5M-glycerol.

The series of alcohol-soluble semi-solutes were all examined in molecular concentration (1 gram-mol. per kilo.), an equimolecular mixture of alcohol and water being used as solvent. The results are given in Table III, where it will be seen that in all cases, including that of benzyl alcohol, the partial pressure of alcohol is lowered and that of water slightly raised. The results are thus quite normal, as the solute lowers the vapour pressure of the constituent in which it is soluble and raises that of the other constituent which has no dissolving action on the solute.

Since, as shown by the former investigation, benzyl alcohol, when dissolved in 38 per cent. aqueous alcohol, lowered the partial pressures of both alcohol and water, whilst in the present case, with an equimolecular (71.9 per cent.) alcohol-water mixture, the vapour pressure of the alcohol alone was lowered and that of

It will be seen that the vapour pressure of the alcohol is continuously lowered as the concentration of benzyl alcohol increases, whilst the water vapour pressure is raised to practically the same small extent for all concentrations of the solute. It may be pointed out that the partial pressure of the water could not be continuously raised by the successive additions of benzyl alcohol, as in such an event it would soon exceed the vapour pressure of pure water.

The effect of benzyl alcohol on a more dilute alcoholic solution was also investigated. The composition of the solvent used was 1 mol. of alcohol to 4 mols. of water, that is, about 39 per cent. alcohol. The results are given in Table V, where it will be seen that as usual the effect on the alcohol vapour pressure is a lowering which increases with increasing concentration of solute, whilst

the vapour pressure of water is affected in an unusual manner, being at first lowered and then, as the concentration of solute increases, raised. This effect is somewhat difficult of simple explanation; it may be that, with solutions rich in water, the

benzyl alcohol exhibits an induced solubility in that solvent, and consequently lowers the aqueous vapour pressure; the reverse effect with the higher concentrations of solute may, as before, be explained by the union between benzyl alcohol and ethyl alcohol, but the phenomenon is evidently a complex one, and is probably connected with the very considerable solubility of benzyl alcohol in dilute aqueous ethyl alcohol. It was not found possible to work with more dilute alcoholic solutions, owing to the decreasing solubility of the benzyl alcohol; unfortunately, also, solutes of the nature of benzyl alcohol, insoluble in water but of considerable solubility in dilute, aqueous alcohol, are rare, so that the work could not be extended to a larger series of substances; further information, however, may be obtainable from an investigation of a series of water-soluble semi-solutes.

EXPERIMENTAL.

The purification of the substances used does not require description. The solutes chosen were all very slightly soluble in pure water, fairly soluble in aqueous alcohol, and of very small vapour pressure. The vapour pressures of the solutes were tested by aspirating 2 litres of air first over the pure substance at 20° and then through a combustion furnace; the amount of carbon dioxide obtained in no case exceeded 0.001 gram, an amount which would be considerably lessened when the solute was dissolved, and in any case could only affect the result to a fraction of 1 per cent.

The compositions of the various aqueous alcohol solutions used as solvents were found by density measurements. The vapour pressures were determined by the air current method described in the previous paper, but as some slight changes were made,

a brief *résumé* of the method will be given. The solution under investigation was contained partly in a tinned copper vessel, fitted with a sensitive thermometer, and partly in a set of glass bulbs, both of which were placed in a thermostat which was kept at $20^{\circ} \pm 0.1^{\circ}$. By means of an aspirator fitted with a manometer, purified air was drawn through a copper heating coil placed in the thermostat, and then through the solution. The saturated air was then passed through a small combustion furnace and the products of combustion were absorbed in the usual manner. In carrying out a combustion, the furnace was heated and the solution allowed to come to the temperature of the thermostat, the tap of the aspirator was then opened and the air pressure inside the apparatus reduced until the first bubble of air passed through the solution. The tap was then closed, and a 2-litre graduated flask placed so as to collect the water from the aspirator, which was again started, the rate of flow being about 2 litres in three hours. After 2 litres had been aspirated, the flow of water was stopped, the solution bulbs were disconnected, and air was drawn through the furnace to sweep out any products of combustion. From the weights of carbon dioxide and water absorbed, the weights of alcohol vapour and water vapour present in the aspirated air can be calculated. These weights, divided by the molecular weights of alcohol and water and then multiplied by 22,425, give the volumes of the vapours at *N.T.P.* The volume of air aspirated is also reduced to *N.T.P.* and to it is added the volume of oxygen used in the combustion of the alcohol vapour. We then have

$$\frac{\text{V.p. of ethyl alcohol}}{\text{Total pressure in the apparatus}} = \frac{\text{Vol. of ethyl alcohol vapour}}{\text{Vol. of air + EtOH and H}_2\text{O vapour}};$$

a similar calculation will give the vapour pressure of the water.

It is doubtful if great accuracy can be claimed for the determination, but the relative vapour pressures are probably correct to within 5 per cent.

Conclusions.—The general effect of the addition of an alcohol-soluble semi-solute to an equimolecular water-alcohol mixture is to lower the vapour pressure of the alcohol and to raise slightly the vapour pressure of the water.

Increasing concentration of solute further lowers the alcohol vapour pressure, but does not raise the water vapour pressure beyond a very small limit.

Benzyl alcohol, which is very soluble in dilute alcohol although insoluble in pure water, when dissolved in fairly dilute aqueous alcohol (1 mol. of alcohol to 4 mols. of water), first lowers the water

vapour pressure and afterwards, at greater concentrations of solute, increases it. Thus in some cases benzyl alcohol behaves as though it were dissolved in the aqueous as well as in the alcoholic constituent of the mixed solvent.

I desire to thank Prof. A. W. Stewart for the interest he has shown in these investigations.

CCLXXXVII.—*Nitrosation of Phenols. Part I.*
3-Chloro-4-nitrosophenol and its Conversion into
Two Isomeric Chloroquinonemonoximes.

By HERBERT HENRY HODGSON and FRANCIS HARRY MOORE.

p-NITROSOPHENOL and its tautomeride, *p*-benzoquinonemonoxime, have hitherto never been definitely isolated as such, and in consequence have been regarded as existing either in dynamic equilibrium or entirely in the quinonoid form. The simple homologues and halogenated derivatives are regarded in like manner.

The authors claim to have obtained the individual tautomerides of 3-chloro-4-nitrosophenol, to have worked out the experimental conditions for the preparation of the real nitroso-compound, $\text{OH}\cdot\text{C}_6\text{H}_3\text{Cl}\cdot\text{NO}$, and to have accomplished its conversion by means of acids or alkalis of definite concentration into the quinoneoxime, $\text{O}\cdot\text{C}_6\text{H}_3\text{Cl}\cdot\text{NOH}$, which exhibits geometrical isomerism. The geometric isomerides are interconvertible, but such reversibility does not seem to apply to the nitroso- and quinonoid modifications.

The two general methods of preparing nitrosophenols, namely, the direct action of nitrous acid on phenols and the alkaline decomposition of the *p*-nitroso-derivatives of aromatic tertiary amines, will be shown to involve conditions which favour the stability of the quinonoid structure.

The direct action of nitrous acid on a phenol would appear to involve the minimum of complication, and the regulating influence of steric hindrance suggested to the authors a means of controlling any transformation likely to occur from the initial form of the product into its tautomeride. For such a purpose 3-chlorophenol appeared eminently suitable; moreover, its nitrosation was of interest in view of the very exhaustive investigations of Bridge and of Kehrman on the quinoneoxime derivatives from 2-chlorophenol.

The first method employed for the nitrosation of 3-chlorophenol was an adaptation of that described by Bridge (*Annalen*, 1893,

277, 85) for the preparation of *p*-nitrosophenol. The low melting point of the product indicated an equilibrium mixture of tautomers. Owing to steric hindrance, the rate of nitrosation was slow, so that during the reaction there were present together for an appreciable interval of time, 3-chlorophenol, 3-chloro-4-nitrosophenol, mineral acid, and nitrous acid. A discovery then considerably facilitated the quest for a more economical method. In the attempt to purify the final product by recrystallisation from hot dilute mineral acid, its melting point was raised by about 40°, owing to its conversion into a tautomeric form. Mineral acids, therefore, were detrimental to the preservation of the product in its initial form; steric hindrance, on the other hand, favoured its permanence. Baeyer and Caro (*Ber.*, 1874, 7, 807, 963) have shown that mineral acids promote the formation of condensation products of *p*-nitrosophenol and free phenol, and hot glacial acetic acid converts *p*-nitrosophenol into a complex capable of functioning as a substantive brown dyestuff (the Clayton Aniline Co., D.R.-P. 106036).

The exclusion of such acids so far as practicable from the nitrosating mixture should therefore favour the production only of the initial form of the reaction product. This deduction proved to be sound, for by the means described in the experimental section there was obtained in 60 per cent. yield from 3-chlorophenol a substance which the authors claim to be the first true nitrosophenol to be isolated.

The steric hindrance which favours the maintenance of the initial nitroso-structure also permits a regulated conversion into the quinoneoxime modification. This result, accomplished with the aid of hot acid or cold alkali, is in striking contrast to the extreme instability of unsubstituted nitrosophenols towards hot acids. Two stereoisomeric monoximes have been prepared which display the characteristic properties of geometric isomerides. The red modification of the quinoneoxime, produced by the action of hot dilute hydrochloric acid, is readily converted into an almost colourless form by alkalis, and *vice versa*. For the red oxime, the *syn*-configuration has been tentatively adopted as best accounting for its colour through the greater exertion of partial valencies or electronic interplay, whilst the *anti*-configuration has been assigned to the almost colourless, alkali-stable isomeride:

This view is in consonance with the fact that hydrochloric acid is an effective agent for transforming *anti*-aldoximes into the hydrochlorides of the corresponding *syn*-compounds (Luxmoore, T., 1896, 69, 181). Hantzsch ("Grundriss der Stereochemie," 2nd edn., p. 130) classifies the oximes as acid- and alkali-stable, respectively, and notes the instability of the *anti*-compounds in presence of acids, especially hydrochloric acid. Our *anti*-compound is liberated in stable condition from its alkaline solutions by hydrochloric acid, a stability which is to be ascribed to the presence of the nuclear chlorine atom.

The occurrence of well-defined, isomeric nitrosophenols and quinoneoximes, and the knowledge of the conditions necessary for their isolation, render possible the interpretation of many of the difficulties encountered by previous workers on nitrosophenols. When nitroso- β -naphthol is treated with aniline in alcoholic solution, a yellow, crystalline compound, $C_{16}H_{12}ON_2$, is obtained, whereas in hot glacial acetic acid a more complex, dark red product, $C_{22}H_{16}ON_2$, results. It may be assumed that, in presence of basic aniline, nitroso- β -naphthol, reacting in the quinonoid form, condenses normally to give the compound $NPh \cdot C_{10}H_6 \cdot NOH$, whilst, in the second reaction (we have found acetic acid to bring about conversion very slowly), the nitroso-form prevailing, an azo-compound such as $OPh \cdot C_{10}H_6 \cdot N \cdot NPh$ is furnished by double condensation.

Bridge has shown (*Amer. Chem. J.*, 1892, 14, 276) that α -benzylhydroxylamine converts *p*-benzoquinone quantitatively into the quinoneoxime ether, $OC_6H_4 \cdot N \cdot O \cdot CH_2Ph$, a substance identical with the compound he obtained from sodium or silver nitrosophenoxide and benzyl chloride. Bridge's conclusion, which is perfectly sound, is a natural consequence of the conditions employed inasmuch as the sodium and silver salts, having originated in an alkaline environment, would possess quinonoid formulæ at the outset. A more interesting result from our point of view was Bridge's preparation from silver nitrosophenoxide and acetyl chloride of *p*-benzoquinoneoxime acetate identical with the product from nitrosophenol and acetic anhydride. We have found that acetic anhydride converts 3-chloro-4-nitrosophenol into the corresponding oxime, and therefore Bridge's two products were identical owing to the conditions of reaction. It may be mentioned here that we have obtained *p*-nitrosophenol of much higher melting point than that officially recorded, which is evidence that the product as usually prepared is a mixture of tautomerides.

A long discussion between Bridge (*Annalen*, 1893, 277, 79) and Kehrman (numerous papers) settled the question of the existence

of stereoisomeric alkyl and acyl derivatives of 2-chlorobenzoquinone-4-oxime. Kehrman found that ortho-substitution in the quinones retards or inhibits the formation of oximes, but his conclusion that the retardation or inhibition is due less to the nature of the substituent than to its presence in the ortho-position to the quinone oxygen needs modification, for we have found that a halogen atom exerts a far greater influence than a methyl group, and have obtained indications of a specific effect for each halogen.

When hydroxylamine salts are used for oxime formation, the effect of the acid, generally hydrochloric acid, cannot be ignored, and failure of attempts to prepare dioximes by prolonged boiling with excess of the reagent is attributable to the acid producing a feebly reactive geometric isomeride.

The dark red and the yellow modification of nitroso-orcinol prepared by Henrich (*Ber.*, 1896, **29**, 989; 1899, **32**, 3419) from the corresponding sodium derivatives by hot and cold acid, respectively, now appear to furnish an example of geometrical isomerism analogous to that of 3-chlorobenzoquinone-4-oxime. Similar cases are found in the monoethyl ether (Kietaibl, *Monatsh.*, 1898, **19**, 536) and the methyl ether (Henrich and Rhodius, *Ber.*, 1902, **35**, 1475; *J. pr. Chem.*, 1904, [ii], **70**, 313, 332; 1905, [ii], **71**, 56) of nitrosoresorcinol. The latter authors describe what they believe to be the two modifications, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{OMe})\cdot\text{NO}$ and $\text{O}\cdot\text{C}_6\text{H}_3(\text{OMe})\cdot\text{NOH}$. In view of their identical melting point and ready interconvertibility, we believe them to be stereoisomeric oximes; in which case the nitroso-form should exist as a third modification, a possibility contained in Henrich's data, in which he describes a soluble, brown compound of m. p. 138°. This work is at present under our consideration.

The isolation of pure, well-defined nitroso- and quinoneoxime isomerides affords an example of inhibited dynamic isomerism. By the ordinary methods of forming nitroso-compounds, 3-chlorophenol affords mixtures of the tautomeric isomerides, the state of equilibrium being determined by the character of the acidic medium. The change from nitroso- to oxime form is, however, very slow at the ordinary temperature in an acid environment owing to steric hindrance, but in its absence, as in ordinary phenol, it appears probable that the oxime form will predominate. Our examples afford direct evidence against Laar's speculative theory of tautomerism, according to which the phenomenon is regarded as being intramolecular.

EXPERIMENTAL.

3-Chloro-4-nitrosophenol.—After many trials with the object of improving the yield and obviating the formation of resinous

by-products, Bridge's method (*loc. cit.*) was modified as follows: Eight c.c. of concentrated sulphuric acid, diluted with 12 c.c. of water, were added during two to three hours to a vigorously stirred solution of 4 grams of 3-chlorophenol in 300 c.c. of water containing 2 grams of caustic soda and 10 grams of sodium nitrite, the temperature being maintained at about 0°. After many hours, a greenish-yellow, crystalline substance (3 grams; 60 per cent. of the theoretical yield), m. p. 129°, separated and the liquor contained nitrous acid; on one occasion, after the product was filtered off, the mother-liquor, which had been retained over the weekend, deposited large, star-shaped crystals, m. p. 129·6°, which were seen under the microscope to consist of aggregates of long needles.

The compound so formed is moderately soluble in cold alcohol or ether, giving greenish-yellow solutions (a characteristic of nitroso-compounds), but is almost insoluble in cold benzene. From alcohol diluted with water it crystallises in orange-yellow needles, m. p. 135°, from hot water in dark orange-yellow needles, m. p. 130°, and from hot benzene in greenish-yellow crystals melting at 135·8°. It dissolves in molten phenol or molten naphthalene, forming deep red solutions, gives a bluish-violet colour in Liebermann's reaction, and is non-volatile in steam. In the attempted steam-distillation a black residue, m. p. (if any) above 250°, was obtained and from the aqueous solution a red substance separated, its melting point, 130—165°, indicating partial conversion. No silver, mercury, or lead salt could be formed, and the nitroso-compound appeared to react as an alcohol rather than as a phenol (Found: Cl = 22·77; *M*, in freezing phenol, 152, 159. Calc. for $C_6H_4O_2NCl$, Cl = 22·52 per cent.; *M* = 157·5). From its low melting point, inability to form metallic salts, ease of conversion into the tautomeride, and general behaviour as an alcohol, the substance appears to be a true nitroso-compound.

The dissolution of 3-chloro-4-nitrosophenol in phenol should be effected at a temperature only slightly exceeding the melting point of the solvent, on account of its acidic nature. To establish whether the phenol had exerted any conversion influence or not, it was extracted from the cryoscopic mixture by cold water; a yellow solid, m. p. 130°, remained and therefore the phenol had acted merely as a solvent.

It has been proved experimentally that the nitroso-group is in the para-position to the hydroxyl group, but as the work has involved the preparation of several new compounds, the authors reserve this proof for a later publication.

Conversion of 3-Chloro-4-nitrosophenol into Stereoisomeric 3-Chloro-benzoquinone-4-oximes.—When a solution of 3-chloro-4-nitroso-

phenol in boiling dilute hydrochloric acid (1 part of acid to 2 of water) is cooled, dendritic crystals are deposited which vary in colour from reddish-orange to scarlet in different preparations and melt at about 170° . Crystallised from hot benzene, in which they are sparingly soluble, these yield clusters of orange or brownish-red plates, m. p. 172° (decomp.); occasionally, broad parallelograms are obtained. The melting points vary slightly according to the duration of the treatment with hydrochloric acid; the products having the lower melting points are doubtless mixtures of the geometrical isomerides produced by the acid. Prolonged boiling with moderately concentrated hydrochloric acid produces a red, crystalline substance, m. p. $210\text{--}215^{\circ}$ (compare Bridge, *loc. cit.*).

The red oxime forms a deep orange-yellow solution in alcohol, an orange solution in ether, and a deep red solution in phenol, and responds to Liebermann's nitroso-reaction, the colour being permanganate blue. No silver salt has as yet been obtained (Found: Cl = 22.03; M , in phenol, = 157.3. Calc. for $C_6H_4O_2NCl$, Cl = 22.52 per cent.; M = 157.5). The orange-red crystals recovered from phenolic solution melted at 170° .

Conversion of the Red into the Pale Yellow Isomeride.—When the above red compound was dissolved in dilute sodium hydroxide solution, no frothing (see later) occurred, and the cold solution on acidification deposited a very pale yellow precipitate which, under the microscope, was seen to consist of very characteristic, long, slender needles. The substance was practically pure, melting at $176\text{--}178^{\circ}$, and at 178° after recrystallisation from benzene (Found: Cl = 22.91 per cent.; M , in phenol, = 161.3, 155.7). The higher the melting point the paler is the colour of the product, indicating the removal of the original coloured isomeride. The substance forms pale yellow solutions in alcohol and ether, from which it crystallises readily, and an orange-yellow solution in phenol. It is sparingly soluble in cold or hot benzene, and on prolonged heating with benzene an insoluble resinous substance gradually forms. It responds to Liebermann's nitroso-reaction, giving a pure blue colour, and reacts with alcoholic silver nitrate to form a silver salt.

Interconversion of the Geometrical Isomerides.—The pale yellow compound of m. p. 178° is sparingly soluble in boiling dilute hydrochloric acid; the solution on cooling deposits the red form in dendritic masses, m. p. $170\text{--}172^{\circ}$, which are reconverted into the pale yellow form by treatment with alkali as above. A mixture of equal quantities of the two modifications melted at 170.6° .

Action of Alkalis on 3-Chloro-4-nitrosophenol.—In order to find

out whether the pale yellow isomeride could be obtained directly from 3-chloro-4-nitrosophenol, a series of experiments with alkalis was undertaken.

The nitroso-compound dissolved in dilute solutions of caustic soda (2—10 per cent.) with much frothing (in contrast to the dissolution of the red oxime, which occurs without frothing), forming a deep red solution. Frothing commenced after an interval of a few seconds, and if the solutions were acidified prior to its appearance, brown precipitates having melting points varying from 166° to 146° were obtained, the more dilute solutions furnishing the substances of higher m. p.'s. Conversion had therefore taken place, but prolonged exposure to the alkali caused further changes and black precipitates of indefinite nature were produced.

In 2 per cent. sodium carbonate solution the nitroso-compound dissolved forming a red solution, from which it was reprecipitated unchanged by dilute hydrochloric acid. In 10 per cent. solution, however, the yellow precipitate obtained on acidification melted at 153—154°, indicating partial conversion, whilst dissolution in a cold saturated solution (about 16.5% Na_2CO_3 at 15°) followed immediately by acidification in the cold gave a pale yellow substance of m. p. 173—174°, showing that complete transformation had occurred. If the alkaline solution was kept for two hours before being acidified, a dull red substance of indefinite m. p. (140—160°) was then obtained, prolonged exposure having again caused complex changes.

Results could not be obtained with 2 per cent. sodium bicarbonate solution, the nitroso-compound being too insoluble, but it dissolved in the saturated solution (about 8 per cent. at 15°), giving a red solution which on acidification yielded a reddish-yellow product of m. p. 172°. Complete transformation into the quinoneoxime had therefore occurred, but only partial conversion into the pale yellow tautomeride; the acidic character of the sodium bicarbonate may have not only produced a mixture of the geometrical isomerides but also prevented complications.

Ammonia and pyridine also bring about conversion. The direct conversion of 3-chloro-4-nitrosophenol into the pale yellow quinoneoxime by alkalis is therefore free from complication only under special conditions, in contrast to the quantitative character of the transformation of the red isomeride.

Conversion during the Direct Nitrosation of 3-Chlorophenol.—When nitrosation was carried out so that mineral acid or even acetic acid was in excess, products were obtained melting at 160° and upwards, the best yields being obtained when the dilution was sufficient to retain most of the product in solution. It is

this result that led to the realisation of the correct conditions for the formation of the true nitroso-compound.

*Comparative Reactions of the Three Isomerides. Solubility in Dilute Alcohol (3 parts of Alcohol to 1 part of Water).—*The nitroso-compound is the most soluble, giving a greenish-yellow solution. The red oxime is much more soluble than its pale yellow isomeride; both solutions have an orange tinge.

Coloration with Ferric Chloride.—When ferric chloride was added to the above solutions, the nitroso-compound developed a deep olive-brown, and the two oximes a much lighter orange-brown colour.

An alcoholic solution of the nitroso-compound and excess of ferric chloride was kept until crystallisation occurred, when crystals of m. p. about 172° were obtained, showing the converting influence of ferric chloride.

Liebermann's Nitroso-reaction.—To 0.05 gram of each isomeride, 0.1 gram of phenol and 1 c.c. of concentrated sulphuric acid were added.

	Nitroso-compound.	Red oxime.	Yellow oxime.
First colour to appear	Green	Deep green	Deep green
Changing to	Prussian blue	Slowly to blue	Rapidly to blue
Colour after addition to 30 c.c. of 10% NaOH	Very intense blue	Greenish-blue	Greenish-blue
Colour of 10 c.c. of above solution diluted to 50 c.c. with water	Weak lilac blue	Deep pure blue	Deep pure blue
Colour of original alkaline solution after two days	Violet	Permanganate blue	Permanganate blue, not quite so deep as with the red oxime

Summary.

(1) 3-Chloro-4-nitrosophenol, the first true nitrosophenol to be isolated, has been prepared by a modification of the general nitrosation method.

(2) This 3-chloro-4-nitrosophenol is changed into quinoneoxime tautomerides by the regulated action of acids or alkalis. The difference of the melting points of the nitroso- and oxime forms is $40-50^{\circ}$.

(3) Acids produce a red tautomeride, which appears to be the *syn*-form, whilst alkalis convert this into the *anti*-modification, which is almost colourless in the solid state, but forms deep red solutions in aqueous alkalis.

(4) The *syn*- and *anti*-forms are interconvertible, but so far neither modification has been reconverted into the nitroso-compound.

(5) The moderate stability of 3-chloro-4-nitrosophenol which has

enabled it to be isolated is ascribed to the steric effect of the chlorine atom.

In conclusion, the authors desire to express their thanks to the British Dyestuffs Corporation for gifts of chemicals which have enabled this work to be carried out.

THE TECHNICAL COLLEGE, HUDDERSFIELD.

[Received, June 26th, 1923.]

CCLXXXVIII.—*The Aryl and Alkyl Sulphonamides.*

By PERCIVAL WALTER CLUTTERBUCK and JULIUS BEREND COHEN.

It is well known that aryl sulphonamides yield with sodium hypochlorite aryl sulphonosodiochloroamides which possess active antiseptic properties :

The alkyl sulphonamides and alkylene disulphonamides, as Clutterbuck and Cohen have shown (T., 1922, **121**, 120), do not react in this way. The property of forming chloroamines seems therefore to depend on the presence of an aromatic nucleus, which property is unaffected by the presence of such nuclear substituents as the halogens, methyl, methoxy-, or nitro-groups.

In order to find to what extent the aromatic nucleus determines the behaviour of aromatic and aliphatic sulphonamides towards sodium hypochlorite, we have prepared substances in which the nucleus is removed from the sulphonamide group by aliphatic chains of varying length and have studied the action of sodium hypochlorite upon them. Toluene-*o*-sulphonamide and all the substitution products which we have examined react readily with sodium hypochlorite in a normal fashion. An attempt to prepare the homologue, sodium β -phenylethanesulphonate, by the action of sodium sulphite on β -phenylethyl chloride failed owing to the separation of hydrogen chloride and the consequent production of styrene :

The reaction is similar to that between ammonia or an amine and ethylenedisulphonyl chloride described in the former paper (*loc. cit.*), which yields vinylsulphonamide. On the other hand,

γ -phenylpropyl bromide reacts normally with sodium sulphite and gives a sulphonic acid and sulphonamide in the ordinary way :

Phenylbutyl bromide also acts normally with sodium sulphite and gives a stable and well-defined sodium sulphonate resembling the phenylpropyl compound. This again resembles the disulphonyl chlorides of $\alpha\gamma$ -propane and $\alpha\epsilon$ -pentane, which react normally with ammonia and amines. It appears, therefore, that an aliphatic chain of two carbon atoms to one of which a halogen atom is attached is unstable in presence of sodium sulphite. γ -Phenylpropanesulphonamide, although readily prepared, does not react with sodium hypochlorite. Thus an aliphatic side-chain of three carbon atoms prevents chloroamine formation.

In the course of this inquiry we have examined from the same point of view the behaviour of *cyclohexanesulphonamide*, which we find shares the general character of the aliphatic compounds and is unchanged by sodium hypochlorite, and the same is true of vinylsulphonamide, $\text{CH}_2\cdot\text{CH}\cdot\text{SO}_2\cdot\text{NH}_2$, in spite of the presence of a double bond.

Among the substituted naphthalene derivatives containing an aliphatic side chain we prepared *sodium 2-methoxy-1-naphthylmethanesulphonate*, $\text{OMe}\cdot\text{C}_{10}\text{H}_6\cdot\text{CH}_2\cdot\text{SO}_3\text{Na}$, but attempts to convert it into the sulphonyl chloride led to decomposition and therefore it was unsuitable for the preparation of a chloroamine.

To complete the list of substances recorded in the previous paper, methane- and dichloromethane-sulphonamides were prepared, but they yielded no chloroamines.

EXPERIMENTAL.

Sodium p-Chlorotoluene- ω -sulphonate.—*p*-Chlorobenzyl chloride was prepared by the chlorination of boiling *p*-chlorotoluene (*Ber.*, 1878, 11, 904). On cooling in ice, the chloride crystallised, and was purified by crystallisation from alcohol. The chloride was then boiled with the required amount of a concentrated solution of sodium sulphite and the sulphonate recrystallised from hot water.

Sodium p-Bromotoluene- ω -sulphonate.—*p*-Bromobenzyl bromide was obtained by the bromination at 185° of *p*-bromotoluene (*Ber.*, 1884, 17, 2922). The bromide was then boiled for several hours with a concentrated solution of sodium sulphite and the sulphonate recrystallised from hot water.

Sodium p-Iodotoluene- ω -sulphonate.—*p*-Iodobenzyl bromide was prepared (*Ber.*, 1876, 9, 931), and sulphonated as above.

Sodium o-, m-, and p-Nitrotoluene- ω -sulphonates.—These were prepared by boiling the corresponding nitrobenzyl chlorides with a concentrated solution of sulphite. On cooling, the sulphonates crystallised and were filtered and recrystallised. Careful boiling is required and excess of sulphite must be avoided, since these sulphonates readily char.

Sodium β -Phenylethanesulphonate.—This substance has not as yet been obtained. Phenylethane was prepared by Fittig's method by condensation of bromobenzene and ethyl bromide in presence of metallic sodium. The phenylethane was extracted with ether, the ether removed, and the residue fractionated. The portion boiling at 134–136° was collected. This was boiled under reflux and chlorine passed in until the weight had increased by the required amount. The liquid was then fractionated in a vacuum and a portion collected at 90–95°/17 mm. When β -phenylethyl chloride was treated with sodium sulphite, ammonium sulphite, or with silver sulphite, sulphur dioxide was evolved and a liquid obtained not miscible with water which was found to be styrene. It appears, therefore, that β -phenylethyl chloride loses hydrogen chloride, which decomposes the sulphite.

Sodium γ -Phenylpropanesulphonate.—Cinnamic ester when reduced gives γ -phenylpropyl alcohol. The reduction was carried out under different conditions with sodium and absolute alcohol (*Compt. rend.*, 1903, 136, 1676), but the yield was in no case very good. A slightly increased yield was obtained by the method of Levene and Allen (*J. Biol. Chem.*, 1916, 27, 443), the "absolute" alcohol for these experiments being dried by the addition of a little sodium and redistilling. After reduction, a little alcohol was added and the whole boiled to remove any unused sodium. After cooling, water was added to decompose the sodium ethoxide and the ethyl alcohol distilled on the water-bath. The remaining solution was extracted with ether and the ether extract fractionated. The higher alcohol boiled at 234°. A considerable part of the cinnamic ester was hydrolysed in the process and the free cinnamic acid was recovered by acidifying the aqueous solution, filtering off the acid, and recrystallising. The required amount of phosphorus pentabromide was then added gradually to the alcohol, which was cooled in water. The reaction proceeded quietly, heat being evolved and hydrogen bromide liberated. A little ice and iced water were added and the bromide was extracted with ether. The ethereal solution was shaken with water, then with dilute sodium carbonate solution, again with water, and finally dried and fractionated. The portion boiling at 111°/16 mm. was collected. The bromide, on boiling with a strong solution of sodium sulphite, readily gave

the sulphonate, which crystallised in shining, colourless leaflets from the concentrated, cooled solution.

Sodium δ -phenylbutanesulphonate was prepared by the method of von Braun (*Ber.*, 1911, **44**, 2872). Dried magnesium turnings were added to γ -phenylpropyl bromide in dry ether, the solution was boiled on the water-bath until the magnesium had disappeared, finely powdered trioxymethylene added, and the mixture boiled for twenty-four hours, cooled, and acidified. The ethereal layer was then separated and dehydrated, the ether evaporated, and the residue fractionated in a vacuum. The fraction boiling at $140^{\circ}/17$ mm. was δ -phenylbutyl alcohol. This was converted into δ -phenylbutyl bromide by the action of phosphorus pentabromide. The bromide, when purified as described in the case of the phenylpropyl bromide, boils at $132^{\circ}/12$ mm. This method was found to be more convenient than von Braun's, in which the alcohol is heated with fuming hydrobromic acid at 100° . The bromide was readily sulphonated on boiling it with a solution of sodium sulphite and gave a crystalline sulphonate closely resembling the benzyl and phenylpropyl compounds.

Sodium 2-Methoxy-1-naphthylmethanesulphonate.— β -Naphthol was boiled for several hours with the required amounts of formaldehyde and sodium sulphate solution (Baeyer & Co., D.R.-P. 87335). The mechanism of the reaction appears to be as follows :

β -Naphthol was suspended in water and mixed with a concentrated solution of sulphite. On adding formaldehyde, the naphthol immediately dissolved, but on heating, a precipitate of fine needles separated. Some of these remained after boiling for several hours. They contained no sulphur and were shown to be 2-hydroxy-1-naphthylmethyl alcohol. This substance melted with decomposition at 193° (compare C., 1907, I, 966; m. p. $188-189^{\circ}$). After boiling, the solution was filtered and acidified with acetic acid, when the free sulphonic acid was precipitated; it was filtered, and recrystallised from dilute spirit. The free acid was dissolved in excess of caustic soda and stirred with methyl sulphate, the mixture becoming hot and gradually solidifying. The resulting sodium 2-methoxy-1-naphthylmethanesulphonate was pressed on a filter and recrystallised from aqueous spirit.

Potassium cycloHexanesulphonate.—*cycloHexyl* iodide was first made by the method outlined in *Compt. rend.*, 1905, **141**, 593, and modified as follows: a solution of 127 grams of iodine in 1 litre of dry carbon disulphide was added gradually with shaking to a filtered solution of 10.3 grams of yellow phosphorus in about 30 c.c. of dry carbon disulphide, and the whole kept for about two hours. Instead of using a current of carbon dioxide to remove the carbon disulphide, the greater part was distilled from the water-bath maintained at 55°, and the rest was aspirated off under reduced pressure; 100 grams of *cyclohexanol* were then added gradually (to prevent loss by too violent a reaction). After the mixture had been cooled in water for several days, water was added to decompose any excess of phosphorus tri-iodide and the resulting liquid was extracted with ether. The ethereal solution was washed successively with water, sodium carbonate solution, and water, and dried over calcium chloride. It was fractionated in a vacuum, the bulk boiling at 74.4°/9 mm. The yield of *cyclohexyl* iodide was 88 per cent. The iodide was converted into the sulphonate by a method similar to that of Borsche and Lange (*Ber.*, 1905, **38**, 2766), who used *cyclohexyl* chloride. Fifty-five grams of *cyclohexyl* iodide, 6 grams of dried magnesium shavings, and 100 c.c. of dry ether were gently warmed until the reaction began. The flask was then cooled to moderate the reaction. After the magnesium had dissolved, 100 c.c. of dry ether were added, and a rapid stream of dry sulphur dioxide was passed into the mixture, cooled in a freezing mixture. Water was added, the by-products were removed by extraction with ether, and the aqueous solution was evaporated, giving crusts of magnesium *cyclohexanesulphinate* contaminated with magnesium iodide. This was dissolved in water and oxidised with potassium permanganate. Any remaining magnesium was precipitated with potassium carbonate and the liquid after filtration evaporated until the potassium *cyclohexanesulphonate* crystallised.

Sodium o-, m-, and p-Methoxytoluene- ω -sulphonates.—*o-, m-, and p-Methoxybenzyl* bromides were made from the corresponding hydroxybenzaldehydes by reduction, methylation, and treatment of the methoxybenzyl alcohols with hydrobromic acid, as described by Lapworth (*T.*, 1922, **121**, 1396). The bromides readily give sulphonates on boiling with a concentrated solution of sodium sulphite.

The following were also prepared:

Methanesulphonate.—The usual method of preparation (*Annalen*, 1868, **148**, 103) by heating methyl iodide and potassium sulphite in a sealed tube was rejected in favour of a much improved method privately communicated by Mr. P. K. Dutt.

Dichloromethanesulphonate.—Trichloromethanesulphonyl chloride was prepared (A., 1886, i, 1000) by allowing a mixture of carbon disulphide, hydrochloric acid, and potassium perchlorate to stand for several weeks in sunlight. This was then converted (*J. pr. Chem.*, 1884, [ii], 30, 284) into trichloromethanesulphonic acid, which, on treatment with zinc, gave zinc dichloromethanesulphonate. The zinc was precipitated with potassium carbonate, the filtrate evaporated to dryness, and the sulphonate extracted with alcohol.

Analysis of the Sulphonates.

Sodium sulphonate.	Sodium per cent.		Sulphur per cent.

Preparation of the Sulphonyl Chlorides.

The above sulphonates were carefully dried at 120°, finely powdered, and mixed with a slight excess of phosphorus pentachloride, and warmed. When the mass had liquefied, the phosphoryl chloride was distilled from the water-bath in a vacuum and the residue shaken with ice-water and extracted with ether. The ethereal solution was dried and used for the preparation of the amides. In some cases decomposition occurred. In the case of sodium γ -phenylpropanesulphonate it was found advisable to suspend the sulphonate in dry chloroform and to add the pentachloride gradually. In the case of sodium 2-methoxy-1-naphthylmethanesulphonate decomposition also occurred.

Preparation of the Sulphonamides.

Dry ammonia gas was passed into the dried chloroform or ether solutions of the sulphonyl chlorides, and the product extracted with acetone. The sulphonamides can generally be crystallised from boiling water, from which they separate on cooling. They are obtained by precipitation of an acetone solution with water. The following table gives the melting points and analyses :

Sulphonamide.	M. p.	Nitrogen per cent.	
		Found.	Calc.

* Solidifies only after long standing.

Preparation of the Chloroamines.

The sulphonamides were warmed with a freshly prepared solution of sodium hypochlorite. The chloroamines can in most cases be crystallised by evaporation of the aqueous solution in a vacuum over sulphuric acid or they can be precipitated by the addition of a saturated brine solution. The nitro-substituted benzyl compounds afforded some difficulty in purification owing to their greater solubility. γ -Phenylpropanesulphonamide, *cyclo*hexanesulphonamide, methane- and dichloromethane-sulphonamides, and ethylenesulphonamide did not give chloroamines, but the original sulphonamide was recovered unchanged in almost theoretical quantity.

The table below gives a list of those chloroamines which were prepared and their analysis :

Sulphonsodiochloroamide.	Sodium.		Nitrogen.

Action of Hydrazine on the Sulphonyl Chlorides.

Toluene-o-sulphonylhydrazide.—Toluene-*o*-sulphonyl chloride (2 mols.) was dissolved in absolute alcohol and to it was added an alcoholic solution of hydrazine hydrate (3 mols.). The water in the hydrate retained most of the hydrazine hydrochloride in solution; the precipitate, which was mainly *toluene-o-sulphonylhydrazide*, was recrystallised from hot water. It was slightly soluble in ether, absolute alcohol, or cold water, but very soluble in hot water or acetone. The pure substance melted with decomposition at 124—125°. Sodium hypochlorite decomposed the hydrazide, liberating

nitrogen (Found : $N = 14.78$. $C_7H_{10}O_2N_2S$ requires $N = 15.0$ per cent.).

p-Chlorotoluene- ω -sulphonhydrazide was prepared as above and recrystallised from boiling water. It melted with decomposition at $130-131^\circ$ (Found : $N = 12.5$. $C_7H_9O_2N_2ClS$ requires $N = 12.7$ per cent.).

p-Nitrotoluene- ω -sulphonhydrazide was obtained as described above and recrystallised from water (below 90°). It melts with decomposition at 87° (Found : $N = 18.0$. $C_7H_9O_4N_3S$ requires $N = 18.18$ per cent.).

Action of Phenylhydrazine on the Sulphonyl Chlorides.

Toluene- ω -sulphonphenylhydrazide.—The equivalent of two molecules of phenylhydrazine in ether was mixed with one mol. of toluene- ω -sulphonyl chloride in ether. Phenylhydrazine hydrochloride and the phenylhydrazide were precipitated together. After standing, the mass was pressed on a filter and washed with ether. The precipitate was then boiled with water, when the hydrochloride went into solution. The *phenylhydrazide*, which is sparingly soluble in water, was filtered off and purified by dissolving in acetone, filtering, and adding water. It melted with complete decomposition at 173° (Found : $N = 10.45$. $C_{13}H_{14}O_2N_2S$ requires $N = 10.69$ per cent.).

p-Chlorotoluene- ω -sulphonphenylhydrazide was prepared from *p*-chlorotoluene- ω -sulphonyl chloride as in the preceding experiment. The reaction was not immediately complete. After standing, the mass was pressed on a filter and purified as above. *p*-Chlorotoluene- ω -sulphonphenylhydrazide melted with total decomposition at 178° (Found : $N = 9.2$. $C_{13}H_{13}O_2N_2ClS$ requires $N = 9.4$ per cent.).

p-Nitrotoluene- ω -sulphonphenylhydrazide, prepared from the sulphonyl chloride as above, melted with total decomposition at 156° (Found : $N = 13.45$. $C_{13}H_{13}O_4N_3S$ requires $N = 13.6$ per cent.).

Action of Aniline on Sulphonyl Chlorides.

Toluene- ω -sulphonanilide.—The aniline (2 mols.) in ether solution was added to the toluenesulphonyl chloride (1 mol.) in ether. The reaction was slow, but after standing over-night the whole solidified. It is therefore better to use a higher-boiling solvent (benzene) and to boil the mixture. After recrystallisation from dilute spirit, the *anilide* melted at 101° (Found : $N = 5.5$. $C_{13}H_{13}O_2NS$ requires $N = 5.67$ per cent.).

p-Chlorotoluene- ω -sulphonanilide.—Aniline (2 mols.) in ether solution was added to *p*-chlorotoluenesulphonyl chloride (1 mol.) in ether. Precipitation was not complete for some time. The

anilide, recrystallised from diluted spirit, melted with decomposition at 235° (Found: N = 4.7. $C_{13}H_{12}O_2NCIS$ requires N = 4.95 per cent.).

p-Nitrotoluene- ω -sulphonanilide.—The reaction carried out as above in ether solution with *p*-nitrotoluenesulphonyl chloride and aniline was more rapid. After standing, the precipitate was filtered and washed with ether. The product was boiled with water and filtered hot. The *anilide* separated in long needles which appeared to decompose at 220° (Found: N = 9.4. $C_{13}H_{12}O_4N_2S$ requires N = 9.6 per cent.).

CCLXXXIX.—*The Absorption Spectra of the Vapours and Solutions of Various Ketones and Aldehydes.*

By JOHN EDWARD PURVIS.

THE absorption spectra in the visible and ultra-violet regions of various saturated aliphatic aldehydes and ketones have been described by Purvis and McClelland (T., 1912, **101**, 1810). The facts there disclosed are (1) the considerable number of absorption bands in the vapours of formaldehyde, glyoxal, and diacetyl as compared with the one or two in the solutions and thin films, and (2) the general resemblance of the vapour bands with the solution bands in other more complex aldehydes and ketones. In a later investigation of unsaturated aldehydes and ketones (T., 1913, **103**, 433) a considerable number of narrow bands were found in the vapours of acraldehyde and crotonaldehyde, and such bands were absent from the vapours of more complex aldehydes. Later it was shown (*ibid.*, p. 1088) that benzaldehyde vapour had a considerable number of narrow bands which were absent in acetophenone and benzophenone.

The author has investigated the following substances containing an aldehydic or a ketonic group: camphor (vapour), fenchone (vapour), camphorquinone (vapour), carvone (vapour). Camphoric anhydride (vapour and solution), carvoneoxime (solution), camphorimide (solution), and solutions of sucrose, dextrose, lævulose, and lactose were also examined.

The experimental methods have been described before.

Camphor.—The absorption spectrum in the ultra-violet regions of alcoholic solutions of camphor has been described by Baly, Marsden, and Stewart (T., 1906, **89**, 979), by Hartley (T., 1908,

93, 961), and by the author (T., 1915, 107, 644). They showed that the substance has a band the head of which is at about $1/\lambda 3500$ ($\lambda 2850$).

The vapour of the substance was investigated at the following temperatures and pressures:

At 120° and 785 mm. The rays were slightly weakened between $\lambda 310$ and $\lambda 276$, and were then transmitted to $\lambda 212$.

At 130° and 790 mm. The rays were a little weaker than the last between $\lambda 310$ and $\lambda 276$, and were then transmitted to $\lambda 212$.

At 140° and 795 mm. The rays were a little weaker than the last between $\lambda 312$ and $\lambda 270$, and were then transmitted to $\lambda 212$.

At 150° and 800 mm. The rays were weak between $\lambda 314$ and $\lambda 270$, and were then transmitted to $\lambda 212$.

At 160° and 805 mm. The rays were very weak between $\lambda 316$ and $\lambda 267$, and were then transmitted to $\lambda 212$.

At 170° and 810 mm. The rays were almost completely absorbed between $\lambda 318$ and $\lambda 262$ —except at the edges which were diffuse. The rays were then transmitted to $\lambda 214$.

At 180° and 815 mm. The rays were absorbed between $\lambda 320$ and $\lambda 259$ —except at the edges which were diffuse. The rays were then transmitted to $\lambda 214$.

At 190° and 820 mm. The rays were absorbed between $\lambda 325$ and $\lambda 250$ —except at the diffuse edges, and were then transmitted to $\lambda 220$.

At 200° and 825 mm. The rays were absorbed between $\lambda 328$ and $\lambda 240$, and were then transmitted to $\lambda 223$.

This band showed therefore no signs of division into a series of narrow bands, and it appeared to be more diffuse on the more refrangible edge. It is comparable with the solution band, the head of which is at about $\lambda 285$ (*loc. cit.*), except in position, when, as in all cases, the solution band is moved more towards the red end.

Fenchone.—Solutions of this substance have been investigated by Henderson, Henderson, and Heilbron (*Ber.*, 1914, 47, 876), and they found no difference in the absorptive capacity when compared with camphor. The solution band was at about $1/\lambda 355$ ($\lambda 282$).

The author has investigated the vapour of the substance at the following temperatures and pressures:

At 130° and 790 mm. The rays were a little weak between $\lambda 310$ and $\lambda 278$, and were then transmitted to $\lambda 214$.

At 150° and 800 mm. The rays were weaker than the last between $\lambda 316$ and $\lambda 267$, and were then transmitted to $\lambda 214$.

At 170° and 810 mm. The rays were very weak between $\lambda 320$ and $\lambda 260$, and were then transmitted to $\lambda 220$.

FIG. 1.
Vapour of camphorquinone.

The four bands are fairly well seen at the lower temperatures and pressures. The gradually increasing absorption is well marked as the temperature and pressure are increased.

(To face Times, p. 2317.)

At 190° and 820 mm. The rays were almost completely absorbed between λ 325 and λ 247, and were then transmitted to λ 220.

At 210° and 830 mm. The rays were completely absorbed between λ 325 and λ 240, and were then transmitted to λ 225.

As in camphor, the vapour of fenchone showed no signs of division into a series of narrower bands. The general appearance is like that of the vapour of camphor, and is also comparable with its own solution band.

Camphorquinone.—Stewart and Baly (T., 1906, 89, 489) found a strong band at $1/\lambda$ 207 (λ 483) in alcoholic solutions.

The vapour of the substance has been investigated at various temperatures and pressures. At 148° and 800 mm., between λ 458 and λ 420, there were four weak and diffuse bands divided into two groups; the more refrangible of each couple was weaker than the other; the rays were then transmitted to λ 225. These narrower bands became clearer and better defined as the temperature and pressure increased. At 198° and 825 mm. the rays were almost completely absorbed between λ 459 and λ 410 and then transmitted to about λ 300; the strong cadmium lines beyond this to about λ 255 were just visible. At 208° and 830 mm. the rays were completely absorbed between λ 459 and λ 400, and then transmitted to about λ 310.

The solution band, therefore, splits up into a series of narrower vapour bands, and this is quite unlike the phenomena observed in camphor and fenchone. Attention may be directed to the vapour bands of benzoquinone and its derivatives (this vol., p. 1841). The vapour bands of camphorquinone are much fewer than in the vapour of benzoquinone, and they are moved more towards the red end. A reproduction of an enlarged original photograph is shown in Fig. 1.

Camphoric anhydride.—An alcoholic solution of this substance was examined. No absorption band was observed and the line of general absorption for various strengths has been drawn (Fig. 2, III). The vapour of the substance was also examined at the following temperatures and pressures:

At 180° and 815 mm. The rays were transmitted to λ 215.

At 190° and 820 mm. The rays were transmitted to λ 215, but were weak between λ 250 and λ 235.

At 200° and 825 mm. The rays were transmitted to about λ 250, and were then absorbed, except for the strong cadmium lines beyond.

At 210° and 830 mm. The rays were transmitted to about λ 250, and were then absorbed.

At 220° and 835 mm. The rays were transmitted to about λ 260, and were then absorbed.

At 230° and 840 mm. The rays were transmitted to λ 263.

The substance both in solution and in the vaporous condition is remarkably transparent, and shows no signs of specific absorption.

Camphorimide.—An alcoholic solution of this substance was examined, and, as was to be expected, no absorption band was observed. The line of general absorption has been drawn (Fig. 2, II). The line of general absorption is shifted more towards the red end as compared with camphoric anhydride; this is probably connected with the NH-group in the molecule.

FIG. 2.

I. Carvoneoxime. II. Camphorimide. III. Camphoric anhydride.

Carvone.—Henderson, Henderson, and Heilbron (*loc. cit.*) found a band at $1/\lambda$ 310 (λ 319) in alcoholic solution. The author has investigated the vapour of the substance at the following temperatures and pressures:

At 140° and 795 mm. The rays were transmitted to about λ 252.

At 150° and 800 mm. The rays were a little weak between about λ 337 and λ 305, and were then transmitted to λ 256.

At 160° and 805 mm. The rays were weaker than in the last between λ 344 and λ 300, and were then transmitted to λ 257.

At 170° and 810 mm. The rays were still weaker than in the last between λ 354 and λ 299, and were then transmitted to λ 258.

At 180° and 815 mm. The rays were almost completely absorbed between λ 357 and λ 297, and were then transmitted to λ 260.

At 190° and 820 mm. The rays were completely absorbed between λ 364 and λ 296, except for the strong cadmium lines, and were then transmitted to λ 273.

At 200° and 825 mm. The rays were completely absorbed between λ 365 and λ 293, and then the strong cadmium lines were transmitted to λ 275.

At 210° and 830 mm. The rays were transmitted to λ 366.

At 230° and 840 mm. The rays were transmitted to λ 367.

At 250° and 860 mm. The rays were transmitted to λ 368.

The band therefore showed no signs of division. It is comparable with the solution band.

Carvoneoxime.—Alcoholic solutions of this substance showed no absorption bands. The curve of general absorption has been drawn (Fig. 3, I). Similar results with other oximes have been described before by Hartley and Dobbie (T., 1900, 77, 318) with acetaldoxime and acetoxime, and by Baly, Marsden, and Stewart (T., 1906, 89, 979), Hartley (T., 1908, 93, 961), and the author (T., 1915, 107, 643) as regards camphoroxime. In all these oximes the absorption bands of the mother-substances disappear.

Sucrose, Dextrose, Lævulose, and Lactose.—Aqueous solutions of these substances were examined and the curves drawn (Fig. 3). It will be seen that sucrose has no absorption band and is remarkably transparent. The other three substances show the specific absorption characteristic of aldehydes and ketones. The lævulose band

is a little wider than the dextrose band and is shifted a little more towards the red end. As compared with lævulose, the dextrose molecule opens out earlier, for the dextrose band shows itself in a normal solution and the lævulose band in a decinormal solution. The lactose band is a little wider than the dextrose one and is not so persistent; its position is about the same as that of dextrose. These facts indicate that the specific absorption is independent of the weight of the molecule and is closely connected with the structure. The primary oscillation centre is the C=O group, and the oscillations producing absorption are modified by the orientation of this group with the other atoms, that is, whether the group is aldehydic or ketonic.

Results.

The general results are (1) that camphorquinone vapour exhibits a few bands in the visible regions of the spectrum, whereas camphor, fenchone, and carvone have each a single band in the ultra-violet regions similar to the solution band, and camphoric anhydride has none; (2) that carvoneoxime, camphoric anhydride, and camphorimide have no solution bands in the visible or the ultra-violet regions; (3) that dextrose, lævulose, and lactose have specific solution bands in the ultra-violet regions characteristic of aldehydes and ketones, and sucrose has none.

These results show, therefore, that the substances examined are comparable with the more complex aldehydes and ketones described before (*loc. cit.*). On the other hand, the vapour of camphorquinone, possessing a diketonic structure, is comparable with that of diacetyl and *p*-benzoquinone (*loc. cit.*). The fundamental oscillation centre appears to be the C=O group, for the band disappears in carvoneoxime just as it does in acetaldoxime and in camphoroxime (*loc. cit.*).

Now, formaldehyde and glyoxal exhibit numerous bands which disappear in the more complex acetaldehydes and acetones. On the other hand, complex substances possessing a diketonic structure, like *p*-benzoquinone and diacetyl, show numerous bands in the visible regions; and in this respect camphorquinone is comparable with them. It may be that the closer position of the two C=O groups in camphorquinone and diacetyl as compared with benzoquinone restricts their oscillatory movements, the free valencies of the oxygen atoms tend to neutralise one another, and fewer bands result.

The author has also pointed out (this vol., p. 1841) that the group of vapour bands of *p*-benzoquinone in the visible regions are different from the two groups in the ultra-violet regions. It was suggested that these different types are produced by different

types of oscillating centres. Again, different substances, like camphorquinone and benzoquinone, possess similar vibrating centres—the two $\begin{smallmatrix} \text{C}:\text{O} \\ \text{C}:\text{O} \end{smallmatrix}$ groups—and the colour of such substances may be connected therewith, but modified in shade by their position and their relationship with the other atoms of the molecule. Such vibratory centres in different substances may show close resemblances in the individual groups of vapour bands. Solution bands can only exhibit general resemblances; they are not sufficiently detailed for the purpose; and the author is trying to investigate the vapour bands under similar conditions of temperature and pressure of different substances containing similar atomic groups which are supposed to be the origin of the bands.

I desire to convey my thanks to the Government Grant Committee of the Royal Society for their assistance in the purchase of the apparatus used in these experiments.

CCXC.—*Styrylbenzopyrylium Salts. Part III. The γ -Styryl Derivatives of 7-Hydroxy-2-phenyl-4-methylbenzopyrylium Chloride.*

By JOHANNES SYBRANDT BUCK and ISIDOR MORRIS HEILBRON.

In a former communication (Buck and Heilbron, T., 1922, **121**, 1198), various styrylbenzopyrylium salts were described having the styryl group in the α - or 2-position of the pyrylium ring. The present investigation was undertaken in order to ascertain whether γ - or 4-styrylpyrylium salts could also be prepared, a question which, at the same time, would determine whether or no a methyl group in the 4-position to the pyrylium oxygen atom is actually reactive. This problem was previously discussed by Borsche (*Annalen*, 1916, **411**, 38) in his study of the condensation reactions of 7-hydroxy-2:4-dimethylbenzopyrylium chloride, without, however, any conclusion being drawn. As suitable starting material for the work in hand, 7-hydroxy-2-phenyl-4-methylphenopyrylium chloride was selected. This was originally prepared by Bülow and Wagner (*Ber.*, 1901, **34**, 1782), who describe it as a yellow, crystalline substance containing one molecule of water of crystallisation. A brownish-yellow, less soluble modification is also mentioned, but was not apparently further investigated. Carrying out the preparation exactly as described by these authors, a product was obtained

answering approximately to their description, and a *perchlorate* which we prepared as a check gave satisfactory analytical results for an anhydrous salt. We found, however, that on attempting to condense this material with aldehydes, not only was much difficulty encountered owing to the formation of insoluble substances, but also that the styryl derivatives, when analysed, showed variable and inexplicable deviations. It thus appeared necessary to examine more closely our starting material, with the result that we found that, under the conditions described by Bülow and Wagner, neither the anhydrous compound nor the stated monohydrate was obtained, but a complex having a composition corresponding to one molecule of the anhydrous chloride plus one-half molecule of resorcinol. This addendum is remarkably firmly attached and is not removed even by repeated crystallisation from either alcoholic hydrochloric acid or glacial acetic acid. For some considerable time the presence of the resorcinol escaped notice, it being finally detected in the mother-liquors remaining after separation of the perchlorate. From these sufficient resorcinol was isolated to enable its identity to be established and also its *dibenzoyl* derivative to be prepared. The difficulty of preparing pure styrylpyrylium salts from this resorcinol compound arises from the fact that, although the resorcinol is in the main displaced during the condensation, small quantities are always retained in the styryl derivatives, owing to the practical difficulties involved, due to the rapid separation of the product during recrystallisation.

By carrying out the condensation of resorcinol with benzoyl-acetone as described by Bülow and Wagner (*loc. cit.*), but using 80 per cent. formic acid in place of the glacial acetic acid employed by them, a product is obtained which, depending on very slight variations in the method of recrystallisation, gives either the anhydrous 7-hydroxy-2-phenyl-4-methylbenzopyrylium chloride (I) or the hydrated chloride containing one molecule of water. This latter compound is quite possibly not a true pyrylium salt, but the hydrochloride of the open-chain unsaturated ketone* (II), a delicate equilibrium existing between the two forms.

The existence of the anhydrous chloride, now isolated for the first time, supplies complete experimental verification of Decker

* This matter will be dealt with in another paper, where more definite proof regarding these views will be given.

and Fellenberg's conclusions (*Ber.*, 1907, **40**, 3851) as to the true pyrylium nature of these compounds. That the methyl group is actually in the 4-position was shown by Bülow by hydrolysis of the compound with 10 per cent. potassium hydroxide, when acetophenone and resacetophenone were obtained. We have independently confirmed this by the synthesis of 7-hydroxy-2-phenyl-1-methylphenopyrylium chloride by direct condensation of acetophenone and resacetophenone in the presence of alcoholic hydrogen chloride, a reaction which absolutely excludes the possible formation of the isomeric 7-hydroxy-4-phenyl-2-methylphenopyrylium chloride. Although the yield in this reaction is very small, sufficient material was isolated to identify the compound both by its reactions and by means of a mixed melting point of its iron chloride double salt with a specimen of the same salt prepared by the ordinary method.

γ-Styryl Derivatives.—These compounds are best prepared by the direct condensation of the resorcinol-free pyrylium chloride with the required aldehyde in hot alcoholic solution by means of dry hydrogen chloride, this being led in at a rate sufficient to maintain the mixture at the boiling point. At first the chloride goes into solution, this acquiring a deep red colour, and after a short time the styrylpyrylium salt commences to separate as a red, microcrystalline sludge. The reaction proceeds smoothly and there is little doubt that the reactivity of the methyl group in the γ -position is certainly not less than in the α -position. The yield of crude condensation product obtained in this way amounts to between 50 and 60 per cent. of that required by theory, depending on the aldehyde employed. On dilution of the mother-liquors with water, red or orange-coloured amorphous precipitates are thrown out of solution in amount approximately sufficient to account for the remainder of the reactants. These substances, which we have been unable to purify sufficiently for accurate analysis, although containing chlorine, fail to give the characteristic reactions of pyrylium salts. If, however, such products are again condensed in the usual manner with a further molecule of the respective aldehyde, the normal pyrylium salts are now obtained. Moreover, by increasing the proportion of aldehyde in the original reaction mixtures, the yield of the styrylpyrylium chloride is increased, whilst the production of the amorphous compound is correspondingly suppressed. It would thus seem as though the latter substances were definite intermediate additive products of the original chloride with the aldehydes.

The 4-styrylpyrylium chlorides are obtained as highly coloured, crystalline salts, perceptibly less soluble in solvents than the 2-styryl

derivatives, but, apart from this, they are peculiarly similar in their reactions. The most striking property is the extraordinarily intense blue colour developed when the red alcoholic solution of 4'-hydroxystyrylpyrylium chloride (IV) is treated with either dilute sodium hydroxide or sodium carbonate. The corresponding 4'-methoxy-salt (III), on the other hand, maintains the red colour unimpaired. This property of the hydroxy-salt agrees absolutely with the views expressed in our previous communications, where the production of a blue colour with the analogous 4'-hydroxy-2-styrylpyrylium chloride was attributed to the formation of a quinonoid anhydro-base. In the present case, this is equally possible, the anhydro-base having the structure shown in (V).

If the alcoholic alkaline blue-coloured solution of this anhydro-base be diluted, the pyrylium colour base (X) will be precipitated, an equilibrium apparently existing between these two forms.

Attention has already been directed (Buck and Heilbron, *loc. cit.*) to the remarkably similar colour changes exhibited by the anthocyanidin chlorides, and the conclusion was drawn that these natural pigments must almost certainly contain a free hydroxyl group in the 4'-position of the 2-phenyl group. Thus the change in colour from red to violet or blue exhibited by cyanidin chloride (VI) on treatment with alkali would be due, according to our views, to change in structure from the pyrylium to the pyronequinonoid form (VII), and not to the formation of a phenol-betaine (VIII), as suggested by Willstätter.

In the present series, the analogy is even more striking, for whereas in the 2-styryl series, where no hydroxyl group was present

in the 7-position, the colour changes could be induced by water alone, 4':7-dihydroxy-2-phenyl-4-styrylbenzopyrylium chloride requires, just as the anthocyanidins do, an alkaline medium such as sodium carbonate to bring these about. Were these colour transformations due to phenol-betaine formation, then there is no reason why the 4'-methoxy-compound (III), which theoretically could readily yield a betaine (Formula IX), should not produce a violet solution in alkaline media.

Colour Bases.—In the case of the 2-styryl derivatives, it was impossible to prepare colour bases analytically pure, but in the present series this has been accomplished by two distinct methods. Aqueous pyridine reacts with both the 4'-hydroxy- and 4'-methoxy-chlorides, producing crystalline deposits of the normal colour bases. These, we suggest, are analogous in constitution to the corresponding chlorides. Thus the 4'-hydroxy-compound would possess the constitution (X). Proof of this is supplied by the fact that this base dissolves in alcohol with a bright red colour. Were it the quinonoid anhydro-base plus water, a blue colour should be produced directly, but this is actually obtained only after making alkaline with a few drops of either sodium hydroxide, sodium carbonate, or ammonia. Again, it might be argued that the base has actually the betaine structure (XI) together with water of crystallisation, but this is, in our opinion, improbable owing to the instantaneous colour change effected by such mild reagents as sodium carbonate or ammonia.

The second method of preparation consists in using potassium acetate. In the case of the 4'-hydroxy-chloride, this procedure gives a base different in appearance from, but identical in reactions with, the colour base previously mentioned. With the 4'-methoxy-chloride, however, a base is obtained for which analysis indicates the structure of a colour or carbinol base less one-half molecule of water. This compound is possibly an ether of the type postulated

by Diltney (*J. pr. Chem.*, 1917, [ii], 95, 107). The same substance is also produced by heating the chloride with pyridine for a short time and then adding water. Further, if the 4'-hydroxy-chloride be treated according to this latter method, a base of analogous composition will also be obtained. This gives a faint green colour with dilute sodium hydroxide or ammonia, but not with sodium carbonate, and is certainly different in structure from the true colour base.

Finally, it must be mentioned that no indication of the existence of carbinol bases has been observed.

EXPERIMENTAL.

7-Hydroxy-2-phenyl-4-methylbenzopyrylium Chloride.

Resorcinol Additive Compound.—This is obtained by following Bülow and Wagner's instruction (*loc. cit.*), in which glacial acetic acid is employed as solvent. Recrystallised from 50 per cent. alcohol containing a small quantity of hydrochloric acid, yellowish-brown crystals of the complex chloride are obtained. On other occasions, glistening violet crystals separate out, but intermediate shades also exist. Thus a pale yellow modification is usually obtained on crystallisation from glacial acetic acid containing hydrogen chloride. Despite the different appearance of the various specimens, analysis shows them all to have the same composition. The chloride, which darkens on heating above 200°, melts at 232–233°. It dissolves in hydrochloric acid, acetic acid, or acetone with a yellow colour, aqueous or alcoholic solutions being orange-red, whilst in concentrated sulphuric acid a marked fluorescence is observed. It might be mentioned that, when equimolecular proportions of resorcinol and benzoylacetone are used in the reaction, unchanged benzoylacetone can be isolated from the reaction mixture. On the other hand, when one and a half molecules of resorcinol are used, the yield of the pyrylium addendum compound is correspondingly increased (Found: C = 69.7; H = 5.0; Cl = 10.7. $C_{16}H_{13}O_2Cl \cdot \frac{1}{2}C_8H_6O_2$ requires C = 69.6; H = 4.9; Cl = 10.8 per cent.).

Isolation of Resorcinol from the Additive Compound.—Twenty grams of the pure pyrylium chloride resorcinol complex are heated on the water-bath with an excess of 12 per cent. perchloric acid, and, after filtering from the insoluble perchlorate, the solution is thoroughly extracted with ether. The ethereal solution is dried over anhydrous sodium sulphate and, after removal of the solvent, a yellow oil which rapidly solidifies is obtained. A portion of the solid recrystallised from light petroleum gave no depression of

melting point when mixed with a specimen of pure resorcinol, and its identity was definitely established by the preparation of the dibenzoyl derivative. Yield about 3 grams. The anhydrous perchlorate, after recrystallisation from glacial acetic acid and drying in a vacuum at 100° , forms a pale chrome-yellow, crystalline powder. A solution in absolute formic acid shows a strong "uranium" fluorescence. On heating, the compound puffs violently; for analysis, it was mixed with powdered quartz (Found: C = 56.7; H = 4.1. $C_{16}H_{12}O_2Cl$ requires C = 57.1; H = 3.9 per cent.).

Preparation of Resorcinol-free Chloride.—Eleven grams of resorcinol and 16 grams of benzoylacetone are dissolved together in 40 c.c. of 80 per cent. formic acid and the solution is saturated with hydrogen chloride, the temperature being kept low by cooling in water. A fine crystalline deposit gradually separates, and, after standing over-night, the product is recrystallised from 50 per cent. hot aqueous alcohol, a small quantity of hydrochloric acid being afterwards added to the filtered solution. Light brown crystals of the anhydrous chloride are thus obtained. Recrystallisation of the crude product from dilute hydrochloric acid again yields the anhydrous chloride, which separates under these conditions in bright yellow crystals which dry to a greenish-yellow powder (Found: C = 69.9, 70.3; H = 4.9, 4.9; Cl = 13.4. $C_{16}H_{12}O_2Cl$ requires C = 70.5; H = 4.8; Cl = 13.0 per cent.). If, on the other hand, the anhydrous chloride is crystallised from aqueous alcohol at a somewhat lower temperature, the hydrated chloride is produced as a mustard-yellow, crystalline product (Found: C = 65.7; H = 5.4; Cl = 12.6. $C_{16}H_{12}O_2Cl \cdot H_2O$ requires C = 66.1; H = 5.2; Cl = 12.2 per cent.). The interconversion of the anhydrous and the hydrated chloride has proved to be a very finely balanced reaction, and appears to depend on extraordinarily small differences of concentration and temperature.

7-Hydroxy-4'-methoxy-2-phenyl-4-styrylbenzopyrylium Chloride
(Formula III).

Twenty-two grams of 7-hydroxy-2-phenyl-4-methylbenzopyrylium chloride are suspended (partial solution) in 120 c.c. of hot absolute alcohol and, after the addition of 10.2 grams (0.1 mol.) of *p*-methoxybenzaldehyde, the mixture is treated with dry hydrogen chloride at a rate sufficient to maintain it at its boiling point. The whole soon forms a deep red solution, from which a red, crystalline deposit of the 4'-methoxy-chloride soon commences to separate. After standing over-night, the product is filtered off and extracted with hot 70 per cent. alcohol containing hydrochloric acid in order to remove unchanged material. The

crude chloride, which weighs 22 grams, is purified by recrystallisation from 80 per cent. formic acid, the solution again being saturated with hydrogen chloride. On diluting the original alcoholic mother-liquors with water, 5 grams of an amorphous, red substance are precipitated. This compound, which is not a true pyrylium salt, was not further investigated.

The styrylpyrylium chloride, when freshly prepared, is red, but, on drying, rapidly loses solvent, yielding reddish-violet, glistening crystals having a fine blue reflex which decompose violently at 263°. It is moderately soluble in alcohol, acetic acid, or formic acid, giving deep red solutions, and practically insoluble in water and in dilute hydrochloric acid. When the alcoholic solution is treated with sodium carbonate or potassium acetate, red flocks of a base are precipitated, whilst dilute sodium hydroxide solution produces a red solution changing to orange in presence of excess of the reagent. For analysis, it was dried at 100° (Found: C = 73.8; H = 5.0; Cl = 9.1. $C_{24}H_{19}O_3Cl$ requires C = 73.8; H = 4.9; Cl = 9.1 per cent.).

The *perchlorate* is obtained by the addition of 20 per cent. perchloric acid to a solution of the chloride in formic acid. It forms violet-red crystals only very sparingly soluble in alcohol or formic acid (Found: C = 63.6; H = 4.5. $C_{24}H_{19}O_7Cl$ requires C = 63.4; H = 4.2 per cent.).

The *ferripyrylium chloride* is obtained by dissolving 3 grams of the chloride together with 4 grams of commercial ferric chloride in 130 c.c. of hot glacial acetic acid. The crystalline product which separates on cooling is purified by recrystallisation from glacial acetic acid. It forms tiny, glistening, violet needles (m. p. 199°) sparingly soluble in cold, moderately soluble in hot formic acid or acetic acid. It is only very slightly soluble in alcohol or chloroform, but extraordinarily soluble in acetone, giving an intensely red solution (Found: C = 51.8; H = 3.4; Fe = 10.1. $C_{24}H_{19}O_3Cl_4Fe$ requires C = 52.1; H = 3.4; Fe = 10.1 per cent.).

7-Hydroxy-4'-methoxy-2-phenyl-4-styrylbenzopyrylium hydroxide is formed by treating 1.5 grams of the pure chloride with 10 c.c. of pyridine together with 4 c.c. of water. On very gently warming, the liquid develops a deep ruby-red colour and, on the careful addition of more water, fine crystals of the base separate. After filtering and repeatedly washing with water, during which process the crystalline structure is usually destroyed, the base is obtained as a reddish-brown powder with a distinct golden-bronze reflex. It is somewhat sparingly soluble in glacial acetic acid or alcohol, more readily soluble in formic acid, the solutions being deep red in colour. The addition of alkali to the alcoholic solution produces only a

brighter red tinge, no violet or blue colour being developed. The compound, in common with the rest of the series, rapidly gains weight on the balance, and all analytical specimens were dried at 100° (Found: C = 77.2; H = 5.3. $C_{24}H_{20}O_4$ requires C = 77.4; H = 5.3 per cent.).

By employing potassium acetate in place of pyridine, a product is obtained giving analytical results corresponding to an ether. The preparation is as follows: 1.0 gram of the chloride, suspended in 30 c.c. of absolute alcohol, is treated with 10 grams of potassium acetate dissolved in 150 c.c. of water. The light red, flocculent precipitate which separates is filtered off and washed with water until the washings are free from chloride. After drying at 100° , the compound forms a light purple-brown powder, moderately soluble in formic acid or alcohol with a deep red colour. The latter solution gives an orange-red colour with dilute sodium hydroxide. This same product can also be obtained by dissolving the chloride in pyridine, heating the solution for a few moments, and precipitating with water (Found: C = 79.4; H = 5.2. $2C_{24}H_{18}O_3 \cdot H_2O$ requires C = 79.3; H = 5.2 per cent.).

4' : 7-Dihydroxy-2-phenyl-4-styrylbenzopyrylium Chloride
(Formula IV).

22.0 Grams of pure chloride are partly dissolved in 80 c.c. of hot methyl alcohol and, after the addition of 9.2 grams (1 mol.) of *p*-hydroxybenzaldehyde, the mixture is saturated with hydrogen chloride, when a dark red liquid is formed, from which red crystals rapidly separate. These are filtered off after four hours and thoroughly washed with 50 per cent. alcohol containing hydrochloric acid. The crude chloride, which weighs 13 grams, is recrystallised from absolute formic acid, in which it is fairly soluble. It separates from this solvent in red, prismatic crystals which, on drying, change to bluish-black, due to loss of solvent, and melt with decomposition at 265° . It is only very sparingly soluble in glacial acetic acid or alcohol, and practically insoluble in dilute hydrochloric acid. Treated with a few drops of dilute sodium hydroxide, the deep red alcoholic solution becomes intensely blue, changing on dilution with water first to violet and then to deep ruby-red. In presence of excess of sodium hydroxide solution, the compound is rapidly decomposed. With dilute sodium carbonate, a similar blue colour is developed, passing on further dilution into violet with deposition of the colour base. With ammonium hydroxide, on the other hand, the blue colour persists on further addition of the reagent. The solution in cold concentrated sulphuric acid is orange-red, showing at high dilution a weak greenish-yellow fluorescence

(Found: C = 73.1; H = 4.6; Cl = 9.5. $C_{23}H_{17}O_3Cl$ requires C = 73.3; H = 4.5; Cl = 9.4 per cent.). The *perchlorate*, which is prepared as previously described, separates as reddish-violet crystals which, on drying at 100° , lose formic acid, yielding a greyish-blue product. The colour reactions are similar to those shown by the chloride (Found: C = 62.7; H = 4.2. $C_{23}H_{17}O_7Cl$ requires C = 62.6; H = 3.8 per cent.). The *double ferrichloride* is prepared by dissolving 3.0 grams of the chloride in 100 c.c. of glacial acetic acid. After recrystallisation from this same solvent, it is obtained as a light maroon, crystalline mass containing acetic acid, which is completely lost at 100° . The solvent-free salt forms almost black masses of glistening needles having a dull green reflex (m. p. $225-227^\circ$). It is moderately soluble in both hot acetic and formic acids, but, like the corresponding methoxy-iron salt, is extraordinarily soluble in cold acetone. The alcoholic solution gives with dilute sodium hydroxide the characteristic blue solution, strictly analogous to that produced from the chloride itself (Found: C = 51.4; H = 3.4. $C_{23}H_{17}O_3Cl_4Fe$ requires C = 51.2; H = 3.2 per cent.).

4' : 7-Dihydroxy-2-phenyl-4-styrylbenzopyrylium hydroxide (X) is prepared in a precisely similar manner to that used in the preparation of the corresponding methoxy-base. After drying at 100° , it is obtained as a reddish-brown powder, having lost its crystalline form during washing and drying. It dissolves in formic acid, acetic acid, or alcohol with a red colour. The alcoholic solution produces exactly the same blue colours with alkalis as the chloride itself (Found: C = 76.8; H = 5.1. $C_{23}H_{15}O_4$ requires C = 77.1; H = 5.0 per cent.). If potassium acetate is employed in place of pyridine, the base is obtained in the form of a maroon-coloured powder having a pronounced greenish-golden sheen. This substance gives the same reactions as the above base, but does not appear to be identical, although the analytical results are the same (Found: C = 77.1; H = 5.3 per cent.). As in the case of the methoxy-compound, a base with a higher carbon value can be isolated by heating the chloride with pyridine and then adding water. A chocolate-coloured powder is thus obtained, giving orange-brown solutions in formic acid and alcohol. No blue colours are, however, produced when a solution in the latter solvent is treated with alkalis. Ammonium and sodium hydroxides give weak green colours, whilst with sodium carbonate a reddish-brown coloration is produced. The analytical figures agree well with those required for an ether, but we have been unable to determine the exact composition of this substance (Found: C = 78.8; H = 5.0. $2C_{23}H_{15}O_3.H_2O$ requires C = 79.1; H = 4.9 per cent.).

In conclusion, one of us (J.S.B.) wishes to acknowledge his indebtedness to the Royal Commissioners for the Exhibition of 1851 for a grant which has enabled this research to be carried out.

THE UNIVERSITY, LIVERPOOL.

[Received, July 28th, 1923.]

CCXCI.—*Muconic and Hydromuconic Acids. Part II.* *The Isomerism of the Muconic Acids.*

By ERNEST HAROLD FARMER.

IN view of the concrete character of the evidence regarding van't Hoff's stereochemical principles which is to be obtained by a close examination of the geometrical isomerism of conjugated carbon compounds, it is perhaps remarkable that so little attention should have been directed hitherto to this subject. The requirements of accepted stereochemical theory are simple: a symmetrical conjugated carbon compound such as muconic acid should exist in the geometrically isomeric forms (A, B, and C), corresponding in

configuration with the three forms which the Hantzsch-Werner theory ascribes to the three benzildioximes.

The subject has recently acquired added interest in view of a hypothesis regarding carbon double bonds which has been proposed by Lowry (this vol., p. 822). This theory, which in many respects resembles the polar conception of double bonds put forward by Eastman (*J. Amer. Chem. Soc.*, 1922, **44**, 438), is based fundamentally on the alternate polarity hypothesis of Lapworth and of Robinson and Kermack (*T.*, 1922, **121**, 416, 427). A double bond is written $\overset{+}{\text{C}}\text{---}\overset{-}{\text{C}}$ (the signs representing nuclear charges), and is stated to be made up of one "covalency" and one "electrovalency." A system of conjugated double bonds therefore becomes $\overset{+}{\text{C}}\text{---}\overset{-}{\text{C}}\text{---}\overset{+}{\text{C}}\text{---}\overset{-}{\text{C}}$, and hence in a conjugated system "the distinction between single and double bonds disappears" (Lowry, *loc. cit.*, p. 824).

It is difficult to understand how the line of action of a "covalency" and that of the resultant attraction of nuclear charges can be laterally displaced as classical theory requires; but we may for the present purpose give the polar theory the benefit of this doubt, and suppose that the space configuration around an isolated

double bond of the polar type is identical with that which forms the accepted interpretation of the geometrical isomerism of ethylenic compounds. It follows that, since in conjugated compounds there are, in effect, three double bonds in place of two (the centre bond being exactly like either of the double bonds), the predictions of ordinary stereochemical theory must be profoundly modified. This is but one of many ways in which the polar theory might have been first examined by experiment.

In the present paper, a description is given of a number of derivatives of muconic acid which have been isolated in stereochemical modifications. Ethyl $\alpha\alpha'$ -dibromomuconate, for example, has been isolated in three modifications, and their behaviour and inter-relationship have been shown to be in good accord with classical stereochemical ideas. Indeed throughout the whole of this work no indication has been obtained that classical theory requires modification in any fundamental respect. Muconic acid and its derivatives are typical conjugated substances, exhibiting the phenomenon of 1:4-addition and displaying the abnormal solubility and melting point characteristic of the conjugated grouping; and their investigation in the light of the Lowry hypothesis has served to show that the consequences of the theory are not always borne out by experiment.

Many unsuccessful attempts have been made by various chemists to obtain different forms of muconic acid, either by direct conversion of the ordinary form into its geometrical isomeride, or by the production of the acid in different ways, some of which might be expected to yield the unknown forms. Such being the case, it was thought that the stereoisomeric substituted muconic acids or esters might offer a better prospect of isolation, and for an attempt in this direction the halogenated muconic esters were selected. The method was suggested by an observation as to the remarkable ease and completeness of removal of hydrogen bromide from ethyl $\beta\beta'$ -dibromoadipate by a cold alcoholic solution of ethyl sodiomalonate to give ethyl muconate. So rapid was this reaction that combination of the esters was almost totally excluded. By replacing ethyl sodiomalonate with sodium ethoxide or pyridine and utilising certain halogenated adipic esters, derivatives of muconic acid were readily obtained in excellent yield.

Although the esters of $\alpha\alpha'$ -dibromoadipic acid are well known to exist in *meso*- and *racemic* forms, the existence of stereoisomeric forms of other polybrominated adipic esters does not appear to have been noted. Ruhemann and Dufton (T., 1891, 59, 753), by addition of bromine to ethyl muconate, obtained a solid ethyl $\alpha\alpha'\beta\beta'$ -tetrabromoadipate (I), and Rupe (*Annalen*, 1890, 256, 26),

by bromination of muconic acid and subsequent esterification, obtained a corresponding solid methyl ester. In each case, the production of only one product is recorded. Ethyl tetrabromoadipate was prepared numerous times and by both methods; invariably the product consisted of almost equal quantities of a solid and a liquid tetrabromo-ester, the former corresponding with Ruhemann and Dufton's compound. The difference in nature of these esters was made strikingly manifest by treatment with sodium ethoxide or pyridine. Each substance, under the experimental conditions described later, lost two molecules of hydrogen bromide and yielded an easily separable mixture of two solid ethyl dibromomuconates (II). Of the four substances thus obtained, two were identical. Thus from the two tetrabromo-esters arose three isomeric dibromomuconic esters:

The contrast between the ease of removal of hydrogen bromide from ethyl $\beta\beta'$ -dibromoadipate as seen above, and the inability to perform the similar operation with ethyl $\alpha\alpha'$ -dibromoadipate except under the drastic experimental conditions necessary for the production of muconic acid from the latter (Ingold, T., 1921, **119**, 957) would tend to show that the halogen atoms in the isomeric dibromomuconic esters occupy the $\alpha\alpha'$ -positions. Further proof of this, however, seemed necessary, since Bode's dichloromuconic acid (*Annalen*, 1864, **132**, 95), the product of interaction of mucic acid and phosphorus pentachloride, has hitherto been represented, in the absence of definite knowledge by the formula

Since the results of a new examination of Bode's reaction are dealt with later, it is sufficient at present to state that the correctness of the general formula II was shown in the following way. By the addition of chlorine to Δ^8 -dihydromuconic acid under the special conditions described in the experimental portion of this paper, the sole product was $\beta\beta'$ -dichloroadipic acid (IV). This on conversion into its acid chloride with subsequent dibromination and esterification yielded ethyl $\beta\beta'$ -dichloro- $\alpha\alpha'$ -dibromoadipate (V). Two forms of this ester, a solid and a liquid, were obtained, but the latter was very impure, showing a considerable deficiency in bromine. These substances should give on treatment with sodium ethoxide either ethyl dibromomuconates of the general formula (II) or ethyl dichloromuconates corresponding to the acid III, according as hydrogen chloride or bromide is removed. Actually,

hydrogen chloride was removed and there resulted ethyl dibromomuconates identical with those previously obtained.

The relationship of the substances obtained in the two ways is shown thus:

It will be noted that the intermediate form (m. p. 93.5°) was not obtained from the dichlorodibromo-esters and the identity of the most fusible form from the same source could not be verified owing to experimental difficulties arising out of the impurity of the parent ester.

That these substances are stereoisomerides and do not owe their isomerism to difference in the position of the halogen atoms is further shown by their interconversion; that they do not constitute an example of trimorphism similar to that manifested by *allocinnamic acid* is clear from their properties. They are comparatively stable substances which can be crystallised and fused repeatedly without change. Higher temperatures, however, cause conversion of both the lower-melting forms into the least fusible form, but to varying extents; the reverse change cannot be brought about directly, nor has a means been found for the mutual interconversion of the two lower-melting forms. The extent of conversion during one distillation under reduced pressure, varying from less than 10 to about 50 per cent., indicates a considerable difference in stability. Considerations of this nature as well as differences in chemical behaviour must be taken into account in assigning to each geometrical isomeride its appropriate formula. So far as investigation has yet proceeded, differences in chemical behaviour between the isomerides are well marked, one clear instance being met with in the study of amide formation. The high-melting form is readily and completely converted into its diamide, the intermediate form does not react with ammonia under

similar or even more drastic conditions to yield an amide, whilst the low-melting form yields slowly and very incompletely a second diamide. If, therefore, the three isomerides be represented by formulæ as in the scheme

a variation in capacity for amide formation such as that found might be anticipated on steric grounds and would appear to be comparable to the difference in esterification capacity exhibited by the geometrical isomerides of certain substituted acrylic acids. It was found by Sudborough and Lloyd (T., 1898, 73, 81) that acrylic acids possessing the configuration (D) were, generally speaking, more readily esterified than those of type (E):

If amide formation in halogenated muconic esters (which may be regarded as containing double substituted acrylic acid systems) follows on similar lines, then the behaviour of the *trans-trans*-form in yielding an amide readily and that of the *cis-cis*-form in failing to yield one at all, is explicable. From a *cis-trans*-form, however, an amic-ester (F) might perhaps be expected; actually, as seen above, no such substance was recognised.

The suggested classification of the ethyl dibromomuconates, although it rests at present on very meagre evidence, is in strict

correspondence with the Straus classification of the three diphenylbutadienes (*Annalen*, 1905, **342**, 214) as regards ease of conversion of the isomerides. In both cases, the relative stability of the forms increases from the *cis-trans* through the *cis-cis* to the *trans-trans*.

The desire to obtain halogenated muconic esters in considerable quantities for synthetical purposes led to the reinvestigation of the reaction between mucic acid and phosphorus pentachloride previously referred to. By heating the substances in the proportion represented by the equation

and pouring the product into water, Bode (*loc. cit.*) obtained a dichloromuconic acid in a yield of 35 per cent. of that theoretically possible. The reaction was later investigated by Ruhemann and Elliot (T., 1890, **57**, 932; 1891, **59**, 26), with the result that along with a 25 per cent. yield of Bode's acid a quantity of a second dichloromuconic acid was isolated. It was suggested that the acids represented *trans*- and *cis*-forms, respectively, since the latter changed into the former in the presence of a trace of bromine.

In order to account for the very poor yields obtained, it was decided to isolate the products of the reaction as esters. Accordingly, after removal of phosphoryl chloride, the acid chloride was poured into alcohol. The product was invariably found to consist of four substances:

	Yield.
(1) Ethyl dichloromuconate, m. p. 96°	30 per cent.
(2) " " (liquid)	38 " "
(3) " trichloromuconate (VI)	
(4) Low-boiling halogenated ester not further investigated	25 " "

The first of these substances corresponded with the esterification product of Bode's acid (Wichelhaus, *Annalen*, 1865, **135**, 251; Bell, *Ber.*, 1879, **12**, 1273) and yielded this acid on hydrolysis. The second and third products were obtained together as an oil from which moderately pure specimens of the components were obtained only after exhaustive fractionation. It was found, however, that ethyl trichlorohydromuconate loses hydrogen chloride with the greatest facility; thorough shaking with aqueous ammonia is sufficient to accomplish this, but pyridine was found to be more convenient. By decomposition of the trichloro-ester, a mixture of the two ethyl dichloromuconates was obtained from which the pure substances were readily isolated. Corresponding substances were obtained when ethyl alcohol was replaced by methyl alcohol. Thus the following halogenated muconic esters were obtained:

Ethyl dichloromuconate, m. p. 96°.	Methyl dichloromuconate, m. p. 154°.
" " " 18°.	" " " 68°.

The examination of large quantities of material did not reveal the presence of a third isomeride in either series, but this is not surprising in view of the vigorous nature of the reaction. Attempts to obtain the missing forms in a way analogous to that by which the dibromomuconic esters were obtained were frustrated by lack of success in synthesising tetrachloroadipic acid or its esters in adequate quantities.

On reduction with zinc and acetic acid, each pair of isomeric esters yielded only one Δ^8 -dihydromuconic ester. This behaviour is similar to that of the two less fusible ethyl dibromomuconates, which with the same reagent or with zinc and alcohol both gave rise to the same ethyl Δ^8 -dihydromuconate. Further, contrary to expectation, the trichlorohydromuconic esters also yielded esters of Δ^8 -dihydromuconic acid, the first stage in the process being apparently the loss of hydrogen chloride:

The latter fact is of considerable importance practically. By the method outlined above, the yield of substances from which Δ^8 -dihydromuconic esters are directly obtainable with ease is increased from 25 to 70 per cent. of that theoretically possible. Since the mixture of crude halogenated esters may be reduced without purification, the method is of great convenience in the rapid preparation of considerable quantities of hydromuconic esters. No method of reduction which involved dechlorination only was discovered; the reduction of all the halogenated muconic esters proceeded with such vigour, compared with that of unsubstituted muconic esters, that it could not be arrested at an intermediate stage.

In properties, the dichloromuconic esters correspond closely to the two ethyl dibromomuconates for which *trans-trans*- and *cis-cis*-configurations were suggested. The degree of conversion of the more fusible into the less fusible form on distillation was of a similar low order, but each of the chloro-esters yielded an amide. The formation of amides from forms possessing a *cis-cis*-structure is probably a reflection of the difference in steric effect subsisting between chlorine and bromine.

The appearance of considerable amounts of trichlorohydromuconic esters among the products from the mucic acid reaction makes it fairly certain that the latter is first converted into tetrachloroadipic acid, which subsequently loses hydrogen chloride. This being so, analogy with the method of production of the ethyl

dibromomuconates indicates the probability of the $\alpha\alpha'$ -position of the chlorine atoms which remain in the molecule (VII). Radulescu (*Chem. Zentr.*, 1908, i, 1832), however, unlike previous workers, asserts the correctness of formula III on the grounds that ethyl dichloromuconate yields a disodio-derivative and when submitted to Cannizzaro's reaction gives rise to a small yield of diacetyl. The former of these statements has been tested and it was found that treatment of the ester with a solution of sodium in alcohol gave rise to a copious precipitate, not of a disodio-derivative, but of the sodium salt $\begin{matrix} \text{CH:CCl-CO}_2\text{Na} \\ \text{CH:CCl-CO}_2\text{Et} \end{matrix}$ (VIII), which on acidification yielded ethyl hydrogen dichloromuconate.*

In Part I (T., 1922, **121**, 2015), the author, from the study of the addition of esters to ethyl muconate, was led to suggest the view that what was in effect 1:3-addition,

might be in reality such addition, rather than that of the 1:2-type followed by rearrangement of the valencies. Subsequent work on the esters of muconic and hydromuconic acids, however, indicated that this phenomenon arose in a way which was not dependent on a muconic system comparable in its internal mobility with the glutaconic system. Indeed, it became evident that the unsaturated system in ethyl muconate was little different from the ordinary type, and ought therefore to exhibit geometrical isomerism. Since it is intended to deal with this question of addition in a subsequent paper of this series, it need only be stated that apart from the failure of all attempts to prepare them—a circumstance which lent weight to the conception of a basic system of very mobile type (Ingold, T., 1922, **121**, 1312), there was *a priori* no reason why the isomeric forms of the muconic esters should not be capable of existence. When, later, the dibromomuconic esters described above were obtained it seemed possible that the isomeric muconic esters might be obtainable by similar methods.

By addition of bromine to methyl Δ^8 -dihydromuconate, two methyl $\beta\beta'$ -dibromoadipates were obtained. This addition was effected by Rupe (*loc. cit.*), but only one product (m. p. 78°) was obtained which, apparently through lack of recrystallisation, did not represent a single form. Similarly, two ethyl dibromoadipates were obtained, although Ruhemann and Blackman (T., 1890, 57, 372) record the production of only one (m. p. 64°). Since both the

* Further evidence as to the correctness of the $\alpha\alpha'$ -position of the halogen atoms has since been gained in investigating the behaviour of chloromuconic esters with ethyl sodiomalonate.

methyl esters were solid and readily purified, their employment was most convenient in attempts to obtain isomeric muconic esters. Almost quantitative removal of hydrogen bromide was effected both by pyridine and alcoholic sodium methoxide, although the former reagent was preferable. In this way, isomeric methyl muconates were obtained :

Methyl dibromoadipate, m. p. 95° → Methyl muconates, m. p. 156° and 75°.
 " " " 43° → " " " 156° and 75°
 and a liquid ester.

Ethyl dibromoadipates yielded corresponding products, but only from the solid ester (m. p. 64°) were the latter completely separable.

Ethyl dibromoadipate, m. p. 64° → Ethyl muconates, m. p. 62° and 13°.
 " " b. p. 186°/16 mm. → Ethyl muconates, m. p. 62°
 and a liquid ester.

The small amount of liquid ester which was obtained from the lower-melting methyl dibromoadipate was thought to represent a third isomeride, but owing to experimental difficulties this could not be verified.

Hydrolysis of the new form of methyl muconate with alkali yielded an unsaturated dibasic acid which must be considered a second muconic acid; accompanying this, however, was an isomeric but monobasic acid which appeared to be lactonic in nature. For this the formula IX seemed probable, but on direct comparison

with a substance to which this formula was assigned by Ruhemann (T., 1890, 57, 940) the two acids appeared to be distinct. Further investigation on this point is needed, Ruhemann's product being ill-defined; according to his account, it changed on recrystallisation so much that no definite melting point could be assigned.

EXPERIMENTAL.

(A) Esters of Halogenated Adipic Acids.

Ethyl αα'ββ'-Tetrabromoadipate.—This substance was most conveniently prepared from ethyl muconate by Ruhemann's method (*loc. cit.*), the product being purer than that obtained by Rupe's process (*loc. cit.*). The chloroformic solution of the brominated ester was shaken with very dilute sodium bicarbonate solution, taken up in ether, and dried with calcium chloride. After gentle heating to remove the ether, the chloroform was distilled in a vacuum. The solid tetrabromoadipic ester which separated on

standing was filtered off. The filtrate deposited more crystals on further standing; the process of allowing these to accumulate for a few days and then removing them by filtration was repeated until no more solid would separate. The final filtrate was a viscous, reddish-brown oil which decomposed on heating. It was freed from volatile matter by leaving in an evacuated desiccator for a week (Found: Br = 58.9. $C_{10}H_{14}O_4Br_4$ requires Br = 61.7 per cent.).

The solid ester crystallised from alcohol in large, well-formed, hexagonal prisms melting at 70° . In view of the different products obtained from this ester, its homogeneity was examined by submitting 60 grams of the substance to careful fractional crystallisation. No variation in melting point or crystalline form could be detected in any of the numerous fractions obtained. The total yield was excellent, the solid portion being slightly in excess of the liquid.

$\beta\beta'$ -Dichloroadipic Acid.—The action of chlorine on an acetic acid suspension of Δ^6 -dihydromuconic acid was examined as a possible source of dichloroadipic acid (Ruhemann, T., 1890, 57, 939). This method was found to be unsuitable, only a small fraction of the product being dichloroadipic acid. The remainder was chlorohydromuconic acid (m. p. 119°), similar to that obtained by Ruhemann when an aqueous solution of hydromuconic acid was chlorinated (Found: Cl = 19.6. Calc., Cl = 19.8 per cent.). When, however, the acid was suspended in concentrated hydrochloric acid and kept saturated with chlorine for six to eight hours, conversion into the dichloro-acid was nearly complete and there was no formation of chlorohydromuconic acid. The product was recrystallised from boiling water, when it was obtained as a coarsely crystalline, white powder, m. p. 212° (Found: Cl = 32.5. $C_6H_8O_4Cl_2$ requires Cl = 33.0 per cent.). The rather low halogen content was due to a trace of unchanged hydromuconic acid.

Ethyl $\beta\beta'$ -Dichloro- $\alpha\alpha'$ -dibromoadipate.— $\beta\beta'$ -Dichloroadipic acid (1 mol.) was warmed on a steam-bath with phosphorus pentachloride (2 mols.) until reaction was complete. Bromine (2 mols.) was then added in portions, and the heating continued until no free bromine was left. The cooled product was poured into ice-cold alcohol and kept over-night. The resulting ester was isolated in the usual way. A mixture of solid and liquid ester was obtained; separation was effected in precisely the same way as with ethyl tetrabromoadipate. The solid dichlorodibromoadipic ester was only moderately soluble in boiling alcohol, from which it separated on cooling in long, ragged, colourless prisms, m. p. 139 – 140° (Found: Total silver halide = 99.4 per cent. of that required by

the formula $C_{10}H_{14}O_4Cl_2Br_2$). The liquid could not be distilled and when purified as completely as possible showed a serious deficiency of halogen (Found: Total silver halide = 86.4 per cent. of that required).

Esters of Δ^8 -Dihydromuconic Acid.—These substances, which were required in considerable quantity for the synthesis of $\beta\beta'$ -dibrominated adipic esters, were obtained by three methods: (1) Muconic acid, prepared by the method of Ingold (T., 1921, 119, 966), was reduced with sodium amalgam under essentially the same conditions as those employed by Baeyer and Rupe (*Annalen*, 1890, 256, 26), but allowing of the treatment of 100 grams of acid at one time. The acid, recrystallised from boiling water, was esterified with alcohol and sulphuric acid. The loss of material during reduction and esterification was insignificant, but the series of processes entailed in the synthesis of muconic acid rendered the method very expensive in time. (2) The muconic esters obtained as reaction products in the experiments described hereafter were directly reduced by dissolving them in glacial acetic acid, heated on a steam-bath, and adding zinc dust from time to time. By using excess of zinc dust and shaking the mixture frequently reduction was effected in about three hours. The ester and acetic acid were taken up in a large volume of ether, the acetic acid was removed by washing with water and sodium carbonate, and the ester, after drying and removal of the solvent, fractionated. The esters obtained in this way usually contained small amounts of unreduced material. In the case of the methyl ester, the bulk of this could be removed by freezing the ester and filtering off the impurity which remained undissolved when the temperature had been allowed to rise. (3) The mixture of esters obtained by the interaction of mucic acid and phosphorus pentachloride was usually distilled once, and the appropriate fraction (153–170°/14 mm.) reduced by dissolving it in glacial acetic acid and adding zinc dust. In contrast to the reduction of the muconic esters, the development of heat was so great that the violence of the reaction needed moderating by cooling. When the further addition of zinc to the well-shaken mixture caused no further development of heat, the mixture was kept for half-an-hour and then worked up as above. The *methyl* and *ethyl* Δ^8 -dihydromuconates were obtained as colourless, highly refractive, mobile liquids which solidified completely in a freezing mixture and boiled at 125°/14 mm. and 133°/11 mm., respectively.

Methyl $\beta\beta'$ -Dibromoadipate.—The two forms of this substance were obtained by gradually adding slight excess over the theoretical quantity of bromine to an ice-cold solution of methyl Δ^8 -dihydro-

muconate in carbon tetrachloride. As soon as the addition was complete, the product was washed with dilute sodium bicarbonate solution and water and dissolved in ether. The dried ethereal solution yielded an oil, rather more than half of which solidified. This solid material was filtered off and recrystallised from methyl alcohol, from which it separated in well-formed, colourless prisms, m. p. 93° (Rupe, m. p. 78°) (Found: Br = 48.1. Calc., Br = 48.2 per cent.). The liquid portion of the ester solidified on cooling to -25° and liquefied on resuming the room temperature, but a small quantity of the higher-melting form remained undissolved. By removing the latter and repeating the process, an ester was obtained which, after final recrystallisation at -25° from a little methyl alcohol, remained solid at room temperature. Thus it was obtained as a white, coarsely crystalline powder, m. p. 43° (Found: Br = 48.0. $C_8H_{12}O_4Br_2$ requires Br = 48.2 per cent.).

Both forms of the ester distil, when pure, without appreciable decomposition at pressures below 15 mm., but when impure the decomposition is very great.

Ethyl $\beta\beta'$ -Dibromoadipate.—The method of preparation of the stereoisomeric ethyl dibromoadipates was similar to that employed for the corresponding methyl esters. The solid form, m. p. 64°, readily separated and usually represented 55–60 per cent. of the theoretical yield. Recrystallised from alcohol or light petroleum, it was obtained in well-formed, colourless prisms (Found: Br = 44.2. $C_{10}H_{16}O_4Br_2$ requires Br = 44.4 per cent.). Since the residual oil did not solidify on cooling and in its impure state suffered very considerable decomposition on distillation, it was not obtained in a condition of complete purity. A portion which had been distilled (b. p. 180°/14 mm.) was analysed (Found: Br = 39.4. $C_{10}H_{16}O_4Br_2$ requires Br = 44.4 per cent.).

(B) *The Isomerism of Ethyl $\alpha\alpha'$ -Dibromomuconate.*

Ethyl cis-cis- $\alpha\alpha'$ -Dibromomuconate.—Both pyridine and alcoholic sodium ethoxide were used in the preparation of ethyl dibromomuconate from ethyl tetrabromoadipate. In the case of pyridine, the ester was mixed with three times its bulk of pure pyridine and well diluted with dry benzene. After the mixture had been heated for about three hours on a steam-bath, the cooled product was poured into dilute hydrochloric acid and the mixture of bromoesters worked up in the usual way. With sodium ethoxide, the operation could be much more rapidly conducted. The calculated amount of sodium (2 atoms) was dissolved in absolute alcohol and added, after cooling, to a solution of the tetrabromo-ester (1 mol.) in alcohol or in a mixture of alcohol and dry ether. Addition was

effected slowly and with thorough shaking and cooling; when complete, the sodium bromide was at once precipitated by the addition of a large volume of dry ether. Removal of the sodium bromide by filtration and evaporation of the solvent yielded a mixture of the dibromo-esters. In the case of the impure liquid tetrabromo-ester, the unavoidable slight excess of sodium ethoxide caused hydrolysis, but the small amount of sodium salt produced was precipitated with the sodium bromide.

The mixture of dibromo-esters obtained in either way deposited crystals, which were removed by filtration and recrystallised from alcohol. This substance, regarded as the *cis-cis*-isomeride, was obtained in colourless, prismatic needles, m. p. 93·5° (Found: C = 33·90; H = 3·53; Br = 44·85. $C_{10}H_{12}O_4Br_2$ requires C = 33·70; H = 3·40; Br = 44·90 per cent.).

Ethyl cis-trans- $\alpha\alpha'$ -Dibromomuconate.—The filtrate, dissolved in a little alcohol and cooled to -25° , solidified when the containing vessel was vigorously scratched; liquefaction ensued when the mixture assumed room temperature. By repeated freezing, warming, and filtering as in the case of methyl dibromoadipate, the last traces of the ester, m. p. 93·5°, were removed. The ester contained in the final filtrate was recrystallised three or four times from a little alcohol at -25° . It was obtained as a white, crystalline powder, m. p. 28° (Found: C = 33·79; H = 3·75; Br = 44·51. $C_{10}H_{12}O_4Br_2$ requires C = 33·70; H = 3·40; Br = 44·90 per cent.).

Ethyl trans-trans- $\alpha\alpha'$ -Dibromomuconate.—The liquid form of ethyl tetrabromoadipate, treated precisely as above, yielded in the first place a solid and a liquid ester. The former, recrystallised from alcohol, was obtained in colourless, slender needles, m. p. 123° (Found: C = 33·85; H = 3·63; Br = 44·80. $C_{10}H_{12}O_4Br_2$ requires C = 33·70; H = 3·40; Br = 44·90 per cent.). The liquid ester on purification as above was obtained as a white, crystalline solid, m. p. 28° (Found: C = 33·69; H = 3·60 per cent.). This substance was identical in all respects with the one (m. p. 28°) obtained from the solid tetrabromo-ester.

The proportion of high-melting dibromo-ester to the low-melting form from each of the parent esters appeared to be originally about 1 : 4. The loss entailed in the complete purification of the latter form, however, was very considerable. Each of the three esters distilled without decomposition at temperatures which differed slightly (184—190°/12 mm.), but whereas the high-melting form (m. p. 123°) distilled without change, the remaining forms suffered partial conversion as described in the introduction. The mixture obtained by distilling the intermediate form (m. p. 93·5°) could not be resolved into its components by fractional crystal-

lisation, the extent of conversion being approximately estimated on the basis of melting-point depression.

Ethyl $\alpha\alpha'$ -Dibromomuconate from Ethyl $\beta\beta'$ -Dichloro- $\alpha\alpha'$ -dibromoadipate.—The *trans-trans*-ester was the sole product of the action of alcoholic sodium ethoxide on the solid form of ethyl dichlorodibromoadipate. Treatment of the very impure liquid form of the latter ester with sodium ethoxide yielded in addition to ethyl *trans-trans*-dibromomuconate a liquid ester which set to a paste in a freezing mixture. This appeared to be a solution of the *cis-trans*-ester in an ester of quite different nature, but owing to the small proportion of the former and its great solubility in the impurity separation was not effected. Distillation of the crude substance after freeing as far as possible from the *trans*-ester resulted in the production of a further quantity of the latter dibromo-ester.

$\alpha\alpha'$ -Dibromomuconamide.—The *trans-trans*-form of ethyl $\alpha\alpha'$ -dibromomuconate was heated in a tightly-stoppered bottle with concentrated aqueous ammonia at 40–50° for three days, when the ester had completely disappeared. The diamide was obtained as a very pale yellow, crystalline powder, insoluble in water or alcohol. Before analysis the crude substance was boiled in turn with alcohol and water. It decomposed without melting, slowly at 245° and rapidly above 255° (Found: C = 24.5; H = 2.3. Calc., C = 24.2; H = 2.0 per cent.).

The conversion of the *cis-trans*-ester into its amide by similar treatment with aqueous ammonia at 40–50° took place very slowly. After five days, a quantity of ester still remained unchanged. The diamide, which was obtained in very small yield, crystallised from a moderately large volume of boiling water in rosettes of colourless needles. These darkened above 200° and decomposed completely at 221° (Found: C = 24.4; H = 2.3. $C_6H_6O_2N_2Br_2$ requires C = 24.4; H = 2.0 per cent.).

The *cis-cis*-ester was not readily affected by ammonia. Prolonged heating at 40–50° caused its gradual disappearance without the formation of an amide.

(C) *Esters of $\alpha\alpha'$ -Dichloromuconic and $\alpha\alpha'\beta'$ -Trichlorohydromuconic Acids.*

Methyl $\alpha\alpha'$ -Dichloromuconate.—Mucic acid (225 grams) was heated with phosphorus pentachloride (1360 grams) on a steam-bath until reaction ceased. The product was then heated at 130° in an oil-bath, the phosphoryl chloride being allowed to distil. The vigorous reaction which occurred when the residue was poured into methyl alcohol was moderated by efficient cooling. The solid ester which separated immediately was filtered off and recrystallised

from methyl alcohol. It formed feathery needles, m. p. 154° (Found: C = 39.9; H = 3.4; Cl = 29.5. $C_8H_8O_4Cl_3$ requires C = 40.2; H = 3.4; Cl = 29.7 per cent.).

The alcoholic mother-liquor yielded a mixture of esters which was submitted to very numerous fractional distillations. Such procedure was quite inadequate as a means of separation for the bulk of the material, but it served to procure reasonably pure specimens of the components for identification. The mixture was found to contain (1) methyl dichloromuconate, m. p. 154°, (2) methyl dichloromuconate, m. p. 68°, (3) methyl trichlorohydromuconate, and (4) a low-boiling halogenated ester, which was not further investigated. The second methyl dichloromuconate (m. p. 68°) crystallised from concentrated alcoholic solutions in colourless needles (Found: C = 40.15; H = 3.51; Cl = 29.7. $C_8H_8O_4Cl_2$ requires C = 40.2; H = 3.4; Cl = 29.7 per cent.).

Methyl $\alpha\alpha'$ -Trichlorohydromuconate.—This substance was obtained as a pale yellow oil (b. p. 162–163°/13 mm.) which would not solidify on cooling to -25° (Found: C = 35.3; H = 3.2; Cl = 38.3. $C_8H_8O_4Cl_3$ requires C = 35.0; H = 2.9; Cl = 38.7 per cent.). It was readily converted into methyl dichloromuconate by shaking thoroughly with strong aqueous ammonia, but more conveniently by boiling with pyridine. When the once-distilled liquid mixture of esters from the mucic acid reaction was boiled for an hour with excess of pyridine, the trichloro-ester was completely decomposed and from the solution a solid mixture of the two isomeric methyl dichloromuconates was obtained. On agitating this with dry ether, only the lower-melting form dissolved. Filtration and removal of the solvent from the filtrate yielded the isomerides in almost pure condition.

Ethyl $\alpha\alpha'$ -Dichloromuconates.—These esters were prepared in a manner exactly analogous to the methyl dichloromuconates. The higher-melting form crystallised from alcohol in colourless prisms, m. p. 84° (Found: Cl = 26.3. $C_{10}H_{12}O_4Cl_2$ requires Cl = 26.6 per cent.). The second form was obtained as a yellow liquid which on cooling solidified to a hard, crystalline mass, m. p. 28°. This substance undoubtedly corresponds with the esterification product of Ruhemann and Elliot's ethyl " β "-dichloromuconate, although these authors state that their product did not solidify in a freezing mixture of ice and salt. It was found that crystallisation did not take place until the vessel containing the well-cooled ester was vigorously scratched with a glass rod (Found: Cl = 26.8. $C_{10}H_{12}O_4Cl_2$ requires Cl = 26.6 per cent.).

In both the methyl and ethyl series the higher-melting dichloromuconic ester distilled without change, but the lower-melting form

was converted to a small but quite definite extent into its isomeride.

Ethyl $\alpha\alpha'$ -Trichlorohydromuconate.—This substance accompanied the isomeric ethyl dichloromuconates and lost hydrogen chloride under the same conditions as the corresponding methyl compounds and with similar results. It was obtained as a pale yellow oil, b. p. 163—165°/15 mm.

Action of Sodium Ethoxide on Ethyl $\alpha\alpha'$ -Dichloromuconate.—When an absolute alcoholic solution of sodium ethoxide was added to a solution of ethyl dichloromuconate in absolute alcohol, a precipitate rapidly formed. This substance was only sparingly soluble in boiling alcohol and separated from it as a white, crystalline powder. This was a monosodium salt of ethyl hydrogen dichloromuconate (Found: Na = 8.75. $C_8H_7O_4Cl_2Na$ requires Na = 8.81 per cent.).

On acidification, the aqueous solution of the sodium salt deposited a crystalline acid. This on recrystallisation from a mixture of alcohol and petroleum was obtained in colourless prisms, m. p. 134°. It gave figures on analysis agreeing with those required for ethyl hydrogen dichloromuconate (Found: C = 39.90; H = 3.43. $C_8H_8O_4Cl_2$ requires C = 40.17; H = 3.35 per cent.).

$\alpha\alpha'$ -Dichloromuconamide.—From the higher-melting dichloromuconic esters on treatment with aqueous ammonia at 40—50° a diamide was readily obtained. This substance, a very insoluble, white powder, was prepared for analysis by boiling in turn with alcohol and water. Like the dichloromuconamide prepared by Ruhemann and Blackman (*loc. cit.*), it decomposed gradually on heating, slowly at 250°, more rapidly at 268° (Found: C = 34.65; H = 2.98. $C_6H_6O_2N_2Cl_2$ requires C = 34.46; H = 2.90 per cent.).

The two lower-melting dichloromuconic esters yielded a diamide which appears to be identical with the one obtained by Ruhemann and Elliot (*loc. cit.*) from the esterification product of their " β "-dichloromuconic acid. It crystallised from boiling water in colourless needles, m. p. 232° (decomp.) (Found: C = 34.31; H = 3.12. Calc., C = 34.46; H = 2.90 per cent.).

(D) Isomerism of Muconic Esters.

Methyl Muconate, m. p. 156°.—The removal of hydrogen bromide from methyl dibromo adipate, m. p. 93°, was accomplished with extreme ease. The vigorous reaction which set in when the latter was warmed at 100° with pyridine soon subsided; on cooling, the mixture set to a mass of crystals. Shaking with water left ordinary methyl muconate suspended in the aqueous liquor. This substance, which was in a very pure condition, was filtered off and washed

with water. Its identity was confirmed by direct comparison with an authentic specimen and by reduction to methyl dihydromuconate. The yield of this substance was very constant, representing about 77 per cent. of the theoretical. The removal of hydrogen bromide can also be effected with methyl-alcoholic sodium methoxide (sodium ethoxide causes considerable conversion of methyl into ethyl esters) with similar results.

Methyl Muconate, *m. p.* 75°.—The filtrate (above) on acidification and cooling in ice deposited a quantity of crystalline flakes. These were crystals of an almost pure, new ester. Extraction of the filtrate with ether yielded a further amount of this substance contaminated with a little ordinary methyl muconate. In the recrystallisation of the new ester from light petroleum it was found that a trace of the ordinary ester affected considerably both the crystalline form and the melting point. If, however, before recrystallisation the crude substance was agitated with dry ether, the ordinary methyl muconate remained undissolved and could be satisfactorily separated. The soluble ester, after removal of the ether and recrystallisation several times from petroleum (b. p. 60–80°), was obtained in long, stout needles, *m. p.* 75°. Analysis showed the new substance to be a second form of methyl muconate (Found: C = 56.56; H = 5.80. $C_8H_{10}O_4$ requires C = 56.47; H = 5.88 per cent.). The yield represented about 16 per cent. of the theoretical. No indication of a third reaction product was obtained.

Methyl dibromoadipate, *m. p.* 43°, also yielded the two methyl muconates described above on treatment with pyridine. In addition, a small quantity of an oily ester was obtained. Owing to experimental difficulties, it could not be ascertained whether or not this substance represented a third isomeric methyl muconate.

Ethyl Muconate, *m. p.* 62°.—By precisely similar methods to those described above, isomeric ethyl muconates were obtained from ethyl dibromoadipate. The principal product was ordinary ethyl muconate (*m. p.* 62°), identified by its "mixed melting-point" and by hydrolysis.

Ethyl Muconate, *m. p.* 13°.—A minor portion of the product from ethyl dibromoadipate consisted of an oil which solidified in a freezing mixture. This was recrystallised from a very small quantity of ethyl alcohol at –25° and obtained as a white, microcrystalline powder, *m. p.* 13°. The substance was still slightly impure, but owing to insufficiency of material it could not be further recrystallised (Found: C = 59.98; H = 6.92. $C_{10}H_{14}O_4$ requires C = 60.60; H = 7.07 per cent.). On long standing in a

warm room, crystals of ordinary ethyl muconate separated from the liquefied ester.

Muconic Acid.—The acid derived from the higher-melting methyl and ethyl muconates by hydrolysis with moderately concentrated sulphuric acid was deposited on slow crystallisation from a large volume of boiling water in well-defined, colourless plates. These melted on slow heating at 289° (decomp.). The higher melting point (300 – 305°) recorded by Ingold (*loc. cit.*) was obtained only on rapid heating (Found: C = 50.89; H = 4.31. Calc., C = 50.70; H = 4.23 per cent.).

Methyl muconate, m. p. 75° , was hydrolysed by keeping it overnight in contact with the calculated quantity of methyl-alcoholic sodium hydroxide (prepared by adding water to sodium methoxide). The resulting white sodium salt was freed from alcohol, dissolved in water, and acidified. Thorough extraction with ether yielded a mixture of two acids the separation of which was effected by taking advantage of their different solubilities in dry ether and water. Of the two substances, one, which was very sparingly soluble in dry ether but readily soluble in boiling water, separated from the latter solvent in minute, silky crystals, m. p. 187° . This substance was a highly unsaturated dibasic acid conforming to the requirements of a geometrical isomeride of ordinary muconic acid [Found: C = 50.90; H = 4.23. Calc., C = 50.70; H = 4.23 per cent. 0.0722 neutralised 20.6 c.c. of 0.04911 *N*-baryta. Calc. (dibasic), 20.6 c.c.].

The second substance after recrystallisation from dry ether was obtained as a white, crystalline powder, m. p. 93° . It was a monobasic acid isomeric with muconic acid, but probably lactonic in nature. Comparison with a substance regarded by Ruhemann as the lactone of γ -hydroxy- Δ^2 -dihydromuconic acid (IX) indicated that the substances were different; their relationship has not yet been ascertained [Found: C = 50.53; H = 4.27; *M* (monobasic) = 141. $C_6H_6O_4$ requires C = 50.70; H = 4.23 per cent.; *M* = 142].

The author desires to express his indebtedness to the Government Grant Committee of the Royal Society for a grant which has defrayed a portion of the cost of this research; also to Professor J. F. Thorpe, F.R.S., and Dr. C. K. Ingold for their interest and encouragement during the course of the work.

CCXCII.—*Studies in the Anthracene Series. Part VI.*

By EDWARD DE BARRY BARNETT and MARCUS AURELIUS MATTHEWS.

GENERALLY speaking, there are three methods available for passing from an anthracene to a dianthranyl derivative, namely, by heating a *ms.*-bromoanthrone with copper powder (K. H. Meyer, *Annalen*, 1911, **379**, 44), by oxidising the anthrone, for example, with ferric chloride (Dimroth, *Ber.*, 1901, **34**, 219), and by the pinacol reduction of the anthrone (Barnett and Matthews, this vol., p. 380). It will be observed that in all three cases the anthrone serves as the initial material, but that whereas the first two methods lead to the union of the two anthracene ring systems through the methylene groups, the last leads to union through the cyclic carbonyl groups.

As these dianthranyl derivatives are interesting compounds, it was decided to undertake a systematic examination of their formation and properties, with special reference to their formation by the pinacol condensation, and the present communication deals with the chloro-compounds.

The *Bz.*-chloroanthrones are best prepared by the reduction of the corresponding chloroanthraquinones, and for this purpose there are two methods available, namely, reduction with tin and hydrochloric acid in boiling glacial acetic acid solution and reduction with aluminium powder in warm concentrated sulphuric acid solution. The former method does not seem to have been applied previously to the chloroanthraquinones, but by the latter method Eckert and Tomaschek (*Monatsh.*, 1918, **39**, 839) prepared several chloroanthrones. Their products, however, seem to have been extremely impure and therefore the present authors have repeated the greater part of their work and have compared the products obtained by the two methods.

1-Chloroanthraquinone on reduction with aluminium powder and concentrated sulphuric acid gives an anthrone which melts at 118° and must be 1-chloro-9-anthrone (I), since Eckert and Tomaschek have shown that the corresponding dianthraquinone (III) on exposure to light passes into 4:4'-dichloromesonaphtha-

dianthrone (IV), a compound which they were also able to obtain from 1:4-dichloroanthraquinone by converting this into dichloro-dianthraquinonyl (V), reducing this to the helianthrone (VI), and then exposing this to light :

If 1-chloroanthraquinone is reduced by tin and hydrochloric acid in boiling glacial acetic acid solution, a chloroanthrone which melts at 118° is also obtained, but this is not identical with that obtained by the aluminium powder-concentrated sulphuric acid method, the difference being shown by the fall in the melting point on mixing and by the different behaviour on oxidation and on reduction with zinc and hydrochloric acid. This second isomeride must be 4-chloro-9-anthrone (II).

2-Chloroanthraquinone on reduction either by the aluminium-sulphuric acid or by the tin-hydrochloric acid method gives a mixture of isomerides from which by repeated recrystallisation a pure substance melting at 156° can be obtained. This must be either 2(or 3)-chloro-9-anthrone (VII or VIII), but up to the present it has not been possible to determine which formula is correct.

The product described by Eckert and Tomaschek as 2-chloroanthrone was probably a very impure mixture of the two isomerides, as they give the melting point as 115–120°.

1:5-Dichloroanthraquinone is scarcely attacked by tin and hydrochloric acid in boiling glacial acetic acid, possibly owing to its very sparing solubility, but is readily reduced by aluminium powder and concentrated sulphuric acid and then gives a dichloroanthrone (IX), for which only one formula is possible.

1:8-Dichloroanthraquinone is readily reduced by both methods, but whereas the tin-hydrochloric acid method leads to a mixture of isomerides which can be separated only with great difficulty, the aluminium powder-concentrated sulphuric acid method gives a product from which a single isomeride (m. p. 167°) is readily obtained in the pure state. This might be 1:8- or 4:5-dichloro-9-anthrone (X or XI), but since in the case of 1-chloroanthraquinone the chlorine atom appears to protect the carbonyl group in the ortho-position, the first formula is the more probable.

This is supported by Eckert and Tomaschek's statement that the dichloroanthrone obtained from 1:8-dichloroanthraquinone on oxidation gave a tetrachlorodianthraquinone from which a tetrachloromesonaphthodianthrone was obtained on exposure to light. No great reliance, however, can be placed on this argument, as Eckert and Tomaschek were obviously dealing with very impure substances, the melting point of their dichloroanthrone being 115°, that is 52° too low.

All the above chloroanthrones pass on oxidation with ferric chloride in boiling acetic acid solution into the corresponding dianthrones, the reaction taking place very easily except in the case of 4-chloro-9-anthrone (II). With this compound the oxidation is difficult, and even when a large excess of ferric chloride is used and the boiling continued for six hours the greater part of the anthrone remains unattacked and can be recovered unchanged.

In view of the ease with which anthrone itself undergoes the pinacol condensation when reduced with zinc and hydrochloric acid in boiling glacial acetic acid solution, it was hoped to obtain a series of chlorodianthranyls from the above chloroanthrones by this method. This expectation has not been fulfilled, as it has been found that the course of the pinacol condensation is pro-

foundly affected by the presence of substituents in the benzene ring.

1-Chloro-9-anthrone (I) on reduction with zinc and hydrochloric acid gives a very easily soluble substance with a low melting point. This appears to be a dihydroanthracene derivative, but as it refused to crystallise it could not be obtained pure.

4-Chloro-9-anthrone (II) on reduction with zinc and hydrochloric acid undergoes the pinacol condensation, but analysis shows that the product is neither dichlorodianthranyl nor the α -pinacolin, but a compound, $C_{28}H_{18}Cl_2$, which must be a dihydrodianthranyl derivative (XII or XIII), or possibly a mixture of these owing to a tautomeric change of the three-carbon type :

The compound is strongly fluorescent, but does not react with bromine in carbon disulphide solution.

2(or 3)-Chloroanthrone (VII or VIII) on reduction with zinc and hydrochloric acid undergoes the pinacol condensation with the production of the corresponding dichlorodianthranyl, but the yield is poor and a considerable quantity of a colourless, non-fluorescent, and easily soluble product with a low melting point is formed simultaneously. On attempting to recrystallise this, it became resinous, and its examination has been postponed until a better method of preparing the chloroanthrone has been devised.

Neither 1:5-dichloroanthrone (IX) nor 1:8-dichloroanthrone (X or XI) undergoes the pinacol condensation when reduced with zinc and hydrochloric acid. In both cases, reduction takes place easily, but the sole product is the corresponding dichloroanthracene.

The influence of halogen atoms in the benzene rings on the behaviour of the carbonyl groups is interesting and is reminiscent of the observations made by Liebermann (*Ber.*, 1914, 47, 1011) on the stability of the "bridge" bond in the chloroanthracenes. Since the influence of substituents on the reactivity of the *meso*-carbon atoms is being systematically examined in these laboratories, it will be best to postpone a theoretical discussion of the above results.

EXPERIMENTAL.

- * In all cases, the reduction of the chloroanthraquinone by the aluminium powder-concentrated sulphuric acid method was carried out by dissolving 10 grams of the anthraquinone in 110 c.c. of concentrated sulphuric acid and then slowly adding 3 grams

of aluminium powder, the temperature being kept at 20–30°. A series of colour changes usually took place, and towards the end of the reaction, which required about three hours, there was considerable tendency to froth. The end of the reaction was easily seen by the final change of the colour to yellow. The whole was then poured into a large volume of ice-water and the precipitate collected and digested with warm, dilute hydrochloric acid in order to remove the greater part of the unchanged aluminium.

1-Chloro-9-anthrone (I).—This was prepared from 1-chloro-anthraquinone by the aluminium-concentrated sulphuric acid method and purified by recrystallisation from a mixture of chloroform and light petroleum. It then formed long, yellow needles and agreed with the description given by Eckert and Tomaschek, except that it melted at 118° and not at 106°.

Oxidation with ferric chloride in boiling acetic acid took place easily, and the resulting dianthrone agreed in its properties with that described by Eckert and Tomaschek.

Reduction with zinc (granulated or dust) and hydrochloric acid in acetic acid solution also took place easily, but the resulting product was very readily soluble in most media, and as it invariably separated in an oily state it could not be purified.

4-Chloro-9-anthrone (II).—1-Chloroanthraquinone (10 grams), 15 grams of tin, 75 c.c. of glacial acetic acid, and a few drops of a dilute solution of platinic chloride were boiled under reflux, and 20 c.c. of concentrated hydrochloric acid slowly added. The solution at first became dark and then much lighter in colour. After two hours, it was filtered, the filtrate cooled, and the crystals were washed first with cold acetic acid and then with water. It was purified by recrystallising twice from boiling dilute alcohol and finally from a mixture of chloroform and light petroleum. It then formed pale yellow needles which melted at 118°. The melting point was not changed by several further recrystallisations of the product from various solvents, but declined by about 10° if the substance was mixed with the chloroanthrone obtained by the aluminium powder-concentrated sulphuric acid method (Found: C = 73.2; H = 4.10. $C_{14}H_9OCl$ requires C = 73.5; H = 3.94 per cent.).

Oxidation to 1:1'-*dichloro-9:9'-dianthrone* was carried out by boiling the chloroanthrone under reflux with a large excess of ferric chloride in glacial acetic acid solution. After six hours, the precipitate was collected, washed, and recrystallised twice from xylene, when colourless crystals which darkened at about 270° and melted and decomposed at 292° were obtained (Found: C = 73.7; H = 3.77. $C_{28}H_{16}O_2Cl_2$ requires C = 73.8; H = 3.52).

per cent.). The yield did not exceed 2.3 grams, and could not be improved by substituting potassium persulphate for the ferric chloride. It seemed possible that a more satisfactory yield might be obtained by preparing 4-chloro-10-bromo-9-anthrone and treating this with copper powder. 4-Chloro-9-anthrone (10 grams) was therefore suspended in 150 c.c. of carbon disulphide and treated with 2.2 c.c. (1 gram-mol.) of bromine. After the greater part of the carbon disulphide had been removed by distillation, the solution was cooled and the resulting crystals were purified by recrystallisation from chloroform, when they melted at 125–126° (Found: Cl + Br = 37.3. $C_{14}H_8OClBr$ requires Cl + Br = 37.5 per cent.). When boiled in xylene solution with copper powder, the chlorobromoanthrone gave dichlorodianthrone, but the yield was poor and the product difficult to purify.

Reduction was carried out by boiling 23 grams of the chloro-anthrone and 10 grams of granulated zinc under reflux with 150 c.c. of glacial acetic acid and slowly adding 30 c.c. of concentrated hydrochloric acid. Crystals began to separate in ten minutes, but the reduction was continued for four hours. After being washed with acetic acid and water, the solid was recrystallised three times from pyridine (Found: C = 78.9, 79.1; H = 4.24, 4.28. $C_{28}H_{18}Cl_2$ requires C = 79.0; H = 4.23 per cent.).

Dichlorodihydrodianthranyl (XII or XIII) forms almost colourless nodules which melt at 288°. Its solutions show a purple fluorescence. It does not react with bromine in carbon disulphide solution even on keeping for several days, and it was recovered unchanged after boiling for six hours in nitrobenzene solution with copper powder.

2(or 3)-*Chloro-9-anthrone* (VII or VIII).—2-Chloroanthraquinone (70 grams) and 100 grams of tin were boiled with 500 c.c. of glacial acetic acid, and a few drops of a dilute solution of platonic chloride and 130 c.c. of concentrated hydrochloric acid added slowly. The reduction required about three hours; the solution, which at first became very dark, was then pale yellow. After filtration and cooling, the solid was washed with acetic acid, dilute hydrochloric acid, and water, and dried in a vacuum desiccator. It melted very indefinitely at 120–140°. A similar product was obtained when the reduction was carried out with aluminium powder and concentrated sulphuric acid according to the directions given by Eckert and Tomaschek, but the above is the more convenient method.

By repeated recrystallisation first from mixtures of benzene and light petroleum and then from mixtures of chloroform and light petroleum, an almost colourless product was obtained which melted at 156°, the melting point remaining unchanged by further

recrystallisation. This was soluble in hot, dilute solutions of sodium hydroxide and in every way behaved like an anthrone derivative (Found: C = 73.4, 73.5; H = 4.12, 4.11. $C_{14}H_8OCl$ requires C = 73.5; H = 3.94 per cent.).

The substance obtained by Eckert and Tomaschek (m. p. 115–120°) must have been a very impure mixture of isomerides.

The isolation of the above isomeride is a very tedious process and is accompanied by great loss of material, the yield of the pure product being only 7–8 grams. Attempts to improve the method by the use of different solvents were not successful. Attempts to isolate the more soluble isomeride also failed to yield any definite product.

Oxidation to the dianthrone was carried out in the usual way by means of ferric chloride. The product after recrystallisation from xylene was colourless. It darkened at 240° and melted and decomposed at 270° (Found: C = 73.6; H = 3.74. $C_{28}H_{16}O_2Cl_2$ requires C = 73.8; H = 3.52 per cent.).

Reduction was carried out by boiling 5 grams of the anthrone and 10 grams of zinc dust with 100 c.c. of glacial acetic acid and slowly adding 20 c.c. of concentrated hydrochloric acid. The reduction was complete in forty minutes and the solid was then recrystallised twice from aqueous pyridine and twice from a mixture of benzene and light petroleum (Found: C = 79.3; H = 4.12. $C_{28}H_{16}Cl_2$ requires C = 79.4; H = 3.80 per cent.).

Dichlorodianthranyl forms colourless, glistening crystals which melt at 254–255°. Its solutions exhibit a strong purple fluorescence.

1:5-*Dichloroanthrone* (IX).—As it was found that 1:5-dichloroanthraquinone was not reduced by tin and hydrochloric acid in glacial acetic acid, the preparation of the anthrone was carried out by the aluminium powder-concentrated sulphuric acid method. The product was purified by recrystallisation first from acetic acid and then from benzene, and was obtained as fine, yellow needles which melted at 192° (Found: C = 64.1; H = 3.29. $C_{14}H_8OCl_2$ requires C = 63.9; H = 3.04 per cent.).

Oxidation was carried out in the usual manner and the product recrystallised from boiling nitrobenzene. In order to obtain a pure product, it was found necessary to avoid prolonged contact with the hot solvent and to work as far as possible in the absence of daylight. The purified substance was quite colourless and on heating darkened at 280° and melted and decomposed at 304–305° (Found: C = 64.0; H = 2.96. Calc., C = 64.1; H = 2.72 per cent.).

Reduction was effected by dissolving 10 grams of the dichloro-

anthrone in 400 c.c. of boiling glacial acetic acid and then adding 20 grams of zinc dust. The whole was then boiled under reflux and 25 c.c. of concentrated hydrochloric acid were added slowly. After two and a half hours the whole was cooled and the product recrystallised from pyridine. It then formed glistening, yellow needles which melted at 187–188°, alone or when mixed with an authentic sample of 1:5-dichloroanthracene (Schilling, *Ber.*, 1913, 46, 1066, gives the m. p. as 185°).

1:8-Dichloroanthrone (X or XI).—Reduction of 1:8-dichloro-anthraquinone either by the tin-hydrochloric acid or by the aluminium powder-concentrated sulphuric acid method gives rise to what is obviously a mixture of isomerides, but whereas it is extremely difficult to isolate any definite compound from the product obtained by the first method, that furnished by the second method easily yields a definite substance (long, white needles) melting sharply at 167°. The purification is best effected by a mixture of chloroform and light petroleum, two or three recrystallisations from this solvent being sufficient treatment (Found: C = 64.1; H = 3.39; Cl = 27.1. $C_{14}H_8OCl_2$ requires C = 63.9; H = 3.04; Cl = 27.0 per cent.). The substance described by Eckert and Tomaschek as 1:8-dichloroanthrone must have been very impure, as they give its melting point as 115°, whereas the crude mixture of isomerides before recrystallisation always melts at about 140°.

Oxidation was carried out in the usual manner and the product purified by recrystallisation from boiling nitrobenzene, in which it was sparingly soluble. It then formed colourless crystals which darkened at 290° but did not melt below 325° (Found: C = 64.2; H = 2.86. $C_{28}H_{14}O_2Cl_4$ requires C = 64.1; H = 2.72 per cent.).

Reduction was carried out under the conditions described in connexion with 1:5-dichloroanthrone. The product was recrystallised from benzene and from glacial acetic acid and then formed yellow needles which melted at 160°, alone and when mixed with an authentic sample of 1:8-dichloroanthracene (Schilling, *loc. cit.*, gives the m. p. as 156°).

Summary.

1. The reduction of the chloroanthraquinones by tin and hydrochloric acid and by aluminium and concentrated sulphuric acid has been studied, and it has been shown that most of the compounds previously described in the literature as chloroanthrones are not pure substances.

2. The chloroanthrones have been oxidised and the corresponding dianthrones obtained in the pure state.

3. The behaviour of the chloroanthrones on reduction with zinc and hydrochloric acid has been studied, and it has been found that only β -chloroanthrone and 4-chloro-9-anthrone undergo the pinacol condensation, the former compound giving dichlorodianthranyl in poor yield and the latter dichlorodihydrodianthranyl. 1-Chloro-9-anthrone, on the other hand, gives only products with low melting points which could not be obtained pure. Under similar conditions, 1:5- and 1:8-dichloroanthrone are converted into the corresponding dichloroanthracenes.

In conclusion, the authors desire to express their thanks to the Research Fund Committee of the Chemical Society for a grant which has defrayed some of the expenses of this research. One of them (M. A. M.) is also indebted to the Department of Scientific and Industrial Research for a grant which has enabled him to take part in this work.

CCXCIII.—*The Resolution of Hydratropic Acid.*

By HENRY STANLEY RAPER.

In the course of an investigation of the mode of oxidation of hydratropic acid (α -phenylpropionic acid) in the animal body (Kay and Raper, *Biochem. J.*, 1922, **16**, 465), it was found that this acid, when administered in the optically inactive form to dogs, in doses of 0.25 gram per kilo. of body weight, was oxidised to the extent of about two-thirds. The unoxidised acid was recovered from the urine partly in the free state and partly in combination with glycine. In both cases, the acid was dextrorotatory and had $[\alpha]_D^{25}$ varying from $+21.2^\circ$ to $+26.9^\circ$ in ethyl alcohol. This indicated that the laevo-acid was preferentially oxidised, and it seemed desirable to find out to what extent resolution in the body had taken place. Since no data on the optical activity of hydratropic acid could be found in the literature, its resolution was undertaken. By means of the strychnine salt, the pure dextro-acid has been obtained. In ethyl alcohol, it gives $[\alpha]_D^{25} + 81.1^\circ$, $c = 3.108$, so that the resolution in the animal body, referred to above, was by no means complete. Attempts to obtain the pure laevo-acid by the use of other bases were unsuccessful, brucine, quinine, and quinidine being tried. Inactive hydratropic acid is a liquid, but it seemed possible that

VOL. CXXIII.

4 R

the optically active acids might be solid at the ordinary temperature. This was not found to be the case. The pure dextro-acid remained liquid even when kept at 0° for some days.

EXPERIMENTAL.

Preparation of Inactive Hydratropic Acid.—Forty grams of tropic acid were boiled for twenty hours under a reflux condenser with 112 grams of baryta and 400 c.c. of water. The solution was cooled, acidified strongly with hydrochloric acid, and the precipitated atropic acid filtered off and washed with cold water. It was obtained pure by one crystallisation from methylated spirit. Yield of the pure acid, 70 per cent. of theory. Fifteen-gram portions of atropic acid were converted into the sodium salt by adding the requisite amount of sodium hydroxide in 150 c.c. of water. The reduction of the sodium salt was then carried out in the usual way with 250 grams of 2.5 per cent. sodium amalgam. The hydratropic acid thus obtained was purified by distillation under reduced pressure. It boiled at 161°/24 mm.

Preparation of d-Hydratropic Acid.—Twenty grams of inactive hydratropic acid and 44.5 grams of strychnine were dissolved by warming in 200 c.c. of a mixture of 3 parts ethyl alcohol and one part water. The solution was allowed to cool and placed in the ice-chest for three days, when a considerable crop of crystals of strychnine hydratropate had separated. The crystals were filtered off, drained, and dried in the air; 24 grams were obtained. A small portion was taken and the hydratropic acid recovered from it for the determination of its rotation. It gave $[\alpha]_D^{25} + 57.94^\circ$ in ethyl alcohol, $c = 3.159$. The acid recovered from the mother-liquor had $[\alpha]_D^{25} - 34.3$, $c = 3.00$. The crystallisation was repeated three times, when it was found that the rotation of the free acid had ceased to change. The specific rotations obtained with these three crops of crystals were $+79.09^\circ$, $+81.10^\circ$, and $+81.09^\circ$, respectively. Owing to an accident to a flask, a portion of the strychnine salt was lost in the second crystallisation, so that the final yield of strychnine salt (6.6 grams) was much less than would have normally been obtained. In ethyl alcohol, the air-dried strychnine d-hydratropate gave $[\alpha]_D^{25} - 15.45^\circ$, $c = 4.207$. The rotation of the pure dextro-acid was also determined in chloroform solution, when it gave $[\alpha]_D^{25} + 76.2^\circ$, $c = 2.834$.

Portions of the impure laevo-acid recovered from the mother liquor from the first crystallisation of the strychnine salt were combined with brucine, quinine, and quinidine. The brucine salt was much too soluble in those solvents in which it dissolved to make it suitable for further resolution of the acid. The quinine

salt crystallised well and had a solubility in alcohol and aqueous alcohol appropriate to the practical purposes of resolution. The quinine salt of the dextro-acid was, however, the less soluble, as with the strychnine salt, so that no further resolution of the laevo-acid was obtained. The quinidine salt was obtained as a sticky syrup which refused to crystallise.

CCXCIV.—*Chemical Reactivity and Conjugation: the Reactivity of the 2-Methyl Group in 2:3-Dimethylchromone.*

By ISIDOR MORRIS HEILBRON, HARRY BARNES, and
RICHARD ALAN MORTON.

AN examination of the structural formula of 2:3-dimethylchromone (I) reveals the fact that the methyl group attached to the 2-carbon atom is situated at the end of the conjugated system $O=C-CMe:C-CH_3$ and consequently, according to modern views, a tendency for a more even distribution of valency forces will exist within the molecule (compare *Ann. Reports*, 1922, p. 102). One such condition is represented in formula II, where an activated phase of

the molecule is indicated, resulting in induced alternate polarities being developed (compare Lapworth, T., 1922, **121**, 416; Kermack and Robinson, *ibid.*, p. 427). The reactivity of the methyl group in 2:3-dimethylchromone has been confirmed by direct experiment, the substance condensing readily in presence of alcoholic sodium ethoxide with aromatic aldehydes to yield 2-styryl derivatives of the type shown in formula III. That it is actually the

2-methyl group which takes part in the condensation has been proved by the hydrolysis of 2-styryl-3-methylchromone according to the method employed by Petschek and Simonis (*Ber.*, 1913, 46, 2015), when cinnamic acid was obtained as one of the products.

It has recently been suggested * that the reactivity of the methyl group in ethyl crotonate (Lapworth, T., 1901, 79, 1273) may depend on the formation of an enol form, and it might be argued that the same holds good in the case now under discussion. Collie (T., 1900, 77, 970) has shown that dimethylpyrone forms a definite additive product with sodium ethoxide, and as 2:3-dimethylchromone only reacts in presence of this reagent, it is conceivable that here also an additive compound having the constitution of a pyranol alcoholate (IV) is primarily formed. By removal of ethyl alcohol from this, the enol-methylene compound would result, the structure of which is similar to the reactive methylene forms

of the heterocyclic bases (Mills and Smith, T., 1922, 121, 2724). Now it has previously been shown by one of us that, in the case of doubly-conjugated unsaturated ketones (Heilbron and Buck, T., 1921, 119, 1500; Heilbron and Whitworth, this vol., p. 238), the reactivity of these was very materially affected by substitution in the benzene ring. Thus, whereas 4'-dimethylamino-2-hydroxydistyryl ketone is highly reactive, the substituted 4'-dimethylamino-4-methoxy-2-hydroxydistyryl ketone is unreactive, owing to the complete neutralisation of all free partial valency forces:

If, then, the reactivity of 2:3-dimethylchromone is due to the formation of a polarised molecule of the type shown in (II), as opposed to the enol-methylene (V), it should conceivably be possible to restrain this activity by suitable substitution in the benzene ring. Such a condition is to be anticipated in 7-methoxy-2:3-dimethylchromone, where a closed circuit of partial valency forces could exist. As a result, the residual valency on the carbonyl carbon

* Lowry, Faraday Society Discussion, Cambridge, July, 1923.

atom would be neutralised through or around the benzene ring instead of through the double bond, thus leaving the 2-methyl group inactive. This is represented diagrammatically in formula VI, but the neutralisation effect is doubtless passed on from atom to atom or may even be transmitted through the molecule in the form of a partial valency bond (VII) (compare *Ann. Reports*, 1922, p. 86). That the reactivity is actually due to the polarised active

molecule is clearly shown by the fact that where the neutralisation of valency forces is impossible, as with either 6-methoxy- or 8-methoxy-2:3-dimethylchromone, these react with aromatic aldehydes in the presence of sodium ethoxide at the ordinary temperature to yield styryl derivatives. On the other hand, 7-methoxy-2:3-dimethylchromone, under precisely similar conditions, is recovered unchanged from the reaction mixture. Moreover, even when more drastic conditions are employed (see experimental part), no condensation product can be obtained.

A study of the absorption spectra of these compounds has also been made and provides strong confirmatory evidence of the views outlined above. As this work forms the subject of the succeeding paper, where the question has been taken up from the Baly molecular phase point of view, only such reference will be made to it as bears directly on the question in hand. In the first place, the absorption spectrum of 2:3-dimethylchromone has been examined, two bands being shown with head at $\lambda = 3085 \mu$ and $\lambda = 2690 \mu$. As addition of alkali produces no alteration in the position of these bands, the spectrographic supports the chemical evidence as regards the improbability of an enol form being present. The absorption bands of the isomeric 6-, 7-, and 8-methoxy-2:3-dimethylchromones are plotted in Fig. 1, and it will be seen that in neutral alcoholic solution all three exhibit a single absorption band of similar type. In presence of alkali, a distinct band is present only in the case of the 6-methoxydimethylchromone, although indications of one are shown with the 8-methoxy-isomeride. With 7-methoxy-2:3-dimethylchromone, the effect of alkali, as shown in Fig. 2, is totally different, and there is little question but that, in this case, a rearrangement of the partial valency forces has resulted in such a way as to render the molecule less reactive.

As regards the characteristic properties of the 2-styryl-3-methylchromone derivatives, the effect of introducing auxochromic groups in the benzene ring of the 2-styryl residue is in general agreement with the observations of other investigators. Whereas 2-styryl-3-methylchromone is colourless, the introduction of one methoxyl

FIG. 1.

group changes the colour to yellow. With two methoxyl groups, the colour becomes more pronounced, whilst the introduction of the powerful auxochromic dimethylamino-group into the molecule produces a bright orange-red styryl derivative. It is interesting to note that the introduction of methoxyl groups into the benzene ring of the chromone residue produces no auxochromic effect, the

colour of the styryl derivatives being practically identical with that of the unsubstituted compounds.

Halochromy.—The 2-styryl-3-methylchromones exhibit marked halochromic phenomena, highly coloured hydrochlorides being readily formed by the action of dry hydrogen chloride on solutions of the parent substances in chloroform. These salts are unstable and decompose on standing in moist air. In addition to well-

FIG. 2.

defined monohydrochlorides, somewhat indefinite complex salts can also be isolated by the direct action of hydrogen chloride upon the solid chromone derivatives themselves and, as was found by Stobbe in the case of distyryl ketones (*Annalen*, 1909, 376, 93), the amount of hydrogen chloride absorbed varies with the temperature.

As regards the constitution to be ascribed to the monohydrochlorides, it appears to the present authors that these are true salts similar in constitution to the pyrylium salts of 2:6-dimethyl-

pyrone (Baeyer, *Ber.*, 1910, **43**, 2337) and consequently must be represented as shown in formula VIII.

FIG. 3.

2:3-Dimethylchromone.

Pratt and Robinson have recently expressed the opinion (this vol., p. 739) that the anhydro-base corresponding to 1:3:6:8-tetrahydroxyxanthylum chloride is best formulated as the bipolar molecule (IX) and it may be reasonably concluded that the active salt-forming phase of the pyrone nucleus is similar. On this scheme, 2:6-dimethylpyrone, and also the chromones, must obviously be capable of at least momentary existence in the following two

active phases (X and XI). It will be noted that (X) is essentially similar to the bridged formula suggested by Collie (T., 1904, 85, 973), but, in our opinion, it harmonises better with the chemical properties of the substance.

Finally, it remains to be mentioned that the colour gradations of the various halochromic salts in this series show no specially marked changes in shade, varying only between brick-red and crimson.

EXPERIMENTAL.

The 2-styryl-3-methylchromone derivatives were obtained by the following general method. One part of 2:3-dimethylchromone (1 mol.), the preparation of which was carried out by Petschek and Simon's method (*Ber.*, 1913, 46, 2015), was dissolved in a small quantity of alcohol and treated with a solution of sodium ethoxide containing 1 atom of sodium. The calculated amount of the required aldehyde was then added to the solution, which was kept for twenty-four hours at the ordinary temperature. The condensation product was filtered off and purified by recrystallisation from absolute alcohol. In most cases, a further crop of the substance was precipitated on dilution of the mother-liquors, the total yield being practically quantitative.

2-Styryl-3-methylchromone is obtained in small, colourless crystals melting at 126°. It is readily soluble in alcohol or benzene, and practically insoluble in ether or water (Found: C = 82.4; H = 5.5. $\text{C}_{18}\text{H}_{14}\text{O}_2$ requires C = 82.4; H = 5.3 per cent.). The *monohydrochloride*, prepared by passing dry hydrogen chloride into a solution of the substance in dry chloroform, separates in orange-coloured crystals which readily decompose on exposure to moist air, regenerating the parent substance. The analysis was carried out by titration with standard alkali (Found: HCl = 12.1. $\text{C}_{18}\text{H}_{14}\text{O}_2\cdot\text{HCl}$ requires HCl = 12.2 per cent.). The *polyhydrochlorides* were prepared by passing dry hydrogen chloride over 2-styryl-3-methylchromone contained in a stoppered U-tube according to the method previously employed by one of us in the preparation of semicarbazone hydrochlorides (Wilson, Heilbron, and Sutherland, T., 1914, 105, 2892). An analysis of the salt

4 R*

obtained at 15° shows it to correspond to the addition of $2\frac{1}{2}$ molecules of hydrogen chloride, whilst at -20° the salt agrees with the formula $C_{18}H_{14}O_2 \cdot 3HCl$. The *perchlorate*, which forms yellow crystals melting at 110° , was obtained by the addition of a few drops of a 40 per cent. solution of perchloric acid to a solution of 2-styryl-3-methylchromone in glacial acetic acid (Found: C = 59.3; H = 4.1. $C_{18}H_{14}O_2 \cdot HClO_4$ requires C = 59.4; H = 4.1 per cent.). The *picrate*, prepared by mixing alcoholic solutions of the chromone and picric acid, separated in yellow crystals melting at 135° (Found: N = 8.5. $C_{18}H_{14}O_2 \cdot C_6H_3(NO_2)_3 \cdot OH$ requires N = 8.6 per cent.).

2-Styryl-3-methylchromone tetrabromide is formed by the addition of a slight excess of dry bromine in chloroform solution to a solution of 2-styryl-3-methylchromone in the same solvent. It forms characteristic yellow crystals which decompose on heating (Found: Br = 54.9. $C_{18}H_{14}O_2 \cdot Br_4$ requires Br = 54.8 per cent.).

Hydrolysis of 2-Styryl-3-methylchromone.—Six grams of the substance were dissolved in alcohol and hydrolysed by heating under reflux for thirty hours on the water-bath with an excess of sodium ethoxide solution. After most of the alcohol had been boiled off, the solution was carefully acidified with dilute hydrochloric acid and the organic acids thus precipitated were redissolved by means of dilute sodium carbonate solution. The whole was thoroughly extracted with ether in order to remove any *o*-hydroxy-propio-phenone, the solution again acidified, and the precipitated acids filtered. After two recrystallisations from boiling water, pure cinnamic acid (2 grams) was isolated, whilst from the mother-liquors a small quantity of salicylic acid separated out on cooling.

4'-Methoxy-2-styryl-3-methylchromone separates from alcohol, in which it is only sparingly soluble, in greenish-yellow needles melting at 135° (Found: C = 77.9; H = 5.5. $C_{19}H_{16}O_2$ requires C = 78.1; H = 5.4 per cent.).

The *monohydrochloride* forms bright red crystals which readily decompose on standing in moist air. *Polyhydrochlorides* were also obtained, 3 molecules of hydrogen chloride being taken up by the dry substance at 15° and approximately $3\frac{1}{2}$ molecules at -20° . The *picrate* crystallises in scarlet needles melting at 145° (Found: N = 8.0. $C_{19}H_{16}O_2 \cdot C_6H_3(NO_2)_3 \cdot OH$ requires N = 8.1 per cent.).

The isomeric 2'-methoxy-2-styryl-3-methylchromone forms pale yellow needles melting at 155° (Found: C = 78.0; H = 5.5 per cent.).

3':4'-Dimethoxy-2-styryl-3-methylchromone.—This condensation was brought about by the interaction of veratraldehyde and 2:3-dimethylchromone, the styryl derivative separating from boiling alcohol in brilliant canary-yellow crystals melting at 176°

(Found: C = 74.4; H = 5.6. $C_{20}H_{18}O_4$ requires C = 74.5; H = 5.6 per cent.). The *tetrabromide* is obtained in deep red crystals (Found: Br = 49.7. Calc., Br = 49.8 per cent.). The *monohydrochloride* and the *perchlorate* are both crimson, crystalline solids.

The isomerio 2':4'-*dimethoxy-2-styryl-3-methylchromone* is obtained in yellow crystals melting at 145° (Found: C = 74.3; H = 5.5 per cent.).

2':5'-*Diethoxy-2-styryl-3-methylchromone* crystallises in bright yellow needles, m. p. 150° (Found: C = 75.3; H = 6.3. $C_{22}H_{22}O_4$ requires C = 75.4; H = 6.3 per cent.).

3':4'-*Methylenedioxy-2-styryl-3-methylchromone*.—Piperonal condenses readily with 2:3-dimethylchromone, yielding a bright yellow condensation product melting at 208° (Found: C = 74.4; H = 4.7. $C_{19}H_{14}O_4$ requires C = 74.5; H = 4.6 per cent.). On treatment of a chloroform solution of this methylenedioxy-styryl derivative with dry hydrogen chloride, the *monohydrochloride* is precipitated as a bright red salt. When the dry gas is passed over the solid derivative itself, 3 molecules of hydrogen chloride are absorbed at 15°, whilst at -20°, 4 molecules of the acid are taken up.

2-*Cinnamylidenemethyl-3-methylchromone*,

—This condensation was carried out under the usual conditions, but in this case a considerable quantity of tarry matter was produced. The product was purified by repeated crystallisation from absolute alcohol, animal charcoal being used as decolorising agent. It forms bright orange crystals melting at 225° (Found: C = 83.2; H = 5.6. $C_{20}H_{18}O_2$ requires C = 83.3; H = 5.5 per cent.).

2-*Furfurylidenemethyl-3-methylchromone*,

—This compound separates from the reaction mixture as a semi-solid, resinous mass. After repeated crystallisations from alcohol in presence of animal charcoal, it is finally obtained in orange-yellow needles melting at 132° (Found: C = 75.7; H = 5.0. $C_{18}H_{12}O_3$ requires C = 76.2; H = 4.8 per cent.).

4'-*Dimethylamino-2-styryl-3-methylchromone*.—In this condensation, the crude product which separates is invariably contaminated with traces of sodium. It crystallises from absolute alcohol containing a few drops of glacial acetic acid in brilliant orange-red crystals melting at 195° (Found: N = 4.7. $C_{20}H_{20}O_2N$ requires N = 4.6 per cent.).

6-*Methoxy-2:3-dimethylchromone*.—Twenty grams of 6-hydroxy-
4 R* 2

2:3-dimethylchromone (Simonis and Lehmann, *Ber.*, 1914, 47, 697) were dissolved in 300 c.c. of absolute alcohol and methylated by heating with alcoholic sodium ethoxide and methyl iodide (16 grams) on a water-bath for four hours. The reaction product was poured into dilute sodium hydroxide solution and the oil extracted with ether. On concentration of the dry ethereal solution, the methylated chromone separated in colourless, glistening needles melting at 135°. Hydrolysis with hydriodic acid readily regenerates the parent hydroxychromone (Found: C = 71.3; H = 6.5. $C_{18}H_{14}O_3$ requires C = 71.6; H = 6.4 per cent.).

6-Ethoxy-2-styryl-3-methylchromone.—Two grams of 6-ethoxy-2:3-dimethylchromone were dissolved in a small quantity of alcohol and 1 gram of benzaldehyde together with a solution of sodium ethoxide containing 0.5 gram of sodium was added. After standing over-night, the styryl derivative which had separated was filtered off and, after two recrystallisations from absolute alcohol, obtained pure in colourless needles melting at 145° (Found: C = 78.3; H = 6.0. $C_{20}H_{18}O_3$ requires C = 78.4; H = 5.9 per cent.).

4'-Methoxy-6-ethoxy-2-styryl-3-methylchromone, prepared by an exactly analogous method, crystallises from alcohol in pale yellow needles melting at 155° (Found: C = 75.1; H = 6.1. $C_{21}H_{20}O_4$ requires C = 75.0; H = 6.0 per cent.).

The corresponding 3':4'-methylenedioxy-6-ethoxy-2-styryl-3-methylchromone crystallises in bright yellow needles melting at 171° (Found: C = 71.7; H = 5.2. $C_{20}H_{18}O_5$ requires C = 72.0; H = 5.1 per cent.).

7-Methoxy-2:3-dimethylchromone was prepared by direct methylation of 7-hydroxy-2:3-dimethylchromone (Simonis and Remmert, *Ber.*, 1914, 47, 2231) by means of methyl sulphate. After repeated crystallisation from alcohol, it was obtained in colourless needles melting at 140°. The same substance was previously described by Kostanecki and Lloyd (*Ber.*, 1901, 34, 2948), who give the melting point as 126–127°. These authors employed methyl iodide and alcoholic potash for the methylation of the hydroxychromone, but following their method we again obtained the ether melting at 140°. Demethylation by means of hydriodic acid regenerated the original 7-hydroxy-2:3-dimethylchromone (m. p. 236°) (Found: C = 70.5; H = 6.0. $C_{12}H_{12}O_3$ requires C = 70.6; H = 5.9 per cent.).

7-Ethoxy-2:3-dimethylchromone.—This compound had previously been prepared by Kostanecki and Lloyd (*loc. cit.*) by the action of acetic anhydride and anhydrous sodium acetate on propionyl-resorcinol monoethyl ether. We have now obtained it by direct ethylation of 7-hydroxy-2:3-dimethylchromone by means of

alcoholic sodium ethoxide and ethyl iodide. The mixture was heated under reflux for four hours, after which most of the alcohol was distilled off and the residue poured into water. The precipitate was collected, washed with dilute alkali, and twice recrystallised from alcohol. It was obtained in beautiful, glistening prisms melting at 124°.

Attempted Condensation of 7-Methoxy- and 7-Ethoxy-2:3-dimethylchromone with Aldehydes.—Employing the same method as used in the preparation of 6-ethoxy-2-styryl-3-methylchromone, no reaction whatsoever took place even when the reaction mixture was kept over prolonged periods. On dilution with water, the original 7-methoxy- or 7-ethoxy-dimethylchromone was invariably recovered. Attempts were next made to induce condensation in the heat, but using either alcoholic sodium ethoxide or alcoholic potash as condensing agents, and employing in turn both the 7-methoxy- and 7-ethoxy-2:3-dimethylchromone, we observed no reaction whatever, even when the heating had been continued for several hours. Experiments were also carried out using hydrogen chloride and zinc chloride, but, as was expected, these failed altogether to produce the required styryl derivatives.

8-Methoxy-2:3-dimethylchromone.—This compound had previously been obtained by Simonis and Medlewska (*Ahrensammlung*, 24, 402), but no description of the method employed by the authors was given. The preparation was carried out as follows: A mixture of 25 grams of pure guaiacol with 25 grams of methylacetoacetic ester was cooled in ice, and 30 grams of phosphoric oxide were gradually added, the mixture being thoroughly stirred throughout the process. The whole was then heated on a water-bath for two hours, after which a further 30 grams of phosphoric oxide and 25 grams of guaiacol were again added and the heating was continued for another two hours. The reaction mixture was extracted with water and warmed with 10 per cent. sodium hydroxide solution (1 mol. of sodium hydroxide for each mol. of phosphoric oxide employed), after which it was thoroughly extracted with ether. The ethereal solution was freed from any remaining guaiacol by means of dilute sodium hydroxide solution, washed with water, and dried over anhydrous sodium sulphate. After removal of the ether, a red oil was left which partially solidified on standing. This was pressed on a porous plate to remove oily impurity and recrystallised from light petroleum in presence of animal charcoal. After a second crystallisation from the same solvent, 8-methoxy-2:3-dimethylchromone was obtained in colourless prisms melting at 54°. The yield was exceedingly poor, amounting to only about 1 per cent. calculated on the guaiacol.

4': 8-Dimethoxy-2-styryl-3-methylchromone was prepared in a precisely similar manner to that employed in the preparation of the other styryl derivatives. It separated from alcohol in pale yellow crystals melting at 149° (Found: C = 74.4; H = 5.7. $C_{20}H_{18}O_4$ requires C = 74.5; H = 5.6 per cent.).

In conclusion, we desire to express our thanks to the Advisory Council of the Department of Scientific and Industrial Research for grants which have enabled this investigation to be carried out.

CCXCV.—Absorption Spectra and Molecular Phases. Part I.

By RICHARD ALAN MORTON and HARRY BARNES.

THE interpretation of absorption spectra has been greatly simplified by Baly through his conception of molecular phases (*Phil. Mag.*, 1920, [vi], 40, 1, 15; *Brit. Assoc. Report*, 1922, 294; Baly and Campbell, *Phil. Mag.*, 1921, [vi], 41, 707). Every molecule is regarded as being characterised by a definite amount of energy determined by the quantities of energy which characterise its component atoms. This molecular quantum of energy is the fundamental quantity which governs every reaction of a given molecule, and the critical increment of energy necessary to activate a molecule is always one or more of its molecular quanta.

Since a molecule can gain or lose energy only in terms of its characteristic molecular quantum, it follows that it must exist in one of a number of possible phases according to the number of quanta that it has lost since its original synthesis, each consecutive phase differing in energy content by one molecular quantum. The characteristic quantum of an atom or molecule endows it with the power of absorbing or radiating energy according to the relation $E = h\nu$, where h (the Planck constant) involves the time occupied in the absorption or radiation of the energy unit. Every molecule therefore exhibits a characteristic and fundamental frequency, usually in the short-wave infra-red, and it may readily be proved that it also exhibits a phase frequency which is an integral multiple of the fundamental frequency, this phase frequency lying in the visible or ultra-violet region of the spectrum. The molecular phase in which a substance exists can readily be determined, therefore, by observation of the absorption bands it exhibits in the visible or ultra-violet region, since the frequency for which the absorptive

power is a maximum within an absorption band is the frequency characteristic of one molecular phase.

To this it may be added that the reactivities of the various phases of a given molecule differ, and that in order to enable a molecule to enter into a given reaction it is necessary to bring it into the appropriate molecular phase. The necessary change in phase is brought about by the supply of radiant energy and the energy required must be an integral number of quanta characteristic of the molecule and is the critical increment of energy for the reaction in question.

In this paper we have to record a case where the experimental observations would seem to afford the best support for the phase hypothesis yet brought forward. A spectrographic study of the three isomeric methoxy-2:3-dimethylchromones described in the preceding paper revealed the fact that in neutral alcoholic solution each of these three substances exhibits a single absorption band, whilst in presence of excess of alkali one only of them exhibits a band in the region examined ($\lambda = 3300$ to $\lambda = 2200$). The absorption curves of the neutral solutions are reproduced in the preceding paper (Fig. 1), in which the absorptive powers are plotted against wave-length. The unit of absorptive power is the molecular extinction coefficient given by $M.E. = \log(I_0/I) \times 1/cd$, where I_0/I is the ratio of the intensities of the incident light and the light after passage through an absorbing layer d cm. thick, and c is the concentration in moles. The wave-lengths and frequencies at which the absorptive power is a maximum are given in Table I.

TABLE I.

	Wave-length in tenth- metres.	Frequency $\times 10^{12}$.	Difference.
6-Methoxy-2:3-dimethylchromone	3180	943.4	
7-Methoxy-2:3-dimethylchromone	3110	964.6	21.2
8-Methoxy-2:3-dimethylchromone	3042	986.2	21.6
6-Methoxy-compound in alkali	3255	921.7	

The mean of the two differences in the last column is 21.4×10^{12} and if the frequencies in the third column are consecutive multiples of the same fundamental frequency this frequency must be very near to 21.4×10^{12} . In Table II, the integral relationships are given.

TABLE II.

	Frequency $\times 10^{12}$.	Factors.	Fundamental wave-length.
6-Methoxy-compound	943.4	$44 \times 21.44_1 \times 10^{12}$	13.99_{μ}
7-Methoxy-compound	964.6	$45 \times 21.43_2 \times 10^{12}$	13.98_{μ}
8-Methoxy-compound	986.2	$46 \times 21.43_3 \times 10^{12}$	13.99_{μ}
6-Methoxy-compound in alkali	921.7	$43 \times 21.43_4 \times 10^{12}$	13.99_{μ}

The four frequencies can therefore be expressed with remarkable accuracy as consecutive multiples of the same frequency, which is the fundamental frequency of the methoxydimethylchromone molecule and is independent of the position of the methoxyl group. The last column of Table II contains the wave-lengths corresponding to the fundamental frequency.

These results are not capable of interpretation on the earlier views of a direct correlation between structure and absorption spectra. The fundamental unit of energy is the same in the case of the three isomerides, but the units involved in the ultra-violet absorption bands are different, each being a different multiple of the fundamental unit. As discussed in the preceding paper, the three compounds show a parallel difference in reactivity, and it is significant that the most reactive isomeride, the 6-methoxy-compound, is the only one which exhibits a well-defined absorption band in the presence of alkali. We thus have a definite correlation of three factors:

1. Isomerism.
2. Quantitative energy relationships.
3. Differences in reactivity under strictly comparable conditions.

It is therefore justifiable to claim that these results strongly support Baly's theory of molecular phases.

We have also examined the absorption spectrum of 2:3-dimethylchromone and in this case two bands are shown, so that two phases coexist with frequencies in the ultra-violet. These frequencies also conform to the criteria for molecular phases, the fundamental unit being rather greater than in the case of the substituted compounds, as is shown in Table III.

TABLE III.

λ Obs.	Frequency $\times 10^{-12}$.	Factors.	λ Calc.	Fundamental wave-length.
3085	972.5	$41 \times 23.71_6 \times 10^{12}$	3084.4	12.64 $_{\mu}$
2690	1115.2	$47 \times 23.72_8 \times 10^{12}$	2690.6	12.64 $_{\mu}$

The two values of the fundamental unit given in the third column differ rather more than in the case of the methoxy-compounds, but they lie well within the limits of experimental error. The wave-lengths in the fourth column are calculated from the mean value $23.72_3 \times 10^{12}$ and they are exceedingly near the observed values. The accuracy is also shown by the fundamental wave-lengths calculated from the two values of the fundamental frequency.

We express our thanks to Professors Baly and Heilbron for their interest and advice, and are indebted to the Department of Scientific and Industrial Research for grants in aid of our work.

THE UNIVERSITY, LIVERPOOL.

[Received, July 28th, 1923.]

CCXCVI.—*Colorimetric Estimation of Small Amounts of Oxygen.*

By PERCY GEORGE TERRY HAND.

A NEED arose during the course of work carried out in this laboratory, of a quick and fairly accurate method of estimating very small amounts of oxygen in a stream of gas. The majority of existing methods were not delicate enough. On the other hand, high sensitivity is coupled with either complicated apparatus or the necessity of working in the presence of another gas, for example, purified hydrogen. Furthermore, none of the existing methods (compare Sheaff, *J. Biol. Chem.*, 1922, 52, 35; White, *J. Amer. Chem. Soc.*, 1922, 44, 20; Binder and Weinland, *Ber.*, 1913, 46, 255) suited the particular dynamic experiment in hand.

The method used is a modification of Ridcal and Burgess's (*Analyst*, 1909, 34, 193) colorimetric method for estimating the amount of dissolved oxygen in water, and consists in allowing the gas, containing its impurity oxygen, to come into contact with manganous hydroxide, formed by the interaction of manganous chloride and sodium hydroxide in a vacuum in presence of potassium iodide. Acidification in presence of starch completes the test, giving the well-known colour of the starch-iodine complex. The limit of detectability of oxygen is 1×10^{-7} gram.

Apparatus.—This consists of the main apparatus (Fig. 1) and the auxiliary filler (Fig. 1A), both made of glass.

Made to withstand a high vacuum, the main apparatus consists of (1) three reservoirs, C_1 , C_2 , C_3 , of capacity 40, 40, and 20 c.c., respectively, (2) "mixers," A and B , each 45 c.c. in volume, and (3) "reaction chamber," G , having a capacity of 400 c.c. This chamber is connected to C_3 by means of a ground joint, F , and is also furnished with a side tube ending in a ground joint, E . All taps on the apparatus are well-ground vacuum taps capable of withstanding a vacuum of 1×10^{-6} mm.

Reagents.—All solutions are made with freshly boiled distilled water. The solution for C_1 is 0.5 c.c. of a saturated solution of manganous chloride made up to 10 c.c.; the solution for C_2 is 1.5 c.c. of a solution containing 10 per cent. of potassium iodide and 30 per cent. of sodium hydroxide made up to 10 c.c.; the solution for C_3 is 4 c.c. of 20 per cent. sulphuric acid and 0.5 c.c. of 1 per cent. Lintner's soluble starch.

Colour Standards.—The colour standards were made in the following way:

Six test-tubes of uniform size and material were thoroughly

cleaned and washed, and in each were placed 1.5 c.c. of 10 per cent. potassium iodide, 4 c.c. of 20 per cent. sulphuric acid, and 0.5 c.c. of 1 per cent. Lintner's soluble starch. One c.c. of potassium permanganate solution (0.395 gram per litre) was added to one of these mixtures, and the total volume made up to 24 c.c. The blue colour produced was equivalent to 1×10^{-4} gram of oxygen.

As soon as the colour developed, the test-tube was corked, set against dead white paper, and accurately matched and reproduced

FIG. 1.

FIG. 1A.

in the form of a colour chart. Further colours, corresponding to smaller quantities of oxygen, were made by diluting the permanganate solution so that the range was :

Number	1	2	3	4	5
Gram of oxygen	1×10^{-4}	1×10^{-5}	1×10^{-6}	1×10^{-7}	Nil.

Manipulation.—The main apparatus is connected by means of the ground joint, *E*, to a ground cup of the evacuation leads. This joint is made vacuum-tight by means of Everett's wax. (The evacuation outfit, in this case, consists of a Kraus mercury vapour-pump backed by a Cenco Hyvac oil-pump.)

In order to remove the air entrapped in the bores of taps 1, 2, and 3, the three reservoirs are evacuated to 1 mm. by means of a Geryk oil-pump, with taps 4, 5, and 7 shut. The taps 1, 2, and 3 having been closed, 4, 5, and 7 are opened, thus putting C_1 , C_2 , and C_3 into communication with G . By turning the two-way tap, D , so as to connect G with E , the apparatus is ready to evacuate. This having been done as completely as possible (usually 1×10^{-5} mm.), tap D is closed, likewise taps 4, 5, and 7. The apparatus is now detached from the evacuation leads.

The manganous chloride and potassium iodide-hydroxide solutions are now introduced into their respective reservoirs in the following manner. The solution in question is placed in Z and pressure tubing, previously soaked in dilute sodium hydroxide solution and then well washed and kept in distilled water until ready for use, is attached to X (Fig. 1A) and X_1 (Fig. 1). The bulb, Z , being held in an inclined position so that the 10 c.c. of solution rests on the bottom of the bulb, connexion is made at Y , by means of pressure tubing, to the Geryk oil-pump. Tap 6 is turned in connexion with the pump. The bulb is now evacuated, the solution boiled, and the evacuation carried on until all the air has been expelled from the solution, when tap 6 is closed. The solution (manganous chloride in this case) is allowed to run into C_1 by first tilting Z and then gradually opening tap 1. This tap is closed so as to leave a very small amount of liquid above it. This process is repeated in order to fill C_2 .

The apparatus is now connected to the supply of the gas to be analysed, connexion being made, as before, by fitting E into a ground glass cup, and sealing the joint with Everett's wax. D is now opened so that it is in direct communication with the air, and the gas is allowed to sweep through the part of the apparatus between E and D for half an hour. During this time, the solutions in C_1 and C_2 are admitted into A and B . At the end of half an hour, the temperature of the apparatus having been recorded, the gas flow is directed into G by turning tap D . The normal rate of flow of the gas need not be disturbed even although it is entering a vacuous space, if care is taken in manipulating the capillary two-way tap.

As soon as the gas has attained atmospheric pressure in G , as judged by a manometer in the line of the gas flow, tap D is closed, and the apparatus disconnected at E . The solutions in A and B are mixed and poured, by inclining the apparatus, into G . The suspended precipitate of manganous hydroxide is slowly rocked from side to side frequently during a period of one hour. At the end of this time the gas in G is removed by attaching the Geryk

pump to *E*, securing a vacuum between *D* and *E*, and then turning *D* into connexion with the pump and *G* for a short time.

Reservoir *C*₃ is now filled, in exactly the same manner as *C*₁ and *C*₂ were filled, with starch-acid mixture. A short time is allowed to elapse so that the slightly warmed mixture can cool to room temperature. The glass tubing above tap 3 is now carefully filled with benzene, a small glass Gooch crucible holder is attached to *X*₃ by means of rubber tubing, and the holder filled with benzene. Tap 3 is now carefully opened, and the benzene released on to the top of the starch-acid mixture, until the reservoir is completely filled. With tap 3 open, tap 7 is carefully opened and the solution in *C*₃ run into *G*, care being taken to leave a small amount of the starch-acid mixture above tap 7. Solution of the oxidised and unoxidised manganous hydroxide is effected and the liberated iodine colours the starch. The liquid is carefully washed round the apparatus, and transferred to a test-tube of the same batch as used for making the colour standards. Comparison of the colour is now made.

The amount of starch necessary to give satisfactory tints was arrived at by an exhaustive trial of various concentrations of starch solution.

A blank test was performed with the apparatus evacuated to 1×10^{-5} mm., and no coloration was observed.

In order to test the accuracy of the method, experiments were carried out, using known amounts of oxygen obtained by evacuating the apparatus to a known pressure of air. The colours obtained in this way were in excellent agreement with the standard colours obtained by means of potassium permanganate.

With this apparatus it is possible to detect 1.5 parts of oxygen (by volume) in 10^7 parts of a gas.

This method is not restricted to the range of concentrations given in this paper. For amounts of oxygen greater than 1×10^{-4} gram the iodine tints themselves may be used.

The author's sincere thanks are due to Professor Allmand for his valuable advice and keen interest, and to the Chemical Warfare Committee for permission to publish this work. Acknowledgments are due to Messrs. D. O. Shiels and R. Chaplin for help and kindly criticism, and to Mr. S. Tayler for his work on the colour chart.

CCXCVII.—*The Constitution of Carbamides. Part XV.*
A Delicate and Trustworthy Test for the Recognition
of Cyanic Acid.

By EMIL ALPHONSE WERNER.

THE tests which have been hitherto available for the detection of the cyanic radicle leave much to be desired when it is required to prove the presence of a small quantity of a cyanate in an alkaline solution. When, for example, cyanic acid is generated in solution in the presence of a considerable excess of ammonium hydroxide, or of ammonium carbonate, trustworthy evidence of its existence is difficult to obtain. Even when every care is taken, hydrolytic decomposition of much of the cyanic acid cannot be avoided during the process of neutralisation which is necessary before any of the hitherto known tests can be applied.

The formation of cyanic acid by the oxidation of various carbon-nitrogen compounds in alkaline solution, or by the oxidation of many non-nitrogenous carbon compounds in presence of ammonia, is of special interest, since it explains the origin of the urea which has been obtained from many of these oxidation experiments recorded by Fosse (*Ann. Chim.*, 1916, [ix], 6, 155; *Compt. rend.*, 1919, 168, 1164; 169, 91) and Werner (*T.*, 1922, 121, 2322).

The recent discovery by Spacu (*A.*, 1923, 124, ii, 40)* of a very interesting and remarkably sensitive reaction for the detection of copper, and incidentally of a thiocyanate, has placed in the author's hands the means of securing what was much needed, namely, a trustworthy and delicate test for cyanic acid which can be easily applied to its detection at a high degree of dilution, and when generated under the conditions mentioned above.

When a thiocyanate is added to a dilute solution of a copper salt to which a few drops of pyridine have been previously added, a bright yellowish-green precipitate is formed. This, as Spacu has shown, has the composition $\text{Cu}(\text{SCN})_2(\text{C}_5\text{H}_5\text{N})_2$. The compound is soluble in chloroform, to which it imparts an emerald-green colour. Hence, with solutions so dilute that no precipitate is formed, the presence of copper, or of a thiocyanate, as the case may be, is at once revealed after shaking the solution with a small quantity of chloroform. According to Spacu, the test, when applied in neutral solutions, will detect 1 part of thiocyanate in 50,000 parts of solution. For copper, the limit of sensitiveness is much greater, 1 part in 800,000 parts.

* The original paper (*Bull. Soc. Ştiinţe Cluj*, 1922, 1, 284) was not available.

When a cyanate is substituted for a thiocyanate in Spacu's reaction, a lilac-blue precipitate is formed, which when dried becomes deep ultramarine in colour. The dry precipitate has the composition $\text{Cu}(\text{OCN})_2(\text{C}_5\text{H}_5\text{N})_2$ (Found : $\text{CuO} = 25.94$. $\text{C}_{12}\text{H}_{10}\text{O}_4\text{N}_4\text{Cu}$ requires $\text{CuO} = 26.03$ per cent.). It is soluble in chloroform with production of a sapphire-blue solution. By means of this reaction, it is possible to detect 1 part of cyanate in 20,000 parts of solution, when the test is made in the following manner. A few drops of pyridine are added to two or three drops of a 1 per cent. solution of copper sulphate in about 10 c.c. of water, about 2 c.c. of chloroform are added followed by the solution to be tested, and the mixture is shaken briskly, when the chloroform will be found to subside with a blue colour. As a control experiment, the copper-pyridine solution should be shaken with the chloroform, before addition of the solution to be tested, to make sure that no colour is imparted to the solvent. The final result is very striking if a cyanate is present. The coloured chloroform subsides, leaving the supernatant solution colourless.

Whilst no particular precaution need be observed in the application of the test to the detection of a cyanate in moderate concentration, and in a neutral solution, an excess of copper must be avoided when dealing with very dilute solutions. The copper-pyridine derivative is either decomposed according to the equation

or its formation is prevented, with the result that chloroform extracts no colour from the solution. The addition of an extra quantity of pyridine will bring about the desired effect. In describing the test for copper, or for a thiocyanate, Spacu states that excess of pyridine must be avoided. In the author's experience this applies only to cases where a precipitate is sought for. As a matter of fact, a small excess of pyridine promotes the solubility of the copper cyanate compound, and also of the thiocyanate compound, in chloroform. While the value of the reaction was being tested with dilute solutions of a cyanate, the failures encountered were soon found to be solely due to the use of an excess of copper, none were caused by the presence of an excess of pyridine. The chief merit of this reaction lies in its easy application to the detection of a cyanate in alkaline solution. The copper cyanate-pyridine compound is stable in the presence of a moderate excess of acetic acid. The solution to be tested is added to the copper-pyridine-chloroform mixture; acetic acid is added boldly, the solution being shaken in the meantime between each addition of the acid. As soon as neutralisation is effected, the chloroform will assume a blue colour if a cyanate be

present. There is no danger of decomposition of the cyanic acid on account of the stability of the copper cyanate-pyridine compound. Moreover, the latter is removed from solution so effectively by chloroform that the success of the test is not endangered by over-stepping the addition of acetic acid.

The formation of cyanic acid in the first stage of many of the decompositions of urea can be admirably demonstrated by aid of this test. For example, the small amount of reversion of urea to ammonium cyanate after heating 25 c.c. of a 5 per cent. solution at 100° for five minutes, is sufficient to give a bright blue colour to 2 c.c. of chloroform after the test has been completed.

The reaction has been applied with success to the detection of cyanic acid in solutions containing more or less colloidal matter. It is in dealing with solutions of this nature that the value of the test will be appreciated.

CCXCVIII.—*The Increased Solubility of Phenolic Substances in Water on Addition of a Third Substance.*

By CHARLES REYNOLDS BAILEY.

CONDENSED ternary systems in which two liquid layers are possible have been investigated by a number of workers. An exhaustive theoretical treatment is given in Vol. III, Part ii, of Roozeboom's "Die Heterogenen Gleichgewichte," whilst Timmermans (*Z. physikal. Chem.*, 1907, 58, 129) supplies a very full list of work done up to 1907. Bancroft (*J. Physical Chem.*, 1897, 1, 414) showed that the phenomena observed in such systems could be theoretically predicted from considerations of the phase rule. If the system is represented by the usual triangular method, for any given temperature one has normally a saturation curve and a binodal curve, and the many complications which may arise are due to combinations of the two. The determination of the binodal curves for a series of given temperatures affords one method of examination of the effect of a third substance on the solubility of one liquid in another. The method most frequently employed has been to determine the raising or lowering of the critical saturation temperature due to additions of the third substance. The second method is no more satisfactory for two liquid layers than it would be if applied to the saturation curve of the three-component system; a number of isolated points are obtained which lie on the surface

separating the region of heterogeneity from the rest of the figure and the comparison of results is difficult.

In the present research the binodal curves have been obtained for the following systems :

- (A) Water-phenol-sodium oleate at 0°, 20°, 40°, 60°.
- (B) Water-*o*-cresol-sodium oleate at 20°.
- (C) Water-*m*-cresol-sodium oleate at 20°, 60°.
- (D) Water-*p*-cresol-sodium oleate at 20°.
- (E) Water-phenol-pyrogallol at 20°.

The complete examination of the above systems would present considerable difficulties in analysis of the solutions; furthermore the colloidal nature of the oleate would have to be taken into account.

EXPERIMENTAL.

Materials.—The following call for notice :

- (i) Phenol : redistilled detached crystals, m. p. 41.0°.
- (ii) Cresols (Kahlbaum) : *o*-, m. p. 30.0°, b. p. 191°; *m*-, b. p. 201°; *p*-, m. p. 35.8°, b. p. 201°.

The *m*-cresol was twice redistilled without ridding it of a small trace of impurity which was believed to be present (see p. 2584).

- (iii) Pyrogallol : m. p. 133°.

(iv) Sodium oleate : The usual extreme difficulty was experienced in obtaining a satisfactory sample. The first specimen used made no claim to purity and was a waxy, yellow, greasy solid with a rank odour. Oleic acid was obtained from this by the lead salt-ether method and dissolved in ammonia; the barium salt was then precipitated, extracted with benzene-alcohol, and decomposed with tartaric acid : the oleic acid so obtained had an iodine number of 89.5. Sodium oleate was prepared by dissolving the acid in absolute alcohol and titrating with sodium dissolved in the same solvent. This sample was used as a check on the others prepared from "specially purified" oleic acid supplied by various firms. Certain specimens had iodine numbers of 88—89, but seemed to contain some compensating impurities, since they gave rise to abnormalities on the curves which were not present with the standard sample. A supply of post-war oleic acid "Kahlbaum" was obtained from Germany and the oleate prepared from this gave satisfactory results. The samples of oleate thus obtained were white powders, not in the least greasy and with but very faint odour.

Procedure.—The "synthetic" method was adopted, whereby to certain mixtures of the two liquid components at given temperatures the solid was added until the critical saturation tem-

perature was reached. A thin glass tube of $\frac{1}{2}$ -inch bore with an inch bulb blown at one end and closed by a ground-in glass stopper was used, the whole being about six inches in length. The two components were introduced and weighed and the tube was suspended in a thermostat; the third component was added with constant shaking until that mixture was reached which had its critical saturation temperature at the temperature of the thermostat. The neighbourhood of this concentration was indicated by the appearance of the critical opalescence followed by the sudden increase in turbidity denoting the actual separation into two layers when the original mixture was homogeneous; the reverse process is applicable to originally heterogeneous mixtures. Thus to homogeneous mixtures of (i) phenol-oleate or (ii) water-oleate the third component was added until the required turbidity was produced; any further addition of that component leads to the formation of an emulsion which breaks down on standing with the formation of two layers. If, however, (iii) one continues to add the third component, the point representing the composition of the mixture traverses the heterogeneous region until a single liquid phase results. It is also possible (iv) to start with a heterogeneous mixture and to add solid until the disappearance of one liquid phase results. The four methods were applied and gave concordant results which have been checked by working in a sealed tube. Blank experiments were also carried out to ascertain whether there was any loss by evaporation during the course of the work; this was found to be negligible. The points so obtained were plotted on triangular co-ordinates.

Experimental Results.

Tables I—V give the percentage composition of certain of those mixtures of the three components which have their critical saturation temperature at t° , where t = temperature of the isotherm in question. Thus a mixture of 82.7 parts of water and 16.0 parts of phenol has its critical saturation temperature normally at 58.6° (see p. 2587); by the addition of 1.3 parts of sodium oleate this is lowered to 0° (Table Ia, No. 4). The lowering of critical saturation temperature is represented by $T - t$, where T is the critical saturation temperature for the two liquids in the absence of the solid: this will be considered under "*Theoretical*."

The general form of the binodal curves is given in Fig. 1. The proportion of oleate is exaggerated approximately four times for the purpose of reproduction, as otherwise the curves lie too close to the base of the triangle; the phenomena observed are well represented by the diagram, however. If, for example, one starts

with a mixture of water and oleate given by the point *A* (Fig. 1) and adds phenol, the point representing the composition of the

mixture travels along the line ABC ; at B the solution becomes heterogeneous; on further addition of phenol the point crosses the heterogeneous region until it arrives at C , when the mixture becomes once more homogeneous. The curves give the necessary amounts of oleate to be added to render phenol and water in any given proportions completely miscible at the required temperature. The purity of the substances employed in this research may be tested by determining one or two points on the curves; the nature of the abnormalities to be expected may be seen by reference to the dotted line EF in Fig. 1; the first portion of the binodal curve for an impure substance follows that for the pure very closely, but impurities in either the oleate or the phenol lead to a very large increase in the amount of oleate in the neighbourhood of the maximum of the curve. Inspection of the results obtained for *m*-cresol (Table III) will show that the trace of impurity was not completely removed.

The water-rich side of the binodal curve for the oleate is, for the greater part of its course, a straight line directed to the water vertex. Consequently, if to a mixture of phenol and oleate represented by the point D (Fig. 1) water is added, the composition of the mixture travels along the binodal curve and one has a prolonged critical opalescence.

Theoretical.

Bancroft (*loc. cit.*) has shown that the influence of a third substance on the miscibility of two liquids depends on its comparative solubilities in both. The following cases present themselves:

- (i) The third substance is appreciably soluble in one liquid only: the critical saturation temperature is raised.
- (ii) The third substance is soluble in both liquids, but only to a very small extent; the critical saturation temperature may be either raised or depressed, but only very slightly in either case.
- (iii) The third substance is easily soluble in both liquids; the

critical saturation temperature is depressed and to the greater extent the more nearly the ratio of the comparative solubilities approaches unity.

Many examples may be cited (see Table X) and the above generalities are fully borne out in practice. Several types have been investigated by Timmermans (*loc. cit.*), but the few isolated points chosen do not lend themselves readily to comparison of results.

In the case where the third substance is soluble in one liquid only, considerable analogy exists between the raising of critical

FIG. 2.
Phenol-water-sodium oleate.

saturation temperature and the results of additions of a third non-volatile substance on the critical temperature of a liquid and its vapour. The upper liquid layer in the liquid-liquid system corresponds to the space above the vapour in the other; the classical work on the subject is that of Centnerszwer (*Z. physikal. Chem.*, 903, 46, 427). Certain expressions devised to correlate the change of critical temperature with the additions have been applied to the two-liquid systems, but without much success. That of van't Hoff (*Chem. Weekblad*, 1903, 1, 93) is the simplest, but assumes that the molecular elevation of critical saturation temperature is constant. The values of the molecular elevation have been

calculated for the systems examined and some of the results are recorded in Tables VI—IX and Figs. 2—4. It will be seen that this assumption is far from true and that the elevation depends

FIG. 3.

p-Cresol-water-sodium oleate.

FIG. 4.

Phenol-pyrogallol-water.

on, among other things, the concentration of phenol in the mixture. Van Laar evolved a complicated expression from the results of Centnerszwer's work (*Chem. Weekblad*, 1905, 2, 223), but it involves a calculation of the critical constants of the liquids employed.

By analogy with Raoult's expression for the elevation of boiling point, the molecular elevation of critical saturation temperature may be obtained from the formula

$$E = (t - T)/C,$$

where T = critical saturation temperature before addition of the third substance, t = critical saturation temperature after addition, and C = concentration of the third substance in moles per kgm. of the phenol-water mixture.

Certain of the values given by that expression are detailed in Tables VI—IX, where the numbers of the experiments correspond with those of Tables I—V and the percentages of the phenol in the phenol-water mixture have been recalculated from those experiments. Some results are shown graphically in Figs. 2—4, where the molecular elevation of critical saturation temperature (reckoned positively as a depression) has been plotted against the percentage of phenol in the mixture. The values of T have been extrapolated from the saturation curves for the pairs of liquids examined; the maximal points on those curves are as follows:

Water-phenol: 65.3°, 36.5% phenol (Timmermans, *loc. cit.*).
 „ *o*-cresol: 162.8°, 40.8% cresol } (Sidgwick, Spurrell, and
 „ *m*-cresol: 146.9°, 35.6% cresol } Davies, T., 1915, 107,
 „ *p*-cresol: 143.7°, 35.5% cresol } 1202).

Timmermans's results have been chosen in preference to those of the many other workers on that system, as they are in agreement with values obtained in the present research (see Timmermans, *loc. cit.*).

Examination of Figs. 2-4 shows that certain characteristics are common to the systems considered in the present research. E is numerically greatest in mixtures containing a high percentage of water; this appears to be generally true where the third substance is soluble in the phenol alone or soluble in both liquids; reference to Table X will show that for electrolytes soluble in water only, in the two cases available, the reverse is true. Along the middle portion of the curves the relation between the concentration of phenol and E is approximately linear. There is then a rise to a maximum (except for phenol and sodium oleate, Fig. 2), followed by a fall, which can be extrapolated to the point representing the solubility of water in the phenol for a zero value of E . Where

more than one isotherm has been examined, the E -curves intersect in the neighbourhood of the percentage of phenol corresponding to the maximal point on the saturation curve (p. 2587). Hence it would seem that at that point, no matter to what temperature the critical saturation temperature has been depressed, E is constant. In other words, E is there proportional to the amount of the third substance added.

As a consequence of the above reasoning, it appears that comparisons between the effects of different third substances can only be correctly instituted at the maximal critical saturation temperature, that is, at points lying on the critical curve of the ternary system concerned. Table X shows that even with a knowledge of molecular weights and of comparative solubilities, it is not possible to state beforehand the quantitative value of E . An expression to correlate the molecular concentration of the third substance with the elevation of critical saturation temperature must contain terms involving (a) the temperature to which the critical saturation temperature is raised or depressed, (b) the percentage composition of the liquid-liquid mixture, and (c) very probably the chemical and physical properties of the components.

In the following table a comparison of E for certain third substances in a phenol-water mixture has been made. The values given are extracted either from Timmermans's work (*loc. cit.*) or from the present research. Three representative phenol-water mixtures have been taken, (i) rich in phenol (71%), (ii) at the maximal critical saturation temperature (36.5%), (iii) poor in phenol (9.4%). The critical saturation temperature has in each case been lowered to 20°.

TABLE X.

Substance.	M. wt.	Value of E for mixtures containing			
		71%	36.5%	9.4% of phenol.

VOL. CXXIII.

It will be seen that reasonable constancy is obtained for any one concentration only where the third substance is soluble in phenol alone.

My thanks are due to Professor F. G. Donnan, F.R.S., for suggesting the research and for guidance in carrying it through; and to the Research Fund Committee of the Chemical Society for a grant which has covered the cost of materials used.

UNIVERSITY COLLEGE, LONDON.

[Received, June 9th, 1923.]

CCXCIX.—*Organic Derivatives of Silicon. Part XXVII.*
A Probable Example of Tervalent Silicon.

By FREDERIC STANLEY KIPPING.

THE unsaturated silicohydrocarbon produced by the action of sodium on diphenylsilicon dichloride (Kipping and Sands, T., 1921, 119, 830) is so sparingly soluble that it resists the attack of many reagents by which it would no doubt be immediately decomposed if it were in a dissolved state; thus it is not appreciably acted on by boiling aqueous solutions of alkalis, potassium permanganate, or dichromate, and by such behaviour, together with its stability at high temperatures, gives a totally false impression of its reactivity. It is, as a matter of fact, a very unstable compound. Even in the solid state it changes on exposure to light and air and slowly acquires a distinct yellow colour, and it undergoes atmospheric oxidation in toluene solution at 100°. When its solution in benzaldehyde is boiled on a reflux apparatus, the silicohydrocarbon is completely decomposed with great rapidity; a solution of the same concentration in diphenyl, boiled during incomparably longer periods, still contains a considerable proportion of the unchanged compound. It must be inferred, therefore, that the silicohydrocarbon is acted on by the benzaldehyde.

Under similar conditions, the unsaturated compound is slowly oxidised in benzyl alcohol, acetophenone, or paraldehyde solution, presumably by the combined oxygen of the solvent. Amyl nitrite, at its boiling point, also decomposes it. The silicohydrocarbon is attacked by ozone, giving, apparently, not an ozonide, but a mixture of oxidation products.

More noteworthy even than the above evidence of instability, is the fact that the silicohydrocarbon is attacked by various aliphatic and other halides. It has previously been shown that it is very rapidly changed by boiling tetrachloroethane, giving, probably, a

dihalogen additive product from which the oxide $\text{Si}_4\text{Ph}_8\text{O}$ is produced on subsequent hydrolysis. It is also decomposed when its solution in ethylene dibromide or bromobenzene is boiled under a reflux condenser; the reaction with ethylene dibromide takes place so rapidly in comparison with that which occurs with bromobenzene that it cannot be attributed to atmospheric oxidation and is, doubtless, analogous to the change brought about by tetrachloroethane. Although the silicon compound can be recrystallised from phosphorus tribromide, it is very quickly decomposed when the solution is boiled; here again it seems that a dihalogen derivative is formed. The products of these reactions with halogen derivatives give, on hydrolysis, the oxide already mentioned, the rhomboidal oxide (*loc cit.*), and in some cases the oxide $\text{Si}_4\text{Ph}_8\text{O}_2$, melting at $245\text{--}246^\circ$, is also formed. In spite of its reactivity with the above-named halogen compounds, the silicohydrocarbon seems to be inert towards hydrobromic acid. It is also recovered practically unchanged when its toluene solution is heated with a little diphenylsilicon dichloride, but the boiling dichloride alone rapidly converts it into glue-like products.

It is clear from these observations that the unsaturated silicohydrocarbon is an exceptionally active compound and differs in a most marked manner from its supposed isomeride.* As all the evidence shows that the molecule of the unsaturated compound does not contain the group $\text{>Si}=\text{Si}<$, $\text{>Si}=\text{C}<$, or $\text{>C}=\text{C}<$, it is suggested that it contains two tervalent silicon atoms and may be represented by $\dots\text{SiPh}_2\cdot\text{SiPh}_2\cdot\text{SiPh}_2\cdot\text{SiPh}_2\dots$

The fact that solutions of the silicohydrocarbon are colourless, whereas those of triphenylmethyl and of other substances containing tervalent atoms of elements generally quadrivalent, are more or less highly coloured, is an argument against this view, the weight of which it is not easy to determine; on the other hand, the change in colour of the silicohydrocarbon when it is kept recalls the similar but more rapid change which occurs in the case of triphenylmethyl and phenylbisdiphenylmethyl (Schlenk, Herzenstein, and Weickel, *Ber.*, 1910, 43, 1753). In connexion with this point it may be stated that on several occasions, during the course of the reaction between sodium and diphenylsilicon dichloride, the toluene solution acquired a distinct reddish-yellow colour, which rapidly became much paler when the solution was shaken well and thus brought into contact

* The cryoscopic results obtained with the saturated silicohydrocarbon are not absolutely conclusive evidence that the molecular formula is Si_4Ph_8 , since in the case of trianhydrotrisidiphenylsilicenediol (Kipping, *T.*, 1912, 101 2125) and the corresponding tetrakis derivative the experimental values are about 16 per cent. lower than the theoretical.

with the air; solutions which showed this behaviour could be repeatedly changed from pale to brownish-yellow and back again, but in most of the preparations the solutions remained pale yellow; on one occasion a cold, pale yellow toluene solution of the reaction product gave, when filtered, an orange-coloured liquid and the blue residue of sodium chloride, etc., extracted with toluene, gave an almost blood-red filtrate, which apparently contained a sodium derivative and gradually lost its colour on exposure to the air.

These colour changes have not yet been accounted for, but they may be due to the presence of some compound of tervalent silicon.

The direct combination of the silicohydrocarbon with oxygen is a much more pregnant fact pointing to the presence of tervalent silicon. Owing to the necessarily very low concentration of a toluene solution and other unfavourable conditions, atmospheric oxidation is a relatively slow process, but the silicohydrocarbon abstracts combined oxygen from boiling nitrobenzene with very great rapidity, giving an oxide, $\text{Si}_4\text{Ph}_8\text{O}_2$ (*loc. cit.*); it is also oxidised very rapidly by boiling benzaldehyde, more slowly by certain other liquids containing combined oxygen. The products are usually so numerous that for this and other reasons their complete identification has been impossible, but in every instance there is certainly formed one, if not two oxides, $\text{Si}_4\text{Ph}_8\text{O}_2$, together with the oxide $\text{Si}_4\text{Ph}_8\text{O}$. Whether either of these dioxides is a peroxide analogous to that of triphenylmethyl (or pentaphenylethyl) is still uncertain; the rhomboidal oxide, especially, seems to be very stable, but it is conceivable that a silicon peroxide may have properties very different from those of a carbon analogue; on the other hand, it may be that a silicon peroxide is actually formed, but is unstable, and passes into one or both of the dioxides.

The behaviour of the unsaturated silicohydrocarbon towards iodine, tetrachloroethane, ethylene dibromide, and phosphorus tribromide affords perhaps the strongest experimental evidence in favour of the assumption of tervalent silicon. The reaction with iodine is rapid and quantitative at the ordinary temperature, the well-defined di-iodide being formed (*loc. cit.*); in the other three cases it seems clear that the silicohydrocarbon takes up combined halogen. The behaviour of triphenylmethyl and its analogues towards halogen compounds does not appear to have been recorded; whatever it may be, it must be conceded that the above facts prove that the silicon atoms are most abnormally reactive. The stability of the silicohydrocarbon in presence of hydrobromic acid may be due to the insolubility of the compound in water or to the instability of the silicon-hydrogen union.

When the structure of this unsaturated silicon compound was

first considered, the suggestion of tervalent silicon did not commend itself (*loc. cit.*) because of the existence of the supposed isomeride, which is very probably an octaphenylcyclosilicotetrane (compare foot-note, p. 2591). It was thought that two compounds having such a relationship should be easily convertible one into the other, as, for example, is the case with triphenylmethyl and hexaphenylethane, and also that such an unsaturated compound should give polymerides, $\dots \text{SiPh}_2 \cdot [\text{SiPh}_2]_n \cdot \text{SiPh}_2 \dots$, etc., which might pass into closed-chain compounds.

The results recently published by Schlenk and Mark (*Ber.*, 1922, 55, [B], 2285) and the author's own experiments on the production of saturated open-chain derivatives of silicotetrane (this vol., p. 2598), together with the very striking evidence just summarised, have shown that such arguments cannot be maintained. Since, apparently, triphenylmethyl and pentaphenylethyl do not combine together in solution to form octaphenylpropane, and since pentaphenylethyl does not give decaphenylbutane, it is clear that different or identical molecules containing tervalent carbon may show no tendency to combine; obviously then this may also be so in the case of tervalent silicon.

Whether tervalent carbon compounds owe their formation and existence to the inequality of the binding energies of the quadrivalent carbon atoms, or to steric hindrance, or to a combination of the two causes, in the author's opinion the assumption of steric hindrance gives a reasonable interpretation of all the facts in the case of these silicon compounds.

The silicon atoms represented as tervalent in the molecule of the octaphenyl derivative may be so masked by phenyl groups that their union with one another only takes place with great difficulty; they combine with avidity with atoms of small volume, such as those of oxygen or of halogens, and may be made to unite with ethyl groups with difficulty, but not with phenyl groups (this vol., p. 2598). The action of sodium on diphenylsilicon dichloride doubtless takes place in stages, giving dihalogen compounds such as $\text{SiPh}_2\text{Cl} \cdot \text{SiPh}_2\text{Cl}$, $\text{SiPh}_2\text{Cl} \cdot \text{SiPh}_2 \cdot \text{SiPh}_2 \cdot \text{SiPh}_2\text{Cl}$, etc.; the dichlorosilicotetrane derivative may then be converted by the elimination of chlorine partly into the open-, partly into the closed-chain silicohydrocarbon, but the formation of the latter may only take place when the terminal groups of the molecule are in a favourable position; alternatively, it may be that the closed-chain compound is only formed directly from two molecules of the dichloride $\text{SiPh}_2\text{Cl} \cdot \text{SiPh}_2\text{Cl}$. When under favourable conditions the closed-chain silicohydrocarbon is once formed, the product may owe its relative stability to the masking of the silicon atoms by the phenyl groups.

These views are put forward tentatively; in the near future it is hoped that some further interesting, but more complex products of the action of sodium on diphenylsilicon dichloride will be described and it may then be possible to arrive at more definite conclusions.

EXPERIMENTAL.

A specimen (about 2 grams) of the pure silicohydrocarbon, Si_4Ph_8 , contained in a closed weighing bottle, which had been opened from time to time, acquired a distinct yellow colour diminishing from the outside inwards. The sample had been exposed to diffused daylight on the laboratory bench during a period of at least twelve months; it became colourless when washed with ether, which extracted from it a very minute proportion of yellow, non-crystalline matter.

Evidence of Atmospheric Oxidation.—The pure silicohydrocarbon (0.6 gram) was covered with distilled toluene (20 c.c.) in a platinum basin heated on a water-bath, fresh toluene being added from time to time; at the end of about fourteen hours, all the solvent having evaporated, there was a gain in weight of 0.9 per cent. and the residue was distinctly yellowish-brown. The conversion of the whole of the compound into the oxide $\text{Si}_4\text{Ph}_8\text{O}$ would have required a gain in weight of about 2.2 per cent. The product, extracted with a little cold benzene, gave a residue (0.47 gram) of the original substance and the benzene extract contained matter soluble in cold acetone, which consisted chiefly of the oxide $\text{Si}_4\text{Ph}_8\text{O}$, the remainder being of a glue-like consistency.

Oxidation of the Silicohydrocarbon with Benzaldehyde.—In searching for a suitable solvent for the unsaturated compound, it was noticed that its solubility in boiling benzyl alcohol was greater than in boiling benzene, and that when cooled the solution deposited glistening prisms; when, however, the solution had been boiled during some time, it gave no deposit. Thus 0.25 gram of the compound dissolves readily in 2 c.c. of the boiling alcohol, and the cooled solution gives a relatively large crop of crystals; after having been boiled under a reflux condenser during four hours, the cold solution gives no deposit and on evaporation under reduced pressure leaves a glue which is completely soluble in cold acetone.

As this result might conceivably have been due to atmospheric oxidation, although there was throughout a layer of vapour above the solution, the silicohydrocarbon (0.25 gram) was treated with diphenyl (2 grams) under as nearly as possible the same conditions as before, except that the temperature was nearly 50° higher. At the end of six hours, a large proportion, at least, of the silicon compound remained unchanged, and it was not until after the solution had been boiled during a further period of about twenty-four hours

that decomposition seemed to be practically complete, the addition of 2 volumes of ether then giving no precipitate.

A solution of the silicohydrocarbon in boiling benzaldehyde, which gives a heavy deposit when it is cooled, ceases to do so when it has been boiled during only ten minutes, even when it is seeded with a crystal of the original substance and then diluted with ether, in which the compound is practically insoluble. This extraordinarily rapid action cannot be due to atmospheric oxidation and it is certainly not merely an effect of high temperature.

Other solvents containing combined oxygen have an action comparable with that of benzyl alcohol rather than with that of benzaldehyde as regards rapidity. Thus, in the case of acetophenone, the solution must be boiled during some hours before it ceases to give a deposit when it is cooled. The silicohydrocarbon is only very sparingly soluble in boiling paraldehyde, but on prolonged heating it passes into solution and the liquid on evaporation gives a syrup.

In all the above cases, after the expulsion of the solvent, there remained a yellow or brown oil, which was partly or completely soluble in cold acetone; the insoluble portion, if any, consisted of the rhomboidal oxide (m. p. 221—222°). From the acetone solution, by fractional precipitation with alcohol, crystalline deposits of the oxide $\text{Si}_4\text{Ph}_8\text{O}$ were usually obtained and the mother-liquors then gave viscous oils which possibly consisted of the condensation products of diphenylsilicanediol.

The action of amyl nitrite was tried in the hope of obtaining a better method for the preparation of the dioxide melting at 245—246° (*loc. cit.*) than by the action of boiling nitrobenzene, but the results were not satisfactory. When the silicohydrocarbon (1 gram) is covered with amyl nitrite (about 1½ c.c.) and the liquid heated at its boiling point during about three hours, some 60 per cent. of the original substance is recovered. The portion which is soluble in chloroform gives deposits of the rhomboidal oxide, and the mother-liquors then contain the oxide $\text{Si}_4\text{Ph}_8\text{O}$, but the presence of the dioxide melting at 245—246° could not be detected with certainty.

Action of Ozone.—The silicohydrocarbon (0.5 gram) was covered with carbon tetrachloride (20 c.c.), in which it is only very sparingly soluble, and dilute ozonised oxygen was passed into the liquid during about two hours with occasional warming; all the powder had then dissolved and on evaporating the solution there remained a brown pungent-smelling glue, soluble in hot acetone. The orange-coloured solution had a strongly acid reaction to litmus and gave a heavy precipitate with an aqueous solution of silver nitrate; when warmed with alcohol, it gradually afforded a crystalline deposit

which contained the rhomboidal oxide and the oxide $\text{Si}_4\text{Ph}_8\text{O}$, while the mother-liquors on evaporation gave a glue.

As, under the above conditions, the solvent had evidently taken part in the reaction, the silicohydrocarbon (0.5 gram) was covered with carbon disulphide (20 c.c.), in which it is practically insoluble, and ozonised oxygen was passed through the suspension during about two hours. The solution, filtered from unchanged substance, gave on evaporation a brown crystalline mass, from which the oxide $\text{Si}_4\text{Ph}_8\text{O}$ and the rhomboidal oxide were isolated; the mother-liquors gave a "glue" readily soluble in cold acetone and in benzene and also a gelatinous product miscible with acetone but quite insoluble in benzene, which is obtained from the silicohydrocarbon in very small quantities under the most varied conditions; this product is precipitated as a jelly when its acetone solution is treated with benzene and when free from solvent forms a resinous powder, which cannot be melted.

Action of Ethylene Dibromide.—The unsaturated silicon compound can be recrystallised from boiling ethylene dibromide, in which it is only sparingly soluble, but when the solution is boiled on a reflux apparatus during a few minutes only, a very small proportion, if any, of the original substance is deposited in the cold; after it has been boiled during about ten minutes, decomposition seems to be complete. The action of ethylene dibromide, therefore, appears to be almost if not quite as rapid as that of tetrachloroethane; the two reactions are also similar in type and not in any way due to atmospheric oxidation. Thus, when the cold ethylene dibromide solution which has been boiled is shaken with aqueous acetone, the aqueous liquid has an acid reaction and gives an immediate precipitate on the addition of an aqueous solution of silver nitrate. It must be concluded, therefore, that the silicon compound has been transformed into a dihalogen additive product, and in accordance with this view the oxide $\text{Si}_4\text{Ph}_8\text{O}$ can be isolated from the solution after hydrolysis.

The decomposition of the silicon compound in boiling bromobenzene solution takes place relatively so slowly that it is not comparable with the change just described; probably it is due to atmospheric oxidation because, when, after some six to eight hours, decomposition is practically complete, there is no evidence of the formation of a silicon halide. The product in this case seemed to be free from the rhomboidal oxide, but contained the dioxide melting at $245\text{--}246^\circ$, and probably also the oxide $\text{Si}_4\text{Ph}_8\text{O}$ together with some non-crystalline matter.

Phosphorus tribromide has a very rapid action on the silicohydrocarbon, and although a quickly prepared hot solution gives a

crystalline deposit when it is immediately cooled, there is none if it has been boiled during about ten minutes; when diluted with light petroleum and kept during some hours, the mixture gives a small crop of crystals which is soluble in boiling acetone; this solution then gives crystals of the oxide $\text{Si}_4\text{Ph}_8\text{O}$ and the mother-liquor contains the usual non-crystallisable matter. It is intended to study this reaction on a larger scale in order to ascertain what change is undergone by the phosphorus tribromide.

A saturated benzene solution of the silicon compound seems to be quite unchanged when it is boiled during seven or eight hours on a reflux apparatus in contact with a concentrated aqueous solution of hydrogen bromide. A crystalline precipitate is slowly formed owing to the evaporation of some of the benzene, and when the solution is finally cooled a further deposit is obtained. From a direct comparison of this substance with the original silicohydrocarbon, there was little doubt as to its identity with the latter.

The behaviour of the unsaturated silicon compound towards diphenylsilicon dichloride was examined in the hope of throwing light on the formation of some of the products of the action of sodium on the dichloride. In boiling toluene solution the dichloride seemed to be inactive, as practically the whole of the silicohydrocarbon could be recovered even after the solution had been boiled during four hours; in absence of a diluent, however, the boiling dichloride attacks the unsaturated compound with considerable rapidity, giving a "glue" from which crystals have not yet been isolated.

In order to prove that the changes described above are not temperature effects merely, and also because it was conceivable that at a high temperature the unsaturated might be partly converted into the saturated silicohydrocarbon, a small quantity of the former was heated just above its melting point (about 335°) during some twenty hours in an exhausted sealed tube; when cooled, the pale yellow liquid crystallised almost immediately and proved to be the unchanged compound, contaminated with only a very small proportion of non-crystalline matter.

The author desires to express his thanks to the Department of Scientific and Industrial Research which provided him with an assistant (Mr. J. E. Sands) without whose efficient help it would have been impossible to prepare the necessary material for this investigation.

UNIVERSITY COLLEGE, NOTTINGHAM.

[Received, August 21st, 1923.]

CCC.—*Organic Derivatives of Silicon. Part XXVIII.*
Octaphenyldiethylsilicotetrane.

By FREDERIC STANLEY KIPPING.

THE di-iodide obtained from the unsaturated silicohydrocarbon Si_4Ph_8 (Kipping and Sands, T., 1921, 119, 830) yields with magnesium ethyl bromide a very well-defined crystalline product. As this compound, ignited in oxygen, gives a residue free from carbon and is readily soluble in benzene, all the conditions are favourable for the accurate determination of its molecular formula; the results prove that it is an octaphenyldiethylsilicotetrane, $\text{Si}_4\text{Et}_2\text{Ph}_8$, and thus confirm the molecular formula assigned to the unsaturated silicohydrocarbon. The diethyl derivative, like the silicohydrocarbon Si_4Ph_8 , is decomposed when it is heated with piperidine and aqueous alkali and gives a hydrogen value (Kipping and Sands, *loc. cit.*, p. 849) corresponding closely with that calculated from the equation

In the solution thus obtained it is possible to prove the presence of diphenylsilicanediol and also that of a silicon compound (diphenylethylsilicol?) which is not diphenylsilicanediol or any of the four known condensation products of this diol. This fact is of very great importance, as it affords further evidence that the molecule of the unsaturated silicohydrocarbon as well as that of the saturated isomeride consists of four $-\text{SiPh}_2-$ groups. Both these silicohydrocarbons give a hydrogen value corresponding with that calculated from the equation

and it was suggested that if the molecule of either of these substances contained a $-\text{SiPh}_2$ group, the latter would occur as triphenylsilicol in the decomposition product (*loc. cit.*); the result obtained with the diethyl derivative shows that the failure to identify this silicol—a much better characterised compound than diphenylethylsilicol—among the decomposition products of the compounds Si_4Ph_8 proves that neither molecule contains a $-\text{SiPh}_2$ group.

Octaphenyldiethylsilicotetrane separates from various solvents, in the presence of moisture, in hydrated crystals; except for its much lower melting point, it resembles closely the saturated silicohydrocarbon Si_4Ph_8 and differs altogether from the unsaturated isomeride. It is, for example, very readily soluble in chloroform or benzene and is not attacked by iodine at the ordinary temper-

ature in petroleum solution; it is slowly oxidised when it is heated with acetic acid containing nitric acid.

Attempts to prepare decaphenylsilicotetrane by the action of magnesium phenyl bromide on the di-iodo-derivative were not successful. This failure apparently was not due to the formation of the unsaturated silicohydrocarbon,

as might have been the case, but to the non-occurrence of any reaction; a small proportion of the product, after treatment with aqueous solvents, could not be obtained in crystals, but most of it consisted of the oxide $\text{Si}_4\text{Ph}_8\text{O}$, produced, doubtless, by the hydrolysis of the unchanged di-iodide.

The fact that decaphenylsilicotetrane is not produced from the di-iodide under conditions similar to those which give a fair yield of octaphenyldiethylsilicotetrane may be attributed, in the author's opinion, to spatial considerations. The ethyl radicles may be pushed into the spaces occupied by the iodine atoms in the di-iodide, but the phenyl groups are too large and so no reaction occurs. The case is not quite parallel to that described by Schlenk and Mark in their experiments on pentaphenylethyl (*Ber.*, 1922, 55, [B], 2285), because it would seem that decaphenylbutane is actually produced by the action of sodiotriphenylmethane (2 mols.) on dichlorotetraphenylethane and then immediately undergoes decomposition or dissociation into pentaphenylethyl. It may be assumed, however, that decaphenylsilicobutane and decaphenylbutane are unstable for the same reason and that if a fragment of the latter containing tervalent carbon is capable of existence, the unsaturated silicohydrocarbon, Si_4Ph_8 , may be regarded as a fragment of decaphenylsilicobutane containing tervalent silicon.

The above results are in harmony with the views expressed in the previous communication. The formation of the unsaturated compound (but only with great difficulty) when the di-iodide is heated with sodium (Kipping and Sands, *loc. cit.*) would therefore appear to be due to a steric hindrance of the production of the closed-chain silicohydrocarbon, comparable with, but less effective than, that which seems to bar the existence of decaphenylsilicobutane.

EXPERIMENTAL.

Octaphenyldiethylsilicotetrane.—For the preparation of the di-iodide, a sample (about 5 grams) of a mixture of the unsaturated silicohydrocarbon (A) with the more sparingly soluble compound (C) was used (*loc. cit.*), since the separation of C by fractional crystallisation is rather wasteful, and also because treatment of such a mixture

with iodine is the best method of obtaining C from A. The mixture was partly dissolved and partly suspended in benzene and iodine was added from time to time until the whole of the unsaturated silicohydrocarbon had been converted into the di-iodide. In order to avoid exposure to moist air, the undissolved C was not separated by filtration, but the benzene solution was directly treated with an ethereal solution containing a large excess of magnesium ethyl bromide. After a short interval the ether and benzene were distilled on a water-bath and the residue was heated at about 160° in an oil-bath during about two hours. The cold product, treated first with water and then with dilute acetic acid, gave a pasty mass which was washed with dilute acid and then extracted with hot acetone. The solid residue was then treated with cold benzene, which dissolved everything except the compound C (about 0.5 gram). The benzene and acetone extracts gave on evaporation crystalline and oily deposits, respectively, and, in time, the latter afforded a considerable proportion of crystalline matter, which, when separated from the oil, was only sparingly soluble in cold acetone. The fractional crystallisation of the solid product from many different solvents failed for a long time to give any substance of constant melting point, except a very small proportion of the sparingly soluble rhomboidal oxide (m. p. 221°); all the other fractions had very indefinite melting points, ranging from about 220° up to 240° , and seemed from their appearance to be complex. It was noticed, however, that the solubility of some of the fractions in benzene and chloroform appeared to be diminished in the presence of water; this observation led to the discovery that one of the components of the mixture formed hydrated crystals, which, when grown slowly, could be distinguished under a lens or even with the naked eye. With the help of this knowledge, it was possible by continued fractional crystallisation from a mixture of chloroform and aqueous acetone to isolate about 1 gram of a compound melting at $253-254^{\circ}$. The colourless, crystalline matter which remained, after repeated crystallisations failed to give deposits containing any visible quantity of the diethyl derivative, had still a most indefinite melting point, but seemed to consist entirely of the oxide $\text{Si}_4\text{Ph}_8\text{O}$, produced no doubt by the hydrolysis of the unchanged di-iodide.

No explanation of the indefinite melting point of this oxide has yet been arrived at and it seems difficult to believe that a pure compound would behave in such a way; its identification by examination under the microscope is also not very satisfactory. A portion of the supposed oxide was therefore oxidised with nitric acid in glacial acetic acid solution; it behaved like the oxide $\text{Si}_4\text{Ph}_8\text{O}$, and gave a deposit which consisted of almost pure rhomboidal oxide,

$\text{Si}_4\text{Ph}_8\text{O}_2$. After the separation of the three crystalline substances named above and further fractional precipitation of the acetone solution with alcohol, there remained a product which was very readily soluble in cold acetone and in light petroleum (b. p. 20–80°), but only sparingly soluble in alcohol. This material was a colourless, brittle, resinous mass which was not a mere mixture of the condensation products of diphenylsilicanediol, since it evolved hydrogen on treatment with acetone and sodium hydroxide solution. Possibly it contained the compound $\text{SiPh}_2\text{Et}\cdot\text{SiPh}_2\cdot\text{SiPh}_2\cdot\text{SiPh}_2\cdot\text{OH}$ and the corresponding oxide, but hitherto neither of these substances has been isolated.

Octaphenyldiethylsilicotetranes separates from cold acetone containing water and a small proportion of chloroform in flat, transparent, rhomboidal plates which may be obtained large enough to be recognisable with the naked eye. These crystals become opaque at about 120° when heated quickly, and also, but much more slowly, at 100°. An air-dried sample lost 6.27 per cent. at 100° ($\text{Si}_4\text{Et}_2\text{Ph}_8\cdot 3\text{H}_2\text{O}$ requires $\text{H}_2\text{O} = 6.42$ per cent.). It is somewhat surprising that a silicohydrocarbon should crystallise with water [Found: for the anhydrous compound, $\text{C} = 78.9$; $\text{H} = 6.35$; $\text{Si} = 14.4$; M , in benzene solution (cryoscopic), = 682, 733. Calculated for $\text{Si}_4\text{Et}_2\text{Ph}_8$, $\text{C} = 79.2$; $\text{H} = 6.35$; $\text{Si} = 14.4$ per cent.; $M = 787.6$].

The anhydrous compound melts sharply at 253–254° and the melt solidifies at once when cooled.

Octaphenyldiethylsilicotetranes resembles the saturated silicohydrocarbon Si_4Ph_8 very closely in its behaviour towards solvents, but it is more soluble than the latter in hot acetone; it dissolves very readily in cold chloroform or benzene, but if drops of water are added to the solution the hydrated crystals are deposited from solutions which would not be saturated if dry. It is readily soluble in cold ether, from which it separates in flat, six-sided plates having the outline of a regular hexagon. These crystals do not become opaque when heated at 100° for five minutes. Octaphenyldiethylsilicotetranes is also readily soluble in cold petroleum (b. p. 100–120°), but only sparingly soluble in boiling alcohol and practically insoluble in hot acetic acid. In addition to the above-mentioned forms, it crystallises from ether, acetone, and alcohol in highly lustrous, oblique, six-sided prisms.

Action of Piperidine on Octaphenyldiethylsilicotetranes.—The diethyl derivative is not perceptibly changed when it is heated with a 5 per cent. aqueous solution of sodium hydroxide, but in the presence of acetone it is slowly attacked by the alkali with evolution of hydrogen (0.104 gram, heated with piperidine and sodium hydroxide

solution, gave, in less than thirty minutes, 8.86 c.c. of hydrogen at *N.T.P.* Hydrogen value = 85). This result agrees exactly with the value calculated from the equation given above. The piperidine solution from this decomposition was treated with excess of hydrochloric acid and the precipitated oil washed by decantation; it was then dissolved in aqueous acetone containing sodium hydroxide, and the solution warmed to hydrolyse the condensation products of diphenylsilicanediol. At the end of about one hour water was added, all the acetone evaporated, and the oily deposit separated by filtration, and washed with water. The aqueous alkaline filtrate gave a heavy precipitate of diphenylsilicanediol when acidified. The oil, warmed again with acetone and alkali, did not give any further quantity of the diol and was apparently free from the condensation products of diphenylsilicanediol. In order, if possible, to identify it, attempts were made to convert it into diphenylethylsilicyl oxide (Kipping and Marsden, *T.*, 1908, 93, 208), which melts at 65–66°, but crystals were not obtained.

This failure does not invalidate the argument which has been based on the results of the hydrolysis of the diethyl derivative, because various experiments have shown that the complete conversion of the compound into diphenylsilicanediol seems to be impossible; in this respect its behaviour is quite different from that of the oxide $\text{Si}_4\text{Ph}_8\text{O}$ (see below).

Attempts to Prepare Decaphenylsilicotetrane.—A benzene solution of the di-iodide which had been rapidly filtered from the substance C (see above) was treated with an ethereal solution of a very large excess of magnesium phenyl bromide and the mixture left overnight. As no magnesium salt had separated, the ether and benzene were evaporated and the residue was heated on the water-bath during two hours. At the end of this time the highly lustrous, acute rhomboidal crystals of the di-iodide were distinctly visible in the pasty mass and apparently no reaction had occurred. A further large excess of magnesium phenyl bromide was therefore added and after evaporating the ether, the mixture was heated first at 160° during about three hours and finally at about 180° during an hour.

The pasty product when cold was treated with water and extracted first with dilute acetic acid and then with acetone; there remained a grey powder which dissolved in boiling benzene, leaving a small proportion of mineral matter, principally silica. The colourless deposits obtained from the benzene solution were repeatedly systematically fractionated from various solvents, but every fraction from every solvent used had a most indefinite melting point, ranging from about 210–250°, and varying with the rate of heating. As it

seemed probable from this behaviour that all the fractions consisted of the oxide $\text{Si}_4\text{Ph}_8\text{O}$, representative samples were warmed with acetone and aqueous alkali until the evolution of hydrogen was at an end, and the acetone was then evaporated; all the aqueous alkaline solutions thus obtained gave a precipitate of diphenylsilicanediol with acetic acid and could not have contained any appreciable quantity of triphenylsilicol, which is practically insoluble in dilute aqueous alkalis. It must therefore be concluded that decaphenylsilicotetrasilane was not present in any of the fractions and that they consisted entirely of the oxide $\text{Si}_4\text{Ph}_8\text{O}$ formed by the hydrolysis of unchanged di-iodide. This conclusion was confirmed by oxidising a portion of the supposed oxide with nitric acid in acetic acid solution; it behaved in the expected manner and gave the rhomboidal oxide (m. p. $221-222^\circ$).

The cold acetone extract mentioned above was also examined on the bare possibility of finding traces of the decaphenyl compound. It contained, in addition to diphenyl, a small quantity of glue-like matter which seems to be an almost invariable product in experiments with these silicon compounds; this "glue" gave hydrogen with acetone and alkali, but as it was so readily soluble in acetone and even moderately soluble in hot alcohol, it could scarcely have contained any decaphenylsilicotetrasilane.

The unsaturated silicohydrocarbon used in this investigation was prepared by Mr. J. E. Sands, for whose efficient assistance the author is indebted to the Department of Scientific and Industrial Research.

CCCL.—Reduction Products of Hydroxyanthraquinones. Part III.

By ARNOLD BREARE and ARTHUR GEORGE PERKIN.

IN the continuation of investigations undertaken with the object of preparing, if possible, hydroxydianthraquinones and helianthrones from hydroxyanthranols and dianthranols, the anthranol derived from anthragallol was selected for experiment.* This compound, which was prepared by Liebermann (*Ber.*, 1888, 21, 444) by the reduction of anthragallol with tin and hydrochloric acid in presence of acetic acid, or less satisfactorily with zinc dust and ammonia, does not appear to have been further examined. It

* As it is uncertain whether this substance is the 1 : 2 : 3- or 2 : 3 : 4-trihydroxy-compound, it is referred to in this paper as "anthragallol anthranol."

was observed by this author that the brownish-yellow, alkaline solution of the anthranol on exposure to air rapidly became violet-coloured, and on acidification deposited violet flocks which could be crystallised from a mixture of benzene and alcohol. This product, which was unstable and suffered alteration on drying, appeared to have the formula $C_{14}H_{10}O_5$ and was possibly

tetrahydroxyanthranol, $C_6H_4 \begin{smallmatrix} \text{C(OH)} \\ \diagup \quad \diagdown \\ \text{C(OH)} \end{smallmatrix} C_6H(OH)_3$. A reinvesti-

gation of anthragallol anthranol has confirmed in general the statements of Liebermann, with the exception that his triacetyl compound is, in reality, the tetra-acetyl derivative. With ethereal diazomethane in excess, a dimethyl ether, insoluble in alkaline solutions, is mainly obtained, although in the more soluble viscous by-product the presence of some quantity of the trimethyl compound could be detected. Although further evidence is necessary, it is thus possible that anthragallol anthranol possesses the constitution (I) of 1 : 2 : 3-trihydroxy-9-anthrone

and differs from deoxyalizarin in containing a hydroxyl adjacent to the carbonyl group.

Ferric chloride in presence of acetic acid and alcohol converts the anthranol into the dianthrone, which, when acetylated in the presence of sulphuric acid or pyridine, gives, respectively, the hexa-acetoxydianthrone, or octa-acetylated dianthrone. With diazomethane in excess, the dianthrone gives some quantity of a tetramethyl compound, insoluble in alkalis, and in this respect resembles the anthranol.

Anthragallol anthranol solutions gradually darken at the boiling point, a change apparently due to oxidation, and when cold the brown, crystalline deposit frequently contains violet needles. By addition of benzoquinone to the hot acetic acid solution, preferably diluted with alcohol, a semi-solid mass of violet-black needles, probably this same compound, is formed, and this is soluble in alkali with a violet coloration. This compound, by a short treatment with stannous chloride and hydrochloric acid, is reconverted quantitatively into the anthranol, although when sulphurous acid is employed the dianthrone is produced. Moreover, as the dianthrone gives, with benzoquinone, the same violet-black substance, it seems evident that during its production from the anthranol an oxidation of the latter to dianthrone first occurs. This compound, here

termed anthragallol dianthronequinone, is somewhat unstable, being converted in boiling acetic acid solution into the dianthrone together with a brown, amorphous compound, self-oxidation* evidently occurring. Again, by boiling with water, similar decomposition occurs, a brown, amorphous substance, distinct from anthragallol and interspersed with colourless crystals of the dianthrone, being produced. By digesting a mixture of the dianthronequinone and anthragallol anthranol in boiling acetic acid, the dianthrone is produced. With *o*-phenylenediamine a quinoxaline has not been isolated, and, again, crystalline acetyl and methylated derivatives have not as yet been obtained from this quinone.

Of the formulæ $C_{28}H_{16}O_8$ and $C_{28}H_{14}O_8$ possible for anthragallol dianthronequinone, the former corresponds to hexahydroxydianthronequinone (II), but, on the other hand, the strong oxidising property of the quinone and its consequent instability scarcely support this view. That its formation arises from the pyrogallol nuclei of the dianthrone seems more likely, and the reaction is indeed probably analogous to that which occurs when pyrogallol itself is oxidised with benzoquinone or amyl nitrite (Perkin and Steven, T., 1896, 89, 802). The compound $C_6H_4O_3$ or $C_{12}H_8O_6$ thus produced in small amount, which, by boiling with water, gives purpurogallin, a result evidently of self-oxidation, appears to possess either the hydroxy-*o*-benzoquinone or corresponding peroxide structure.* Similar formulæ may also be applied to anthragallol dianthronequinone.

A study of the reduction of anthragallol dianthronequinone with phenylhydrazine according to Willstätter and Cramer's method (Ber., 1910, 43, 2776), although not fully convincing, gives some support to these formulæ. Thus, whereas in this manner dianthronequinone (for a specimen of which we are indebted to the kindness of Mr. E. de Barry Barnett) takes up at 150° four atoms of hydrogen, evidently with production of anthranol, the dianthronequinone at 110° gives evidence of requiring eight atoms.

There can be little doubt that the rapid air oxidation of alkaline anthragallol solutions observed by Liebermann (*loc. cit.*) results in

* The production of gossypetone from gossypetin by means of benzoquinone is evidently also due to a reaction of this character (T., 1913, 103, 650).

the first instance in the formation of anthragallol dianthronequinone. A repetition, however, of his experiments has indicated that this process is not under control, over-oxidation simultaneously occurring. The product, purified according to his method, is, moreover, scarcely crystalline, and as decomposition takes place on drying, it does not then possess a homogeneous character. A preparation of a similar type can be obtained by exposing the alkaline solution of anthragallol dianthronequinone to air for a short period.

Finally, it is of interest to note that in colour anthragallol dianthronequinone resembles the higher hydroxylated anthradiquinones recently studied by Dimroth and Hilcher (*Ber.*, 1921, 54, [B], 3060), more especially the bluish-violet 5:8-dihydroxy-1:4:9:10-, and the blue 5:8-dihydroxy-1:2:9:10-anthradiquinones.

A further study of anthragallol dianthronequinone and its decomposition products is in progress.

EXPERIMENTAL.

For preparing anthragallol anthranol in quantity the methods of Liebermann (*loc. cit.*) are hardly satisfactory, for in the one process very large amounts of glacial acetic acid are necessary, and in the other, air oxidation is liable simultaneously to occur. A method recently devised in this laboratory gives, however, excellent results.* Pure anthragallol (10 grams), suspended in sufficient of a solution of one part of stannous chloride in five parts of hydrochloric acid (33 per cent.), was digested at the boiling point for three hours, and the pale pink crystals were collected, the filtrate being reserved for a new operation. The product, a pale grey mass (10 grams),† which was pure enough for the purposes of this investigation, could be satisfactorily recrystallised, preferably from acetic acid, only when small amounts were taken and the operation was rapidly performed. It is thus deposited from acetic acid in yellow needles, although if the cooling is slow darkening occurs and the brownish-yellow, crystalline deposit contains needles of a violet colour (Found: C = 69.37; H = 4.15. Calc. for $C_{14}H_{10}O_5$, C = 69.4; H = 4.13 per cent.). When heated, it becomes violet at about 200°, possibly by the action of the alkali of the glass, and melts at 235°. Liebermann (*loc. cit.*) merely states that it is altered by heating, and gives

* This method, it has been found, is serviceable for the production of most anthranols, and its general application for this purpose will be described in a later communication.

† This, by washing with a small amount of acetone, yielded an almost colourless product.

no melting point. It gradually browns on exposure to light and is best kept in the dark.

As by the action of boiling acetic anhydride dark-coloured alteration products are obtained, the acetylation was carried out in the cold by Fischer and Bergmann's method (*Ber.*, 1918, 51, 1797). After keeping for three days, colourless crystals had separated which, by recrystallisation from alcohol and acetic acid, were obtained as short, flat needles, m. p. 200—202° (Found: C = 64.12; H = 4.40; acetic acid = 59.04. $C_{22}H_{18}O_8$ requires C = 64.39; H = 4.40; acetic acid = 59.02 per cent.). This *tetra-acetyl* compound is evidently identical with the triacetyl derivative of Liebermann, which he describes as melting at 202—203°.

By rapid hydrolysis with hydrochloric acid in the presence of acetic acid of small amounts of the acetyl compound, the regenerated anthranol was obtained as pale brown needles melting at 234—235°.

When anthragallol anthranol is added to a boiling mixture of equal parts of acetic anhydride and acetic acid, an energetic reaction occurs with the separation of crystals. These, by recrystallisation from much acetic acid, were obtained as colourless leaflets, which melted with discoloration at 239—240°, and evidently consisted of the *monoacetyl* compound (Found: C = 67.22; H = 4.30; acetic acid = 21.9. $C_{16}H_{12}O_5$ requires C = 67.60; H = 4.23; acetic acid = 21.13 per cent.). If in the preceding operation a larger volume of acetic anhydride is employed, crystals are only gradually deposited on keeping. By recrystallisation from a mixture of acetic acid and alcohol, these formed bright yellow needles which sintered at 185—187° and melted at 194° (Found: acetic acid = 36.1. $C_{18}H_{14}O_6$ requires acetic acid = 35.3 per cent.). This compound consists, therefore, mainly at least of *diacetyl anthragallol anthranol* (or *anthrone*).

An attempted methylation of the anthranol by means of methyl sulphate being unsuccessful, a suspension (2 grams) in pure ether was treated with diazomethane prepared from 18 c.c. of nitroso-methylurethane. After keeping over-night, a mixture of crystals and light flocculent matter had separated, and the latter was removed by decantation. The crystals were washed first with ether and then with dilute alkali (Found: C = 71.11; H = 5.12; CH_3 = 10.93. $C_{18}H_{14}O_4$ requires C = 71.11; H = 5.18; CH_3 = 11.11 per cent.). The *dimethyl ether* consists of stout, pale yellow needles which become red at 220° and melt at 223—225°. From its hot solution in benzene, in which it is sparingly soluble, it separates on cooling, both in the flocculent and the crystalline condition.

The ethereal mother-liquor on evaporation yielded a viscid mass,

which has not been obtained in the crystalline condition. On cautious oxidation with chromic acid in boiling acetic acid solution, subsequently diluting with hot water, yellow needles of anthragallol trimethyl ether, melting at 168–170°, separated, indicating the presence of the anthrone or anthranol trimethyl ether in the original product.

Anthragallol Dianthrone.—The anthranol (1 gram), dissolved in a boiling mixture of acetic acid (7 c.c.) and alcohol (7 c.c.), was treated with a solution of commercial ferric chloride (1 gram) in acetic acid (4 c.c.). A precipitate consisting of minute, yellow prisms quickly separated, and this was collected while the mixture was still warm, washed with alcohol and acetic acid, and finally with benzene. The yield averaged 56 per cent. As in boiling solvents this product, similarly to the anthranol, suffers discoloration, it was dissolved in twice its weight of cold pyridine (dissolution occurs with evolution of heat), the liquid filtered, and the filtrate diluted with alcohol (15 c.c.). Fine, almost colourless plates were deposited, and these, which contained pyridine, possibly of crystallisation, were removed from the magenta-coloured mother-liquor. On solution in hot acetone and boiling, a yellow, crystalline precipitate, free from pyridine, quickly separated, which was collected and washed with acetone (Found: C = 69.54; H = 4.15. $C_{28}H_{18}O_6$ requires C = 69.7; H = 3.78 per cent.). Anthragallol dianthrone is sparingly soluble in acetone and acetic acid (distinction from the anthranol) and when heated becomes violet at 230°, and melts at 258–260°. Its alkaline solutions on exposure to air develop a violet tint.

Octa-acetyl Anthragallol Dianthranol.—A mixture of the dianthrone (0.9 gram), pyridine (2.7 c.c.), and acetic anhydride (3.1 c.c.) was gently warmed to effect solution. On keeping, small prisms soon commenced to separate and these were collected and recrystallised from a large volume of acetone. The substance melted above 300° (Found: C = 64.17; H = 4.12; acetic acid = 59.04. $C_{44}H_{34}O_{16}$ requires C = 64.54; H = 4.15; acetic acid = 58.7 per cent.).

Hexa-acetyl Anthragallol Dianthrone.—The acetone mother-liquor from which the octa-acetyl compound had been deposited was partly evaporated and any crystals of the same compound, which separated, were removed. The filtrate on concentration and dilution with alcohol gave a deposit of prismatic needles which, after recrystallisation from a little acetone, melted at 264–266°. This second acetyl compound was more readily obtained by adding a trace of sulphuric acid to a suspension of anthragallol dianthrone in a little acetic anhydride, and gently warming until a clear liquid was produced. On keeping, crystals separated which, after solution

in acetic anhydride and separation therefrom by addition of alcohol, became red at 250° and melted at $264\text{--}266^{\circ}$ (Found: C = 65.48; H = 4.7; acetic acid = 49.16. $\text{C}_{40}\text{H}_{30}\text{O}_{14}$ requires C = 65.4; H = 4.08; acetic acid = 49.03 per cent.). This acetyl compound again is the main product when the pyridine solution of the dianthrone is treated with excess of acetic anhydride in the cold, only a trace of the octa-acetyl compound being thus produced. When the hexa-acetyl compound is digested with boiling acetic anhydride and a trace of pyridine, crystals of the octa-acetyl compound are rapidly deposited.

An attempt to determine the molecular weight of the tetra-acetyl compound in freezing naphthalene was unsuccessful, the acetyl compound separating simultaneously with the naphthalene.

Tetramethyl anthragallol dianthrone was obtained by treating the dianthrone, suspended in ether, with an excess of diazomethane. The crystalline product was collected, washed with dilute alkali and then with acetone. It could not be satisfactorily recrystallised from the usual solvents, and although from dimethylaniline it separated in pale yellow prisms, melting at $233\text{--}235^{\circ}$, much loss occurred and the mother-liquor possessed a deep red colour (Found: C = 71.13; H = 4.88; CH_3 = 11.57. $\text{C}_{34}\text{H}_{30}\text{O}_8$ requires C = 71.5; H = 5.2; CH_3 = 11.15 per cent.). The ethereal filtrate contained a viscid product, not susceptible of crystallisation. That the hexamethyl ether was here present was evident from the fact that when it was oxidised with chromic acid in acetic acid solution some quantity of anthragallol trimethyl ether, melting at $168\text{--}170^{\circ}$, was produced.

Anthragallol Dianthronequinone.—As attempts to prepare the so-called hydroxyanthranol from anthragallol anthranol by Liebermann's alkaline air oxidation method (see introduction) gave no definite product, the employment of benzoquinone as an oxidising agent was studied. The anthranol (1 gram), suspended in acetic acid (10 c.c.) and alcohol (10 c.c.), was gently warmed and benzoquinone (1 gram) added, in two portions during a few seconds. An energetic reaction thus occurred with production of a reddish-violet liquid, which soon became semi-solid, owing to the separation of crystals. When cold, these were collected,* washed with a trace of alcohol and acetic acid, and finally with benzene. The product (0.55 gram) was recrystallised from toluene (Found: C = 69.82; H = 3.5 per cent.). It consisted of fine violet-black needles, m. p. $206\text{--}208^{\circ}$, soluble in concentrated sulphuric acid with a red violet

* On saturating the deep red filtrate with sulphurous acid and keeping, a crystalline precipitate consisting of anthragallol anthranol admixed with dianthrone separated.

coloration. Its alkaline solution, which possesses the same tint, quickly becomes brown on warming.*

Attempts to prepare a definite acetyl derivative have hitherto failed, Fischer's method yielding a brown, amorphous product.

Suspended in a warm solution of stannous chloride in hydrochloric acid, the violet crystals (0.8475 gram) became of a yellowish-brown colour and then weighed 0.8440 gram. This proved to be anthragallol anthranol and was identified by its melting point, 234–236°, and that of its monoacetyl derivative, 236–238°.

A suspension of anthragallol dianthronequinone in a small amount of 50 per cent. alcohol was treated with a fine stream of sulphur dioxide; the violet crystals, after two days, were thus replaced by minute, dull yellow needles (Found: C = 69.82; H = 3.96. $C_{28}H_{18}O_6$ requires C = 69.7; H = 3.78 per cent.). This compound, which had the properties of anthragallol dianthrone, by acetylation with pyridine and acetic anhydride according to Fischer's method, gave octa-acetyl anthragallol dianthranol, m. p. above 300°, and a small amount of the hexa-acetyl dianthrone, m. p. 264–266°.

When equal parts of anthragallol anthranol and anthragallol dianthronequinone were suspended in alcohol and acetic acid, and the mixture was boiled, the solution became reddish-brown and a finely divided, crystalline precipitate of the dianthrone separated. The anthranol was thus oxidised and the quinone simultaneously reduced to the dianthrone.

Although anthragallol dianthronequinone can be crystallised, in small amounts, from acetic acid and alcohol if the operation is rapidly performed, a considerable loss occurs, whereas if its deep violet saturated solution in acetic acid is boiled for a few minutes the colour becomes pale red. On keeping over-night, yellow crystals separate which melt at 258–260° and consist of anthragallol dianthrone. The acetic acid filtrate contains mainly a brown, amorphous compound, the nature of which has not yet been ascertained.

As the quinone can thus be reduced to the dianthrone, so can the dianthrone, by oxidation with benzoquinone, be reconverted into the quinone. The operation was carried out in the same manner as with the anthranol, a somewhat longer digestion, however, being required to effect complete conversion. The violet needles melted at 206–208° (Found: C = 70.1; H = 3.31. Calc.,

* In case an excess of quinone is employed and the boiling is prolonged, a violet, crystalline powder, consisting mainly of minute needles, is deposited. This, although possessing the same elementary composition, differs from the anthragallol dianthronequinone in that it does not melt below 275°, is more sparingly soluble in acetic acid, and dissolves in sulphuric acid with a maroon colour (Found: C = 70.1; H = 3.31 per cent.).

C = 70.29; H = 2.93 per cent.). Anthragallol dianthronequinone has the properties of a strong dye-stuff; the following shades were obtained on mordanted wool.

	Cr.	Al.	Sn.	Fe.
Quinone	Deep maroon.	Deep bluish-maroon.	Pale dull brown.	Deep black.
Anthragallol	Brown.	Reddish-maroon.	Brownish-orange.	Deep brown.

As, however, on boiling with water the quinone is gradually decomposed with separation of crystals of the dianthrone and a reddish-brown, amorphous compound, soluble in alkali with a brown coloration, which is probably identical with that obtained as described above by means of boiling acetic acid, the dyeing property must be ascribed, not to the quinone itself, but to the latter compound formed from it. As shown above, the shades obtained differ considerably from those given by anthragallol.

In order to obtain some further insight into the constitution of anthragallol dianthronequinone, a determination of the amount of nitrogen which is evolved by the action of phenylhydrazine, according to Willstätter's method (*loc. cit.*), was studied, the behaviour of dianthraquinone in this respect, however, being examined first. As a result, at 150–180°, 15.1 per cent. of nitrogen was evolved from the latter, whereas the theoretical percentage for its conversion into anthranol, which requires four atoms of hydrogen, is 14.6.

From the anthragallol dianthronequinone at 110° 17.8 per cent. of nitrogen is evolved, whereas in case its reduction to the anthranol required six atoms of hydrogen the theoretical amount would be 17.6 per cent. Such an amount of nitrogen would thus correspond either with a di-ortho-quinone or di-superoxide formula (II and III).

Although this result is possibly correct, it was noted at the conclusion of the latter operation that the residual phenylhydrazine solution possessed a brown colour, whilst in the case of the dianthraquinone it had a clear yellow tint. Again, although nitrogen evolution came to an end at 110°, on further heating to 150° gas was steadily evolved which filled the burette and for the evolution of which no theoretical explanation, based on the constitution of the quinone, seems possible. A second experiment gave a similar result, and it can only be inferred that some catalytic action was in progress at this higher temperature.

We are indebted to the Chemical Society for a grant which was in part employed for the purposes of this research.

CCCII.—*Application of the Grignard Reaction to some Acetylenic Compounds. Part I. Preparation of Diacetylenic Glycols.*

By FORSYTH JAMES WILSON and WILLIAM MCNINCH HYSLOP.

BEFORE dealing with the subject of diacetylenic glycols, we wish to record in this communication some observations regarding the action of the Grignard reagent on certain acetylenic compounds which we have been studying for some time.

It has been shown by Kohler and his collaborators that compounds containing a conjugated system frequently react abnormally with the Grignard reagent, addition taking place in the 1:4-position. For example, Kohler and Heritage (*Amer. Chem. J.*, 1905, **33**, 21) obtained methyl $\beta\beta$ -diphenylpropionate and diphenylpropionophenone by the interaction of methyl cinnamate and magnesium phenyl bromide; by varying the experimental conditions, the same authors (*ibid.*, 1905, **34**, 568) obtained other more complex products from the same reactants, but the carbinol, which would be the normal product, was not formed. On the other hand, it was found that the reaction between methyl cinnamate and magnesium methyl iodide proceeded normally, yielding styryldimethylcarbinol; by varying the conditions, some methyl styryl ketone was also produced (*ibid.*, 1905, **33**, 21).

For comparison, we have investigated the interaction of ethyl phenylpropiolate, as a type of acetylenic compound, with magnesium methyl iodide and with magnesium phenyl bromide under different conditions and have found that the reaction proceeded normally with the formation of the carbinol.

With magnesium methyl iodide the reaction took place as follows, $\text{CPh:C}\cdot\text{CO}_2\text{Et} + 2\text{MgMeI} \rightarrow \text{CPh:C}\cdot\text{CMe}_2\cdot\text{OMgI} \rightarrow \text{CPh:C}\cdot\text{CMe}_2\cdot\text{OH}$, giving α -phenyl- γ -methyl- Δ^4 -butinene- γ -ol, already prepared by Skosarewski (*J. Russ. Phys. Chem. Soc.*, 1900, **32**, 652). Similarly, magnesium phenyl bromide gave the carbinol $\text{CPh:C}\cdot\text{CPh}_2\cdot\text{OH}$, $\alpha\gamma$ -triphenyl- Δ^4 -propinene- γ -ol, already prepared by Nef (*Annalen*, 1899, **308**, 282).

Some further experiments with phenylpropionic acid derivatives were carried out. Zalkind and Beburischwili (*Ber.*, 1909, **42**, 4500) found that anhydrous sodium acetate or propionate reacted with the Grignard reagent to give a ketone, although in small yield; thus sodium acetate and magnesium phenyl bromide gave acetophenone. We have found that anhydrous sodium phenylpropiolate and magnesium methyl iodide gave a small yield of

phenylacetylenyl methyl ketone, but with magnesium phenyl bromide no ketone was formed.

It was observed by Béis (*Compt. rend.*, 1903, **137**, 575) that ketones were produced from the Grignard reagent and amides. We have found, however, that phenylpropionamide and magnesium methyl iodide gave phenylpropionitrile, the action being one of dehydration: $\text{PhC}\equiv\text{C}\cdot\text{CO}\cdot\text{NH}_2 \rightarrow \text{PhC}\equiv\text{C}\cdot\text{CN}$. The yield of nitrile was about 20 per cent., the remainder of the amide being recovered unchanged. With magnesium phenyl bromide, only traces of the nitrile were produced. For comparison we carried out a reaction between magnesium methyl iodide and cinnamamide and dihydrocinnamamide, respectively, and again found that the nitrile was formed in both cases. The production of a nitrile in this way does not seem to have been previously recorded; in these cases no ketone was produced.

The action of diketones upon the Grignard reagent, whereby ditertiary glycols are produced, has been investigated chiefly by Zelinsky (*Ber.*, 1902, **35**, 2138) and by Acree (*Ber.*, 1904, **37**, 2753). It has also been shown by Iocitsch (*J. Russ. Phys. Chem. Soc.*, 1902, **34**, 242; 1903, **35**, 430, 1269; 1906, **38**, 656) that dimagnesium acetylenyl dibromide reacted with aldehydes and ketones to give acetylenic glycols according to the general scheme $\text{BrMgC}\equiv\text{CMgBr} + 2\text{R}\cdot\text{CO}\cdot\text{R}' \rightarrow \text{HO}\cdot\text{CRR}'\cdot\text{C}\equiv\text{C}\cdot\text{CRR}'\cdot\text{OH}$. Dupont (*Compt. rend.*, 1909, **149**, 138; 1910, **150**, 1121; 1914, **158**, 714) pointed out that a glycol of this type, containing two asymmetric carbon atoms, should occur in *meso*- and *racemic* modifications, and he in fact showed that many of the glycols prepared by Iocitsch were mixtures of the two stereoisomerides.

With the object of investigating diacetylenic glycols, we were led to prepare these from diketones and magnesium phenylacetylenyl bromide. The latter was found to react with diacetyl according to the scheme,

$\text{MeCO}\cdot\text{COMe} + 2\text{CPh}\equiv\text{C}\cdot\text{MgBr} \rightarrow \text{CPh}\equiv\text{C}\cdot\text{CMe}(\text{OH})\cdot\text{CMe}(\text{OH})\cdot\text{C}\equiv\text{CPh}$,
yielding the diacetylenic glycol, $\alpha\zeta$ -diphenyl- $\gamma\delta$ -dimethyl- $\Delta^{8,9}$ -hexadiene- $\gamma\delta$ -diol, which, containing as it does two asymmetric carbon atoms, was obtained in the two stereoisomeric forms by fractional recrystallisation from a mixture of chloroform and light petroleum; the chief product melted at $117\text{--}117.5^\circ$, the stereoisomeride, melting at $125\text{--}126^\circ$, was present in only small amount. Similarly, from acetonylacetone and magnesium phenylacetylenyl bromide we obtained the two stereoisomeric modifications of the diacetylenic glycol, $\text{CPh}\equiv\text{C}\cdot\text{CMe}(\text{OH})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CMe}(\text{OH})\cdot\text{C}\equiv\text{CPh}$, $\alpha\theta$ -diphenyl- $\gamma\zeta$ -dimethyl- $\Delta^{8,9}$ -octadiene- $\gamma\zeta$ -diol, which were separated by fractional recrystallisation from a mixture of acetone and light petroleum.

In this case the higher-melting stereoisomeride (m. p. 106–107°) predominated, the other constituent, melting at 87–89°, being present in only very small amount.

Experiments with acetylacetone and magnesium phenylacetyl-enyl bromide gave unaltered diketone, no glycol being formed, the acetylacetone evidently reacting in the enolic form as already observed in similar cases by Zelinsky (*loc. cit.*) and by Bhagvat and Sudborough (*J. Ind. Inst. Sci.*, 1919, 2, 187).

We intend to continue this work, particularly with regard to diacetylenic polyhydric alcohols.

EXPERIMENTAL.

Ethyl Phenylpropionate and Magnesium Methyl Iodide.—An ethereal solution of 5 grams of the ester (1 mol.) was added drop by drop and with constant stirring to an ethereal solution of magnesium methyl iodide (2 mols.) cooled in ice and salt. A heavy, brown oil was formed. After standing over-night, the reaction mixture was shaken with crushed ice, acidified with dilute hydrochloric acid, and then extracted with ether. After drying over sodium sulphate, the ethereal solution was evaporated in a current of dry air; the residue solidified on cooling in an ice-salt mixture. After being pressed on porous tile to remove excess of ethyl phenylpropionate, it was obtained in white crystals melting at 53° and possessing an odour of rose-oil. Its identity with α -phenyl- γ -methyl- Δ^4 -butinene- γ -ol was proved by a mixed melting-point determination, using a specimen of the carbinol prepared by Skosarewski's method (*loc. cit.*).

The procedure was varied by carrying out the reaction in the heat, by using equimolecular quantities of the reactants, and by adding the Grignard reagent to the ester; in all cases the only product was the carbinol. Sometimes it was more convenient to isolate the carbinol by distillation; it boiled at 96°/1.5 mm., and ethyl phenylpropionate boiled at 104°/1.5 mm.

Ethyl Phenylpropionate and Magnesium Phenyl Bromide.—This reaction was carried out exactly as in the first of the previous cases, the proportions of the reactants being 1 mol. of ester of 2 mols. of magnesium phenyl bromide. After removal of the ether in a current of dry air, the solid residue was washed with light petroleum and recrystallised from a mixture of benzene and light petroleum; the product separated in needles melting at 80–81° and was identical with $\alpha\gamma\gamma$ -triphenyl- Δ^4 -propinene- γ -ol prepared by Nef (*loc. cit.*) as shown by a mixed melting-point determination.

Variations in the procedure and in the proportions of the reactants led to the same result. Occasionally it was found convenient to isolate the carbinol by distillation; it boiled at 220° (approx.)/1 mm.

Sodium Phenylpropiolate and Magnesium Methyl Iodide.—Ten grams of anhydrous powdered sodium phenylpropiolate were added with constant stirring to an ice-cooled ethereal solution of magnesium methyl iodide prepared from 9 grams of methyl iodide. The mixture was kept in ice over-night, crushed ice added, and the ethereal solution separated, dried over sodium sulphate, and evaporated in a current of dry air. The small residue of yellow oil distilled at $117^{\circ}/14$ mm., in agreement with the value given by Nef (*loc. cit.*) for phenylacetylenyl methyl ketone. It slowly absorbed iodine in ethereal solution and gave the acetylphenylacetylene di-iodide, melting at 102° , described by Nef.

The experiment was repeated using magnesium phenyl bromide, but benzoylphenylacetylene was not obtained.

Phenylpropiolamide and Magnesium Methyl Iodide.—An ethereal suspension of 9 grams (1 mol.) of the amide, prepared by the method of Philippi and Spenner (*Monatsh.*, 1915, **36**, 108), was added gradually with constant stirring to an ice-cold ethereal solution of magnesium methyl iodide (2 mols.), and the solution was then boiled for ten hours with constant stirring, when a dark brown, viscous oil separated. Crushed ice was added, then iced dilute sulphuric acid, the mixture was extracted with ether, and the ethereal solution, after being washed with water and dried, was evaporated in a current of dry air. The crystalline residue was washed with a little carbon tetrachloride and the insoluble phenylpropiolamide filtered off. The filtrate on evaporation gave large transparent crystals possessing an odour of cinnamon and having a very irritating effect on the eyes; the substance was recrystallised from dilute alcohol, from which it separated in colourless leaflets melting at $38-40^{\circ}$ which were very soluble in carbon tetrachloride, alcohol, ether, benzene, or light petroleum, but insoluble in water. From these properties the substance was evidently phenylpropiolonitrile, already prepared by Moureu and Delange (*Comp. rend.*, 1906, **142**, 213) and by Claisen (*Ber.*, 1903, **36**, 3671). No analysis of this nitrile appears to be given in the literature; owing to the relative ease with which it volatilises, the Dumas method was not satisfactory and the analysis was performed by the Kjeldahl method (Found: N = 10.91. Calc., N = 11.02 per cent.). The yield was about 20 per cent. of the theoretical.

The reaction between phenylpropiolamide and magnesium phenyl bromide was carried out in an exactly similar manner, but only traces of the nitrile were found, most of the amide being recovered unchanged.

Cinnamamide and Magnesium Methyl Iodide.—This reaction was carried out as in the previous case, the magnesium derivative being

a green, viscous oil. Unaltered amide was removed by treatment with ether, in which it was insoluble; the ethereal solution on evaporation in a current of dry air gave a yellow oil which distilled at 170—172°/60 mm. or at 257—258° at atmospheric pressure. On cooling in ice, it solidified to a crystalline mass melting at 18° and possessing a pleasant odour and a very sweet taste. Boiling concentrated hydrochloric acid converted the substance into cinnamic acid; it was evidently cinnamionitrile. The boiling point agreed with the value given in the literature, but the melting point found by us is higher than the value recorded (11°) (Found: N = 10.74. Calc., N = 10.85 per cent.). The yield was 30 per cent. of the theoretical.

β-Phenylpropionamide and Magnesium Methyl Iodide.—The amide was prepared by Hofmann's method (Ber., 1885, 18, 2740). The reaction was carried out in the usual way; unaltered amide was removed by treatment with carbon tetrachloride, in which it was insoluble. The carbon tetrachloride solution was evaporated and the residual oil distilled at 128°/15 mm. or at 246—248° at atmospheric pressure; the distillate solidified on cooling in ice. The substance was evidently β-phenylpropiononitrile; boiling concentrated hydrochloric acid converted it into β-phenylpropionic acid (Found: N = 10.51. Calc., N = 10.68 per cent.). Yield, about 45 per cent. of the theoretical.

Diacetyl and Magnesium Phenylacetylenyl Bromide.—8.2 Grams of phenylacetylene were added to an ethereal solution of magnesium ethyl bromide (prepared from 8.7 grams of ethyl bromide) and the solution was boiled for four hours. The solution of the magnesium phenylacetylenyl bromide (2 mols.) so prepared was cooled in ice and salt and 3.4 grams (1 mol.) of diacetyl, dissolved in ether, were added drop by drop with constant stirring. A yellow precipitate was produced. The mixture, after standing in ice for three days, was treated with crushed ice, acidified with iced dilute sulphuric acid, and then extracted with ether. The ethereal solution after being dried, gave on evaporation in a current of dry air a solid residue from which excess of phenylacetylene was removed by washing with carbon tetrachloride. The product, which was evidently a mixture, was fractionally recrystallised from a mixture of chloroform and low-boiling light petroleum, which effected a separation into the two stereoisomeric modifications (referred to below as α and β) of the glycol, αζ-diphenyl-γδ-dimethyl-Δ^{ac}-hexadi-*inene*-γδ-diol.

α-Modification.—This crystallised from alcohol in small crystals, apparently rhombohedra, which melted at 117—117.5°, and were very soluble in alcohol, ether, chloroform, benzene, or acetone,

sparingly soluble in cold carbon tetrachloride, and insoluble in light petroleum.

It gave a reddish-brown solution in concentrated sulphuric acid which became greenish-yellow on dilution. Yield 5.3 grams (Found: C = 82.66, 82.50; H = 6.24, 6.16. $C_{20}H_{18}O_2$ requires C = 82.75; H = 6.21 per cent.). The *diacetyl* derivative was obtained by boiling the diol for an hour with acetic anhydride and a little anhydrous sodium acetate, removing the excess of acetic anhydride by heating in a vacuum, and extracting with chloroform, from which the diacetate was deposited in long prisms melting at 153–154° (Found: C = 76.93; H = 6.09. $C_{24}H_{22}O_4$ requires C = 77.0; H = 5.88 per cent.).

β-Modification.—This separated from a mixture of chloroform and light petroleum in long prisms melting at 125–126°; the yield was only 0.4 gram. With concentrated sulphuric acid, it gave a deep red solution which became greenish-yellow on dilution (Found: C = 82.56; H = 6.31. $C_{20}H_{18}O_2$ requires C = 82.75; H = 6.21 per cent.).

Acetonylacetone and Magnesium Phenylacetylenyl Bromide.—This reaction was carried out as in the previous case, using 6.8 grams of phenylacetylene and 3.8 grams of acetonylacetone; the magnesium derivative was deposited as a white precipitate. After standing in ice over-night, the reaction mixture was worked up as before. The solid product, after being washed with a little carbon tetrachloride to remove phenylacetylene, was evidently a mixture; repeated fractional crystallisation from a mixture of acetone and low-boiling light petroleum ultimately separated it into the two stereoisomeric modifications (referred to below as α and β) of the glycol, *α,β-diphenyl-γ,γ-dimethyl-Δ⁸-octadi-inene-γ,γ-diol*.

α-Modification.—This formed colourless, hexagonal plates melting at 106–107°, which were very soluble in alcohol, ether, chloroform, acetone, or benzene, sparingly soluble in cold carbon tetrachloride, and very sparingly soluble in carbon disulphide or light petroleum. With concentrated sulphuric acid, it gave a deep brown solution which became colourless on dilution. Yield, 6 grams (Found: C = 82.77, 82.60; H = 7.38, 7.03. $C_{22}H_{22}O_2$ requires C = 82.97; H = 6.98 per cent.). The *diacetyl* derivative, prepared as in the previous case, melted at 87° after recrystallisation from alcohol (Found: C = 77.68; H = 6.31. $C_{26}H_{26}O_4$ requires C = 77.61; H = 6.47 per cent.).

β-Modification.—This formed colourless needles melting at 87–89°; the yield was only about 0.2 gram (Found: C = 82.52; H = 7.23. $C_{22}H_{22}O_2$ requires C = 82.97; H = 6.98 per cent.).

A reaction, carried out in the usual way between acetylacetone

and magnesium phenylacetylenyl bromide, gave a yellow oil which proved to be a mixture of acetylacetone and phenylacetylene; no glycol could be detected. The action of magnesium phenylacetylenyl bromide on benzil and on the triketone tribenzoylphenylmethane, prepared by the method of Meisenheimer and Weibezahn (*Ber.*, 1921, **54**, [B], 3195), did not give satisfactory results, considerable resinification taking place: in the latter case a very small quantity of a crystalline product, apparently a mixture, was isolated from the resin.

In conclusion, we wish to express our thanks to the Department of Scientific and Industrial Research for a maintenance grant which has enabled one of us (W. M. H.) to take part in this investigation. We desire also to thank the Carnegie Trust for the Universities of Scotland for a research grant which has partly defrayed the expenses of this work.

CCCIH.—*The Short-lived Radioactive Products of Uranium.*

By WILLIAM GEORGE GUY and ALEXANDER SMITH RUSSELL.

THE work to be described was undertaken to confirm or disprove the existence of the new radioactive product uranium-Z (symbol U-Z), announced by Hahn (*Ber.*, 1921, **54**, [B], 1131), and to ascertain its relation to the main uranium disintegration series. During this work an opportunity occurred to measure the equilibrium ratio of uranium-Y to uranium-X, and to redetermine the half-value periods of uranium-Y and uranium-X₂, so these determinations also have been carried out. Before the completion of our work, a second paper was published by Hahn (*Z. physikal. Chem.*, 1923, **103**, 461) confirming and amplifying his earlier work, and anticipating our results in a striking way. Since our work is independent, and is the first to confirm Hahn's important result that uranium-X undergoes a dual disintegration with the expulsion in both cases of a β -particle, an account of it is given below.

In his first paper, Hahn showed that uranium-Z was present always in a very small amount (about 0.2 per cent.) in a solution of uranium-X, that it was an isotope of proto-actinium, and that

* A preliminary account of part of this work appeared in *Nature*, 1923, **121**, 703.

its half-value period was 6·7 hours. It is with these data that we began our work.

Separation of Uranium-X.—The methods of separating the supposed parent substance of uranium-Z, uranium-X, from large quantities of uranium salts are all based on the original work of Crookes on uranium-X (*Proc. Roy. Soc.*, 1900, A, 66, 409). This separation is customarily effected in two stages :

(1) Uranium-X is concentrated in a solution of a uranyl salt.

(2) Uranium-X is then completely separated from the uranyl salt.

Under (1) have been described :

(a) Crookes's method as employed by Soddy and Russell (*Phil. Mag.*, 1909, [vi], 18, 620) of successive crystallisations of uranyl nitrate, whereby uranium-X is concentrated in the mother-liquor.

(b) Crookes's method as employed by Piccard (*Arch. Sci. phys. nat.*, 1917, [iv], 44, 161) of dissolving uranyl nitrate in ether, adding a few c.c. of water, and separating the aqueous layer containing the greater part of the uranium-X.

We have found the latter method much the better. It is more convenient, quicker, and nearly quantitative. * From 4 kilos. of uranyl nitrate we have obtained as much as 98 per cent. of the total uranium-X associated with only 10 grams of uranyl nitrate in the aqueous layer.

Under (2) have been described methods which depend : (a) upon the adsorption of uranium-X by ferric hydroxide, barium sulphate, lamp-black, and other substances; (b) upon the use of thorium as an isotope of uranium-X or of cerium and lanthanum as quasi-isotopes.

Most workers have found the methods under (b) more efficient than those under (a), and this, too, is our experience. A possible disadvantage of using thorium in effecting a separation is its radioactivity. Because of this, Hahn has employed lanthanum, and Piccard cerium. But apart from its radioactivity, it is obvious that thorium must be the best substance to employ, since it alone is an isotope of the substance to be separated. Blank tests that we have made have shown that if thorium be employed in small quantity only, and if it be freed before use from all its products except its isotope radio-thorium, the radioactivity contributed by it on any occasion we have employed it as an isotope of uranium-X, has been quite negligible. And not only can one be sure that uranium-X is quantitatively separated by separating thorium quantitatively by the usual methods, but, we have found, the products uranium-X₂ and uranium-Z can be more trustworthily separated from uranium-X₁ when the latter is attached to thorium

than when it is associated with elements similar but not identical in chemical properties, such as cerium and lanthanum. In consequence, we have always employed thorium.

We have separated small quantities of thorium from relatively large quantities of uranium most conveniently by first adding ammonia to a solution of both until further addition would cause a permanent precipitate and then adding a solution of potassium fluoride in large excess. In mineral acid solution, oxalic acid, and sodium thiosulphate fail to precipitate thorium from large quantities of uranium completely, and hydrogen peroxide and *m*-nitrobenzoic acid we have found to be useless. In spite of Keetman's statement to the contrary (*Jahrb. Radioakt.*, 1909, 6, 265), we found also that aqueous hydrofluoric acid did not precipitate thorium quantitatively in presence of mineral acid unless that had been reduced to a concentration just enough to retain the thorium and uranium salts in solution. For a given acidity of mineral acid solution, we found that the amount of potassium fluoride necessary to precipitate completely a quantity of thorium of the order of 10 mg. was proportional to the quantity of uranyl salt present. It would therefore appear that the uranyl-ion, in addition to the acidity of the solution, inhibits the action of the usual precipitants of thorium.

The following is a brief account of the method employed to obtain uranium-X for use in the experiments to be described. Uranyl nitrate was added to ether until the solution was saturated, the aqueous layer was removed and acidified to give a clear solution, and to this was added a volume of a solution of thorium nitrate equivalent to 10 mg. of ThO_2 and then ammonia until a precipitate just appeared. This was removed by adding aqueous hydrofluoric acid. Potassium fluoride solution was then added until precipitation was complete. The precipitate was filtered off, washed with hot water, dried, and then fused in a porcelain crucible with potassium hydrogen sulphate, and the melt when cool dissolved in hot water. To this solution were added a few drops of potassium fluoride solution and the precipitate was immediately filtered and washed. This precipitate was found to be free from traces of uranium. It was fused again with potassium hydrogen sulphate and the thorium precipitated with ammonia from the clear solution of the melt. The hydroxide was finally dissolved in dilute nitric or sulphuric acid.

Separation of Uranium-Z.—In Hahn's first paper (*loc. cit.*), the method for obtaining uranium-Z was in outline described as follows. Uranium-X was concentrated from a large quantity of uranyl nitrate by the "crystallisation" method. To the con-

concentrated solution was added a ferric salt and the whole poured into ammonium carbonate solution. Uranium-X, as is well known, is precipitated with the iron. This precipitate was treated with a solution of tantalum in hydrofluoric acid, lanthanum nitrate added, and the mixture digested on the water-bath with dilute hydrofluoric and sulphuric acids. Lanthanum was thereby precipitated as insoluble fluoride and carried uranium-X with it. The filtrate was then evaporated and the residue gently ignited, whereby the tantalum precipitate became insoluble and the iron remained soluble. Concentrated hydrochloric acid was added and the residue warmed with aqua regia, and, after dilution, filtered. Hahn found in the tantalum the new substance uranium-Z, and a second treatment of the iron-tantalum solution with lanthanum nitrate yielded specimens which were 99.5 per cent. radioactively pure. Our method is much less laborious than this one. We prepared a concentrated solution of uranium-X from 3 to 4 kilos. of uranyl nitrate by the method we have described above. Since uranium-Z appears to be of atomic number 91, it should be most efficiently separated from uranium-X and thorium by adding tantalum in solution to the concentrated solution of uranium-X and separating tantalum from thorium by any convenient method. We have found the following way convenient and trustworthy. A solution of tantalum was obtained by fusing a few mg. of tantalum with 0.5 gram of potassium hydroxide in a nickel crucible, and dissolving the melt in water. A measured portion of the clear liquid was added in the cold to the concentrated solution of uranium-X in dilute sulphuric acid and the whole made just acid. No precipitation then occurred, but, on boiling, the whole of the tantalum and with it substances of atomic number 91 were precipitated in a form that allowed of rapid filtration. It is essential in this procedure that, when the alkaline solution containing the tantalum is added to the other, perfect solution at least momentarily occurs. Otherwise the uranium-Z will not be associated quantitatively with the tantalum when later the latter is precipitated by boiling. There is no difficulty in precipitating the tantalum from solution if the latter be not too acid and boiling be vigorous. The precipitate contains always a small quantity of thorium. If it be necessary to remove this, it may be done by two successive fusions with potassium hydrogen sulphate. The oxide of tantalum dissolves easily on fusion, and when hot water is added to the melt the tantalum is quantitatively thrown out of solution, the thorium remaining completely in solution.

In his second paper (*loc. cit.*), Hahn describes a shaking method for the quick separation of uranium-Z from uranium-X. It contains

sists in shaking tantalic acid for about three minutes with a concentrated solution of uranium- X containing thorium, filtering off the tantalum, which contains uranium- X_2 , uranium- Z , and a little uranium- X_1 , and, from a knowledge of the decay periods and absorption coefficients of the three substances, determining the amounts of each present. This way is similar to ours, but has the disadvantage of not separating uranium- Z quantitatively.

Half-value Period of Uranium-Z.—Uranium- Z emits a highly-complex β -radiation, most of which, however, is soft. We decided, therefore, to measure the decay of this substance inside an ordinary α -ray electroscope in order to have easily-measurable effects. The residual activity after presumably the whole of the uranium- Z had decayed was measured and allowed for in calculating the value of the half-value period. Three careful determinations were made. In each case the decay was strictly exponential and the determined values of the half-value period were found to be 6.70, 6.69, and 6.69 hours. These values are in excellent agreement with that found by Hahn, 6.7 hours. One set of measurements is given in Table I.

TABLE I.

Time in hours from first measure- ment.	Activity due to U- Z ex- perimentally determined.	Activity calculated from $P = 6.69$ hours.	Time in hours from first measure- ment.	Activity due to U- Z ex- perimentally determined.	Activity calculated from $P = 6.69$ hours.
0	22.48	22.70	21.5	2.53	2.46
1.0	20.47	(20.47)	23.0	2.11	2.09
1.95	18.58	18.55	24.4	1.85	1.81

7.0	10.83	10.98	96.0	0	0.001
8.1	9.66	9.80			

The Relative Amounts of Uranium-Z and Uranium- X_2 present with Uranium- X_1 .—From the fact that uranium- Z seems to have an atomic number of 91 and is always found with uranium- X , it would appear that it is a branch product of uranium- X_1 , and like uranium- X_2 , the main product, arises from the expulsion of a β -particle. Hahn has put forward strong evidence in support of this view by determining the relative amounts of the two substances in solutions of various ages. His method of separating uranium- Z , that by which he discovered this product, was not quantitative, but by using the element proto-actinium as an indicator he was able to make the necessary corrections with certainty. He found (in his second paper) that the ratio uranium- X to uranium- Z was

constant over a period of 200 days, during which the former substance decayed to 0.4 per cent. of its original amount. He estimates that if uranium- X_1 is not the parent of uranium- Z , the parent substance must have a period within a day of that of uranium- X_1 (24.6 days). On the assumption that uranium- X_1 is the parent, he finds that 0.9965 of its atoms break up to form uranium- X_2 , and 0.0035 to form uranium- Z . In this work, measurements were made in a β -ray electroscope and corrections for absorption of the rays by the base afterwards applied.

In our work, we avoided the use of an indicator by endeavouring to make every separation of uranium- Z quantitative. We have avoided corrections for the absorption of β -particles by the thin base of the electroscope by making all measurements inside an α -ray electroscope. Four determinations of the branching-ratio of uranium- X have been made. The values obtained by us are 0.9968 to 0.0032; 0.9966 to 0.0034; 0.9966 to 0.0034; and 0.9967 to 0.0033. These values have been obtained from the same solution initially, eleven days after, thirty-two days after, and sixty-two days after, respectively. These results, it will be seen, are in good agreement with those of Hahn mentioned above. Our method of obtaining them is as follows:

A measured volume of a solution of a tantalum salt was added to a solution of uranium- X containing about 10^4 units of activity and the whole gently boiled for twenty to thirty minutes. The precipitate of tantalum acid contained uranium- Z , the quick-changing uranium- X_2 , and a trace of uranium- X_1 . It was well washed with hot water, ignited, and transferred to a copper disk of diameter 3 cm., on which it was uniformly spread. The filtrate and washings were made up to 200 c.c. and several quantities of 1 c.c. of this were carefully evaporated to dryness on copper disks, leaving the active material (uranium- X) as a thin, uniform film consisting of about 0.05 mg. of thorium oxide. The mean value of the activities of these disks was taken as the activity of 1 c.c. of the solution. The comparison of the activities of the disks of uranium- Z and of uranium- X was made in an α -ray, instead of in a β -ray electroscope to avoid the necessity of determining the proportion of the β -radiation of each absorbed by the base of the latter electroscope. It was thought that no important source of error was introduced by this procedure, as no α -ray substance was present in either film except the small and negligible amount of thorium in that containing uranium- X .

A detailed account of the method of arriving at one of the results is given below. The units of activity are scale-divisions per minute.

Ta₂O₅ precipitated at 12.15 p.m. 22/5/23, zero hour.

Activity of above at 5.06 p.m. 22/5/23 is 47.71 (U-X + U-Z).

" " at 4.17 p.m. 25/5/23 is 28.79.

" " at 4.31 p.m. 26/5/23 is 28.22 (U-X only).

Activity of U-X present at 5.06 p.m. 22/5/23 is 31.56 (since the period of U-X is 24.6 days).

∴ Activity of U-Z present at 5.06 p.m. 22/5/23 is 16.15.

" " " at zero hour is 26.66 (since the period of U-Z is 6.7 hours).

Activity of 1 c.c. of U-X solution at 2.30 p.m. 22/5/23 is 39.06.

∴ " " " " at zero is 39.16.

∴ Activity of 200 c.c. of U-X solution at zero is 7832.

But activity of U-X separated with U-Z (reckoned to zero) is 31.74.

Therefore total amount of U-X at zero is 7863.7.

Hence

$$\frac{U-Z}{U-X} = \frac{26.66}{7863.7} = \frac{0.0034}{0.9966}$$

It is interesting that our mean value of the branching ratio, 0.9967 to 0.0033, is near to that of Hahn, 0.9965 to 0.0035, although the methods of arriving at these results are so different. The absolute value of this ratio cannot be known, however, until the relative ionisations of equal numbers of β -particles emitted by uranium-X₂ and uranium-Z are known. There is no simple way known at present of arriving at this result for β -particles. The experimental values, however, are very probably of the right order, and their constancy with time, in Hahn's experiments over 200 days, in ours over 62 days, leaves little doubt that uranium-X itself is the parent of uranium-Z.

The Half-value Period of Uranium-X₂.—The chief difficulty in making this determination is to make a quick and efficient separation of uranium-X₂ from its parent. Fajans and Göhring (*Physikal. Z.*, 1913, **14**, 877), who discovered this substance soon after it had been predicted by one of us (*Chem. News*, 1913, **107**, 49), separated it by immersing a lead plate in a concentrated solution of uranium-X for a few minutes. Uranium-X₂ was deposited on the plate. Its half-value period was found to be 1.15 minutes. This work was confirmed by Fleck (*Phil. Mag.*, 1913, [vi], **26**, 528) and by Hahn and Meitner (*Physikal. Z.*, 1913, **14**, 758). The latter separated uranium-X₂ by pouring a concentrated solution of uranium-X₁ containing a little thorium through a filter-paper impregnated with moist tantalic acid. Uranium-X₂ was retained by the tantalum, which it resembles very closely in chemical

properties. Hahn and Meitner's values for the period varied from 1.05 to 1.24 minutes with a mean of 1.17 minutes.

We separated uranium- X_2 for this purpose by the procedure we had found successful with uranium-Z. A quantitative separation was not necessary, but quickness was essential. Both the uranium-X solution and that containing tantalum were hot when mixed. The solution was momentarily perfect, but on boiling precipitation quickly took place; the tantalum was rapidly filtered with the aid of the pump, washed in succession with hot water, alcohol, and ether, transferred to a copper disk, and its activity during the following ten minutes measured. This procedure occupied about three minutes from the addition of the tantalum to the time of the first measurement in the electroscope. We found later that for a good yield of the product by this method quick filtration was alone necessary. Whether the solution be boiled for two or thirty minutes before filtration had little effect on the final yield. This interesting point will be followed up by us. As with uranium-Z, so with uranium- X_2 we found that a much better separation was effected by first having everything in solution and later precipitating out the tantalum, than merely by shaking a solution with, or pouring it through, moist tantalic acid. Some figures in support of these points are given below. They all refer to solutions of uranium-X of equal activity.

TABLE II.

Experi- ment.	Procedure to obtain U- X_2 .	Time in seconds from beginning of filtration to first measurement in the electroscope.	Activity obtained.
1	Solution boiled for three mins. after the addition of tantalum in solution	94.0	58.6
2	As in (1), but boiled for fifteen minutes	96.5	53.6
3	As in (1), but boiled for thirty minutes	100.3	58.9
4	Filtered hot through a quantity of tantalum equal to that used in (1)	103.1	22.0
5	Filtered hot four times through eight times the quantity of tantalum used in (1)	94.4	41.7

All these measurements were made through the base of a β -ray electroscope with a thin base of aluminium.

After the uranium- X_2 had decayed, a residual activity was always left, about 3 to 5 per cent. of the initial activity. This was due to a small quantity of uranium-X, and with it thorium and radio-thorium, adsorbed or mixed with the tantalic acid. As the activity due to these substances is constant over the usual

duration of the decay measurements (ten minutes), no error thereby arose. The decay of uranium- X_2 when corrected for this was strictly exponential. The values of the half-value period in seconds obtained were 69.6, 70.0, 70.2, 72.6, 69.0, 71.4, 70.2, 72.6, 69.0, 70.2, 70.8. The mean value of these, 70.5 seconds, or 1.175 minutes, is in good agreement with the value of Hahn and Meitner (1.17 minutes), and a little higher than the original value of Fajans and Göhring (1.15 minutes).

The Half-value Period of Uranium-Y.—Uranium-Y was discovered by Antonoff (*Phil. Mag.*, 1911, [vi], **22**, 419; 1913, [vi], 26, 1058) and its existence confirmed by Soddy (*ibid.*, 1914, [vi], 27, 215) and by Hahn and Meitner (*Physikal. Z.*, 1914, **15**, 236). It was found always to be present in preparations of uranium, to be probably an isotope of uranium- X_1 and thorium, to emit a weak β -radiation, and possibly to be a branch product of uranium and the head of the actinium series. The period of this substance was found by Antonoff (*loc. cit.*) to be 1.5 days, and by Hahn and Meitner (*loc. cit.*) 25.5 hours. Soddy (*loc. cit.*) estimated it to be between twenty-four hours and thirty-six hours and nearer the former. The value of Hahn and Meitner was the final one obtained in a series of measurements which increased in successive determinations from 21 to 25.5 hours. The smaller values they ascribed to the presence of thorium as an impurity in the uranium with which they worked. This decreased with successive extractions of uranium-Y from the uranium, and so the half-value period of the former gradually tended to the correct value. The period of uranium-Y is not easily determined with great accuracy, as it is always contaminated with its longer-lived isotope uranium- X_1 , which in equilibrium emits about thirty times more β -particles than uranium-Y. In addition, the radiation from uranium-Y is on the average much softer. The consequence is that even in the most favourable case the activity due to uranium-Y in a preparation is not much more than one-third of the total activity. Our method of separating uranium, which followed the usual lines, was as follows:

From 400 grams of uranyl nitrate in ethereal solution the whole of the uranium-X and uranium-Y was removed by two successive extractions with a few drops of water. Fifteen hours later, the uranium-X and uranium-Y which had grown in that time were similarly removed. To this aqueous solution was added a drop of ferric chloride solution and the whole poured into a hot normal solution of ammonium carbonate. The uranium dissolved and ferric hydroxide containing much of the total uranium-X and uranium-Y was precipitated. This precipitate was dissolved in

acid and the treatment with ammonium carbonate repeated. After thorough washing with ammonium carbonate solution and hot water, the precipitate was ignited and made into a film on a disk of copper. Measurements of the decay in activity of this preparation were made in an α -ray electroscope in order to avoid absorption of the soft β -radiation by the base of a β -ray electroscope. From the final activity of the uranium-X, remaining after uranium-Y had decayed to zero, the amount of uranium-X present at each measurement was calculated and subtracted from the joint activity to give that due to uranium-Y only. When uranium-Y had decayed to zero, the residue decayed with the period of uranium-X (24.6 days); there was no evidence of the presence of another substance emitting α -particles. Six determinations were made. The values of the half-value period in hours obtained were 27.5, 28.0, 27.5, 28.2, 27.8, 27.8. The mean of these is 27.8 hours. One set of measurements is given below. The table includes for purposes of comparison the values of the activity of uranium-Y calculated on the new value (27.8 hours) and the old value (25.5 hours) of the period.

TABLE III.

Time (hours).	Activity of U-X + U-Y.		Activity of U-Y.		Activity of U-Y. Calculated.	
	Experimental.	Calculated.	Experimental.		$P = 27.8$ hours.	$P = 25.5$ hours.
0	64.44	42.90	21.54		(21.54)	(21.54)
2.75	62.38	42.76	19.62		20.11	19.99
17.25	56.36	42.02	14.34		14.01	13.48
26.0	52.55	41.58	10.97		11.26	10.63
41.25	48.40	40.82	7.58		7.70	7.02
51.50	46.28	40.32	5.96		5.96	5.31
65.83	44.25	39.63	4.62		4.17	3.60
91.50	40.53	38.43	2.10		2.19	1.79
311.0	29.98	29.98	0		0.008	0.005

It is seen from the table that the agreement between the experimental values and those calculated from $P = 27.8$ hours is fair. The agreement between the experimental values and those calculated from $P = 25.5$ hours is very poor. It is possible, however, that our consistently higher value may be due in some way to our not making the determinations in a β -ray electroscope.

The Ratio of Uranium-Y to Uranium-X in Preparations of Uranium.—The constancy of the activities of these two substances, suggested by early workers on uranium-Y, has been established in detail by Kirsch (*Wien. Ber.*, 1920, 129, 2a, 309). Hahn has found the value of the ratio to be 0.021. It is to be expected that this ratio would be the same as the equilibrium ratio of proto-actinium to ionium in minerals, since uranium-Y is probably a member of the actinium series in the direct line. This latter ratio

has been found by Hahn and Meitner (*Physikal. Z.*, 1919, 20, 529) to be 0.03, by Meyer (*Wien Anzeiger*, 1920, 133) to be 0.042, and by Widdowson and Russell (*Phil. Mag.*, 1923, in the press) to be 0.029. Since both ionium and proto-actinium expel α -particles, a determination of the relative number of α -particles expelled by each when in equilibrium in a mineral is easily deducible from a determination of their relative ionisations, but for substances like uranium-X and uranium-Y which expel β -particles this cannot simply be done. It will be only when the relative ionisations due to an equal number of average β -particles from uranium-X, uranium-X₂, uranium-Y, and (if it exists) from uranium-Y₂ are known and when further it has been decided whether or not uranium-Y consists of two substances expelling β -particles that it will be possible to deduce from the relative ionisations of uranium-X and uranium-Y the relative number of β -particles which they expel in unit time. Our value of the equilibrium ratio was found as follows. The uranium-X and uranium-Y present in about 400 grams of uranyl nitrate in ethereal solution were completely removed. From fifteen to seventeen hours later, the uranium-X and uranium-Y which had grown in that time were separated with a little uranium as an aqueous layer. The uranium was separated from the uranium-X and uranium-Y by adding to their solution either a little iron salt in solution or a little thorium salt in solution, and separating the iron or the thorium completely from the uranium in the usual manner. Uranium-X and uranium-Y were separated with the iron or the thorium. Their combined activity was then measured in an α -ray electroscope in order to avoid the uncertain correction for absorption of their β -particles, and later when the whole of the uranium-Y had decayed. From the known disintegration constants of these substances their relative activities when in equilibrium were deduced. Three determinations were made. In (1) and (2) iron was used, in (3) thorium as mentioned above. Details are given below:

	(1).	(2).	(3).
Activity due to U-X + U-Y when first measured	64.44	28.65	36.21
" " U-X " " "	42.90	19.81	25.65
" " U-Y " " "	21.54	8.84	11.56
Time in hours from separation to first measurement	6.5	7.5	7.25
Activity of U-X at time of separation	43.23	20.04	25.87
" " U-Y " " "	25.40	10.70	13.89
Time in hours of growth of U-X + U-Y in the ethereal solution	15.0	16.25	16.23
Percentage growth of U-X in this time	1.74	1.90	1.90
" " U-Y " " "	31.69	33.81	33.81
Activity of U-X at equilibrium	2484	1054	1362
" " U-Y " " "	80.15	32.1	41.8
Ratio of activity of U-Y to that of U-X	0.032	0.030	0.031

The mean of these values, 0.031, is a minimum one, as possible errors in carrying out the chemical work all tend to make the final ratio low. This value is higher than, but of the same order as, that obtained by Hahn, and is very close to the values obtained for the equilibrium ratio of proto-actinium to ionium (0.03). The agreement is, no doubt, in part fortuitous, but at least it serves to confirm the fact that these ratios are of the same order.

The Position of Uranium-Z in the Disintegration Series.—Hahn (*Ber.*, 1921, **54**, [B], 1131; *Z. physikal. Chem.*, 1923, **103**, 461) represents uranium-Z's position as follows:

We agree with this. It is the simplest way of explaining the experimental facts which are at present known. Reasons for rejecting an alternative scheme due to Piccard have been given in another paper (Russell, *Phil. Mag.*, 1923, [vi], **46**, 429). A third possibility of course exists, namely, that two isotopes of nearly equal periods, each emitting β -particles, might be the parents of uranium-X₂ and uranium-Z respectively. But if this were so, it would be necessary to assume either that one of them comes from an isotope of uranium I and uranium II, or that either uranium I or uranium II itself breaks up dually with the expulsion of an α -particle to give respectively both or one of the two β -ray isotopes of nearly equal period. As there is no known case of two isotopes having periods in a smaller ratio than 1.25 to 1, it is improbable that two isotopes, one with a period of 24.6 days, the other with one of 24.6 ± 1 days (as demanded by the experimental evidence), exist. On theoretical grounds also, there is much to be said for Hahn's scheme. Two disturbances occur in the transformation of uranium-X₁ into uranium II in each of which a β -particle is expelled. It could happen that with a fraction of the atoms of uranium-X₁ the disturbance which usually occurs second occurs first, and later there occurs in the atoms thus produced what corresponds to the first disturbance in the majority of uranium-X₁ atoms. Even on this simple view, it need not follow that the β -particle expelled by uranium-X₁ in

being transformed to uranium- X_2 is that expelled by uranium- Z in disintegrating, or that uranium- X_2 's β -particle is that expelled by those atoms of uranium- X_1 which disintegrate to form uranium- Z , because our lack of knowledge concerning the mechanism of disintegration forces us to leave the matter open. It is to be expected, however, that uranium II would not be the product of both uranium- X_2 and uranium- Z (as the scheme assumes) unless the total amount of energy expelled along the alternative routes to it from uranium- X_1 be equal. This matter has yet to be investigated.

It has been pointed out by one of us (Russell, *Nature*, 1923, 111, 703) that the equilibrium ratio $U\text{-}X_2/U\text{-}Z$ is of the same order as the reciprocal of the periods of these two substances. The former of these is 285 according to Hahn⁴ and 302 according to us, and the latter is 342. If this be not a coincidence, it would appear that the transformation of uranium- X_1 into uranium II occurs in essentially the same manner but at two different rates. The rate along the major branch $U\text{-}X_1 \rightarrow U\text{-}X_2 \rightarrow U\text{ II}$ is about 300 times faster than that along the minor, $U\text{-}X_1 \rightarrow U\text{-}Z \rightarrow U\text{ II}$, for the uranium- X_1 atoms which disintegrate to form uranium- Z have a quasi-period which is 285 or 302 times that of the atoms which go to form uranium- X_2 , and uranium- Z 's period is 342 times that of uranium- X_2 . In support of the possibility of this suggestion is the following. The transformations ionium to radium- B , radiothorium to thorium- B , and radioactinium to actinium- B are all very similar as regards radiations expelled. Also each product in these transformations has a period on the average 800 times smaller than its parent, yet the rate of decay of products of the first transformation is 1.3×10^3 times that of the corresponding products of the second, and 6×10^4 times that of the corresponding products of the third.

Summary.

(1) A method has been outlined for preparing quickly a concentrated solution of uranium- X free from uranium, using the "ether" method of concentrating, and precipitating uranium- X along with a trace of thorium by a solution of potassium fluoride.

(2) A method has been worked out for a quick and efficient separation of uranium- X_2 , using a solution of tantalum as a precipitant. Its half-value period has been found to be 1.175 minutes, the mean of eleven determinations, which is in agreement with the accepted value.

(3) The period of uranium- Y has been found to be 27.8 hours, the mean of six determinations, which is 9 per cent. higher than

the accepted value. The equilibrium ratio uranium-Y to uranium-X has been found to be 0.031.

(4) The existence of uranium-Z has been confirmed, and a method for its preparation in a radioactively pure state described. It emits a weak β -radiation, has a period of 6.69 hours, and the equilibrium ratio uranium-Z to uranium-X has been found to be constant with time and equal to $\frac{0.0033}{0.9967}$.

(5) Hahn's scheme for representing uranium-Z's position in the disintegration series is regarded as most probable, and a suggestion is made connecting periods of substances and their equilibrium ratio.

We wish to thank the Government Grant Committee of the Royal Society for providing us with the instruments and materials employed in this work.

CCIV.—Studies in the Anthracene Series. Part VII.

By EDWARD DE BARRY BARNETT and JAMES WILFRED COOK.

In a previous communication (Barnett, Cook, and Matthews, this vol., p. 1994), it was shown that anthranyl methyl and ethyl ethers (I) on treatment with nitric acid give a mixture of dianthrone (III) and nitroanthrone (V). The production of the former compound is obviously due to dealkylation to anthranol (II) and subsequent oxidation:

The production of nitroanthrone might be due to nitration subsequent to dealkylation, or to addition of nitric acid to the anthranyl ether and subsequent loss of the alkyl group:

This latter view represents the mechanism of the reaction as being essentially similar to that which takes place when anthracene is suspended in acetic acid and treated with nitric acid.

Considerable interest lies in reactions of this type in view of the light which they throw on the mechanism of nitration reactions in the aromatic series, and therefore it was decided to extend the investigation to certain anthracene derivatives in which substituents are attached to the *meso*-carbon atoms in the hope of obtaining definite evidence of the formation of additive compounds with nitric acid. Unfortunately, these additive compounds are unstable and difficult or impossible to isolate, so that, except in the case of anthracene itself, it has only been possible to obtain indirect evidence of their formation.

The nitration of anthrone (VI) to nitroanthrone (V) might possibly be due to the direct replacement of a mobile hydrogen atom, but it is more probable that nitration is preceded by enolisation to anthranol (II), the formation of an additive compound from this and nitric acid (VII) and subsequent loss of water :

That nitration takes place through the enolic form is supported, not only by the nitration of the anthranyl alkyl ethers, but also by the fact that anthranyl acetate when treated with nitric acid passes very easily into nitroanthrone. More rigorous proof, however, would lie in the discovery of anthrone derivatives which are nitrated in the enolic (anthranol) form, but which remain unaffected under similar conditions when in the ketonic form, and if the enolic form contained no replaceable hydrogen atom the proof of the intermediate formation of an additive compound would be complete. For this purpose, it was necessary to select some anthrone derivative the tendency of which to enolise in acetic acid solution at the ordinary temperature is very small, and phenylanthrone (VIII) was found to fulfil this condition, its solutions in cold acetic acid exhibiting no visible fluorescence. As was foreseen, it was found that phenylanthrone remains unaffected when suspended in acetic acid and treated with concentrated nitric acid. Indeed, in one experiment it was recovered unchanged after treatment at 60° for a few minutes with fuming nitric acid (*d* 1.50). On the other hand, the enolic phenylanthranyl acetate (IX) reacts easily with nitric acid (*d* 1.42

or 1.50) under similar conditions and gives rise to a mixture of phenylnitroanthrone (X) and phenylhydroxyanthrone* (XI):

In phenylanthranyl acetate there is no replaceable hydrogen atom in the *meso*-position. Since nitration takes place, but not through the ketonic anthrone, it follows that it must occur by an additive reaction:

In this case it will be observed that the subsequent loss of water takes place from the *gem*.-dihydroxy-grouping, and not by the re-establishment of the "bridge" bond, the above reaction being one in which an "aromatic" compound on nitration gives a compound in which the nitro-group is in the "aliphatic" state. The same remark also applies to the methyl compounds described below.

In order to obtain still further evidence in support of the view that nitration reactions consist in additive reactions followed by loss of water, the behaviour of methyl- and phenyl-anthranyl methyl ethers (XIV) towards nitric acid was examined. Neither of these compounds contains a replaceable hydrogen atom in the *meso*-position, and although they are both demethylated by heating with mineral acids in glacial acetic acid solution, this reaction takes place much less readily than is the case with anthranyl methyl ether,

* Phenylhydroxyanthrone has previously been obtained by Baeyer and Schillinger (*Annalen*, 1880, **202**, 58) by oxidising phenylanthrone by boiling it with potassium dichromate in glacial acetic acid solution. Its formation may possibly be due to the direct replacement of a hydrogen atom by a hydroxyl group, but since, when nitric acid is used as an oxidising agent, phenylanthranyl acetate is oxidised under conditions under which phenylanthrone remains unaffected, it seems much more probable that oxidation takes place through the enolic form. Alternatively, the production of phenylhydroxyanthrone in the above reaction may be due to a consecutive reaction in which the nitro-group of part of the phenylnitroanthrone is replaced by a hydroxyl group. That such a reaction can take place easily will be shown in the sequel, although it is doubtful if it would take place to any appreciable extent under the experimental conditions used.

and it is extremely improbable that simple demethylation would take place under the conditions used for nitration.* Also it was found that methylnitroanthrone was not obtained if methylanthranlyl methyl ether were first demethylated by heating with sulphuric acid in acetic acid solution. Under these conditions, anthraquinone and a resinous substance which was probably unchanged methylanthrone were obtained as the sole products of the reaction, and no traces of the well-defined methylnitroanthrone could be detected. Both ethers react very easily in cold acetic acid suspension with nitric acid, the products being phenylnitroanthrone and methylnitroanthrone (XVI). The only possible explanation of this reaction lies in the assumption that an additive compound (XV) with nitric acid is first formed, and that subsequent loss of methyl alcohol then takes place from the *gem*-hydroxymethoxy-group:

In neither case was it found possible to isolate the intermediate additive compound, but in both cases the suspended ether rapidly dissolved during the addition of the nitric acid, and then after keeping for a few minutes the methyl- or phenyl-nitroanthrone crystallised out. In both compounds the nitro-group is very loosely held, and both liberate iodine from potassium iodide, in this way resembling nitroanthrone. In the case of the phenyl compound, boiling with acetic acid causes a rapid evolution of oxides of nitrogen and the formation of phenylhydroxyanthrone (XI). It may be urged that this excessive reactivity of the nitro-group points to the compounds being anthranlyl nitrates rather than nitroanthrone derivatives. This, however, can scarcely be the case, as they show no fluorescence and the formation of esters of nitric acid under the experimental conditions employed is extremely improbable. Also in the case of the phenyl compound the action of nitric acid on the acetate leads to the simultaneous production of large quantities of phenylhydroxyanthrone, so that the isolation of the nitro-compound is extremely difficult. The action of nitric acid on the methyl ether, on the other hand, leads at once to almost pure phenylnitroanthrone, no phenylhydroxyanthrone being formed. Such a result would be inexplicable if the reaction really consisted in the formation of a

* The ready dealylation of the anthranlyl ethers (Barnett, Cook, and Matthews, *loc. cit.*) is probably due to the addition of the elements of water taking place at the "bridge" bond with subsequent loss of alcohol from the resulting *gem*-alkyloxyhydroxy-compound.

nitric ester from phenylanthranol (XII) produced by hydrolysis, but is readily explicable when the probable relative stability of the intermediate additive compounds (XIII and XV) is considered. That the nitro-group is attached to one of the *meso*-carbon atoms and not elsewhere in the molecule is shown by the conversion of the nitro-compound into phenylhydroxyanthrone by hydrolysis.

From the above, it is evident that in the anthracene series nitration in the *meso*-position consists in the first place in addition of nitric acid to the "bridge" bond, and subsequent loss of water or alcohol, this loss taking place with re-establishment of the "bridge" when this is possible, or from the *gem*-dihydroxy-group when re-establishment of the "bridge" is not possible. Anthracene is the only compound from which the intermediate additive compound has actually been isolated* (in the form of its esters), and in this instance it has already been shown (Barnett, Cook, and Matthews, *loc. cit.*) that the formation of this additive compound is a reversible reaction. The formation and stability of these additive compounds must depend on the reactivity of the "bridge" bond, and this again is dependent on the presence of substituents, not only in the *meso*-positions, but also in the benzene rings. Substituted anthracene derivatives are therefore at present being studied in the hope of discovering other instances in which the intermediate additive compound can actually be isolated, and of finding some general rule governing the influence of substituents on the "bridge" bond. It seems extremely probable that all nitration reactions, and probably also most other substitution reactions, in the aromatic series consist in the first instance in a *reversible* additive reaction, followed by loss of water or halogen acid, usually with re-establishment of a "bridge" bond. Such a conception of the mechanism of nuclear substitution affords a rational explanation of many otherwise obscure reactions, but a fuller discussion is postponed until experimental proof is available of the reversible formation of these additive compounds in the benzene and naphthalene series.

Baeyer and Schillinger (*loc. cit.*) prepared phenylanthrone by loss of water from triphenylmethane-*o*-carboxylic acid. It has been found that a more satisfactory method consists in condensing bromoanthrone with benzene in the presence of aluminium chloride. It was hoped by this means to obtain a considerable number of arylanthrones and from them the arylanthracenes in order to study the effect of the aryl group on the "bridge" bond and to extend the work which has already been published on the tendency of the

* It has been claimed that similar additive compounds can be isolated from 9:10-dichloroanthracene, 2:9:10-trichloroanthracene, and 1:3:9:10-tetrachloroanthracene (D.R.-P. 296019).

carbon atoms in the *meso*-positions to act in the tervalent state. The reaction, however, is not of such general application as would be expected. Thus in the case of benzene it takes place readily, but with toluene with much greater difficulty, and it was found impossible to purify the resulting tolylanthrone, although tolyl-anthranyl acetate was obtained in the pure state. All attempts to prepare xylyl- and naphthyl-anthrone resulted only in resinous products.

The reduction of phenylanthrone to phenylanthracene was effected by Baeyer and Schillinger (*loc. cit.*) by distillation with zinc dust. It has been found that much more satisfactory results are obtained by the use of zinc dust and ammonia, as the reaction is complete in a few minutes and the product is easy to purify. On the other hand, if the reduction is carried out with zinc dust and hydrochloric acid in acetic acid solution, the pinacol condensation takes place, the sole product isolated being diphenyldianthranyl (compare Barnett and Matthews, this vol., p. 380). The different behaviour on reduction in alkaline and in acid solution is probably to be attributed to the fact that in the former case enolisation first takes place and is followed by the addition of hydrogen to the "bridge" bond. In the latter case enolisation does not take place, so that the carbonyl group behaves normally. Probably the abnormal behaviour of the *Bz*-chloroanthrones on reduction in acid solution (Barnett and Matthews, this vol., p. 2549) is also due to their varying tendency to enolisation and to the effect of the chlorine atoms on the reactivity of the "bridge" bond.

Phenylanthracene is readily converted by nitric acid into 9-nitro-10-phenylanthracene, the position of the nitro-group being proved by oxidation to phenylhydroxyanthrone. No intermediate additive compound could be isolated.

EXPERIMENTAL.

Phenylanthrone and its Derivatives.

Phenylanthrone (VIII).—To pure 9-bromoanthrone (32 grams), suspended in 150 c.c. of anhydrous thiophen-free benzene heated under reflux, 30 grams of finely powdered anhydrous aluminium chloride were added slowly, a violent reaction taking place and the solution becoming successively green, purple, red, and finally brown. The whole was then boiled gently for an hour, cooled, and poured into a large volume of dilute hydrochloric acid. The benzene layer, having been washed, was dried with calcium chloride and most of the benzene removed below 45° under reduced pressure. The residue was diluted with a large volume of ether and cooled, when phenylanthrone separated, and was washed with ether. The yield was

16 grams and a further 5 grams of rather less pure material was obtained by concentrating the mother-liquors. It is best purified by recrystallisation from a mixture of methyl ethyl ketone and aqueous alcohol.

In the above preparation it is not essential to remove the benzene by distillation under reduced pressure, but if this is not done the product is less pure and the yield smaller. The yield was not improved by adding bromoanthrone to anhydrous aluminium chloride suspended in benzene nor by the alternate addition of small amounts of bromoanthrone and aluminium chloride to benzene.

Phenylanthranyl acetate (IX) was prepared by Baeyer and Schillinger (*loc. cit.*) by heating phenylanthrone with acetic anhydride at 140°, but is much more conveniently obtained by heating phenylanthrone (3 grams) with pyridine (10 c.c.) and acetic anhydride (3 c.c.) for an hour on the water-bath. The acetate separates on cooling and after being washed with alcohol is recrystallised from a mixture of alcohol and methyl ethyl ketone.

Phenylanthranyl Methyl Ether (XIV).—Phenylanthrone (16 grams) was heated under reflux with 100 c.c. of alcohol and the boiling solution treated alternately with small quantities of potassium hydroxide (in all, 15 grams dissolved in 20 c.c. of water) and technical methyl toluene-*p*-sulphonate (in all, 30 grams dissolved in 50 c.c. of warm alcohol). After the whole of the ester and alkali had been added, the boiling was continued for half an hour and the solution then cooled. After being washed with alcohol and hot water, the resulting pale yellow needles melted at 161–163° and at the same temperature after recrystallisation from a mixture of alcohol and methyl ethyl ketone. The yield of the recrystallised product was 11 grams (Found: C = 88.4; H = 5.82. $C_{21}H_{16}O$ requires C = 88.7; H = 5.63 per cent.).

Phenylanthranyl methyl ether is almost insoluble in cold alcohol, but moderately soluble in hot methyl ethyl ketone or acetic acid. Its solutions exhibit a powerful violet fluorescence. It is demethylated when heated for two hours on the water-bath with glacial acetic acid containing a few drops of concentrated hydrochloric acid.

Phenylanthronylpyridinium Bromide.—Phenylanthrone (10.8 grams) was dissolved in 20 c.c. of hot pyridine, the solution rapidly cooled in a freezing mixture and then treated slowly with bromine (2 c.c.; 1 mol.). After being kept for three hours at the ordinary temperature, the whole was again cooled in a freezing mixture and the solid washed with pyridine and dried in a vacuum desiccator. Owing to its instability, it is rather troublesome to purify, and the purification of the analytical sample was effected by shaking with cold alcohol and addition of ether to the filtrate. On cooling in a

freezing mixture, colourless crystals separated which melted to a red liquid at 101–102° (Found: Br = 18.8. $C_{25}H_{18}ONBr$ requires Br = 18.7 per cent.).

Phenylanthronylpyridinium bromide is very easily soluble in water or alcohol. Its aqueous solution became turbid on keeping at the ordinary temperature for a short time owing to hydrolysis taking place with the formation of phenylhydroxyanthrone, which was identified by the method of mixed melting points.* On attempting to recrystallise the bromide from boiling alcohol, a product containing neither nitrogen nor bromine was obtained which melted at 156–157° alone or when mixed with an authentic sample of phenylethoxyanthrone.

9-Phenylanthracene.—Phenylanthrone (10 grams) was ground with 30 grams of zinc dust and 150 c.c. of water were added. After the zinc had been activated with a few drops of a dilute solution of platonic chloride, 150 c.c. of aqueous ammonia (d 0.880) and 100 c.c. of water were added and the whole was heated under reflux on the water-bath until it was no longer yellow (about fifteen minutes). After the greater part of the zinc had been removed by digestion with dilute hydrochloric acid, the product was crystallised from alcohol. The yield was 7 grams. The very large excess of ammonia was found necessary to insure rapid and complete reduction.

9-Nitro-10-phenylanthracene.—Phenylanthracene (2.5 grams) was suspended in 20 c.c. of glacial acetic acid and 1.4 c.c. of nitric acid (d 1.42) added slowly with cooling. After the mixture had been kept for an hour at the ordinary temperature in the dark, the yellow crystals were washed with cold acetic acid and recrystallised from boiling acetic acid (Found: N = 4.62. $C_{20}H_{13}O_2N$ requires N = 4.68 per cent.).

Phenylnitroanthracene forms glistening, yellow crystals which are easily soluble in carbon disulphide, chloroform, or benzene, and moderately soluble in ether. It rapidly becomes red on exposure to light and for this reason the preparation and purification must be carried out in the dark. It does not liberate iodine from potassium iodide in boiling glacial acetic acid solution. When oxidised by boiling for a few minutes with excess of chromic acid in glacial acetic acid solution, it is converted into phenylhydroxyanthrone, together with a small amount of anthraquinone. The latter was removed by digestion with an alkaline solution of sodium hyposulphite and the residue after recrystallisation from alcohol identified as phenylhydroxyanthrone by the method of mixed melting points.

* Baeyer and Schillinger (*loc. cit.*) give the melting point as 208°, but this is too low. Their product seems to have been contaminated with anthraquinone and dianthrone. The melting point of the pure substance is 214°.

Diphenyldianthranyl.—Phenylanthrone (12 grams), suspended in 75 c.c. of boiling glacial acetic acid, was reduced by the addition of 10 grams of zinc dust (added in four portions) and 10 c.c. of concentrated hydrochloric acid. The reduction was carried on for one and a half hours, although this was probably longer than was necessary. After the removal of excess of zinc by digestion with dilute hydrochloric acid, the product was dried in the steam-oven and then recrystallised three times from toluene (Found: C = 94.8; H = 5.25. $C_{40}H_{26}$ requires C = 94.9; H = 5.1 per cent.). Diphenyldianthranyl forms a yellow, crystalline powder which does not melt below 300°. Its solutions exhibit an intense violet fluorescence. It does not appear to form an additive compound with toluene and in this way differs from dianthranyl.

Tolylanthranyl Acetate.—Bromoanthrone (47 grams) was suspended in 250 c.c. of dry toluene, 35 grams of anhydrous aluminium chloride were added slowly, and the temperature was then gradually raised to 110° (temperature of oil-bath) and maintained at this point for an hour. After cooling, the whole was poured into a large volume of dilute hydrochloric acid, the toluene layer well washed, dried with calcium chloride, and filtered. After the toluene had been removed by distillation in a vacuum at a low temperature, the viscous residue was diluted with ether and the solid well washed with ether. It then melted to a red liquid at 130° after previous sintering, and at appreciably the same temperature after several recrystallisations from different solvents. It was soluble in boiling aqueous solutions of sodium hydroxide with a yellow colour, and there can be no doubt but that it consisted essentially of tolylanthrone, although satisfactory analytical results could not be obtained. It was therefore heated for an hour on the water-bath with pyridine and acetic anhydride. On cooling and diluting the solution with water, a resinous product separated which became solid when kept for several days in contact with alcohol. It was then recrystallised several times from alcohol (Found: C = 84.3; H = 5.64. $C_{23}H_{19}O_2$ requires C = 84.4; H = 5.81 per cent.).

Tolylanthranyl acetate forms a yellow, crystalline powder which melts at 163–164°. It is easily soluble in most media and its solutions exhibit a strong bluish-violet fluorescence. On reduction with zinc dust and hydrochloric acid in boiling glacial acetic acid solution, it appears to be converted into ditolyldianthranyl. The product, however, crystallised with difficulty and retained zinc salts very obstinately, a sample which had been recrystallised several times both from chloroform and light petroleum and from benzene and ether showing on analysis nearly 3 per cent. of ash.

Nitration Experiments.

In all cases the nitrations were carried out by suspending the finely powdered substance in glacial acetic acid and adding nitric acid slowly from a burette. During the addition the solution was kept well stirred, and cooled by immersing the vessel in cold water.

Nitration of Anthranyl Acetate.—Anthranyl acetate (2.3 grams), suspended in glacial acetic acid (10 c.c.), was nitrated by the addition of 0.7 c.c. of nitric acid (*d* 1.42). Most of the acetate dissolved and, on keeping, colourless crystals separated and after recrystallisation from carbon disulphide were identified as nitroanthrone by direct comparison with an authentic sample.

The nitration of the acetate takes place more smoothly than is the case with anthrone, and as anthranyl acetate is very easily obtained by the pyridine-acetic anhydride method* (Barnett and Matthews, *loc. cit.*), this is the best method for making nitroanthrone.

Nitration of Methylanthranyl Methyl Ether.—Methylanthranyl methyl ether was prepared from anthrone, methyl iodide, and potassium hydroxide by the method described by Meyer and Schlösser (*Annalen*, 1920, 420, 113), but it was found desirable to increase by 50 per cent. the amount of alkali recommended by these authors. The ether (2.2 grams), suspended in glacial acetic acid (10 c.c.), was nitrated by the addition of 0.7 c.c. of nitric acid (*d* 1.42), and dissolved rapidly. After a few minutes, when the sides of the vessel were scratched colourless crystals separated, which, washed with a little cold acetic acid, were recrystallised from carbon disulphide, washed with light petroleum and ether, and dried in a vacuum desiccator (Found: C = 70.9; N = 5.53. $C_{15}H_{11}O_3N$ requires C = 71.1; N = 5.53 per cent.).

Methylnitroanthrone (XVI) forms colourless crystals which are easily soluble in chloroform or carbon disulphide, moderately easily soluble in glacial acetic acid or ether, and sparingly soluble in light petroleum. Its solutions in concentrated sulphuric acid are emerald-green and turn red on the addition of a drop of nitric acid. Its solutions in acetic acid liberate iodine from potassium iodide.

Nitration of Methylanthrone.—Methylanthranyl methyl ether (7 grams) was heated on the water-bath with 50 c.c. of glacial acetic acid to which had been added 1 c.c. of concentrated sulphuric acid diluted with 3 c.c. of water. The ether dissolved slowly, about one and a half hours' heating being required. The resulting solution was diluted with a large volume of water and the oil which separated

* The amount of pyridine originally recommended can be reduced to one-half. The pure acetate melts at 136°, and not at 132–134°, as formerly stated.

extracted with ether. After the ethereal extract had been washed with a dilute solution of sodium carbonate until it was no longer acid, it was dried over calcium chloride and the ether removed by distillation. The resulting oil became semi-solid after being kept for several days in a vacuum desiccator over concentrated sulphuric acid and solid potassium hydroxide, but could not be crystallised, and therefore was not obtained sufficiently pure for analysis. However, its method of preparation and its solubility in boiling dilute aqueous sodium hydroxide to form a yellow solution left no doubt as to its being methylanthrone, and this was confirmed by its reduction to methylanthracene. This was effected by means of activated zinc dust and ammonia under exactly the same conditions as were used for the reduction of phenylanthrone. The identification of the 9-methylanthracene, recrystallised from methyl alcohol, was completed by the preparation of the picrate (Krollpfeiffer and Branscheid, *Ber.*, 1923, 56, [B], 1617; Siglitz and Marx, *ibid.* 1619).

The crude methylanthrone (2 grams), dissolved in glacial acetic acid (10 c.c.), was nitrated under the usual conditions by the addition of 0.7 c.c. of concentrated nitric acid (*d* 1.42). Scarcely any solid separated, and the small amount which was obtained by keeping over-night was found to be anthraquinone. On diluting the mother-liquors with water, a pasty substance separated which behaved exactly like unchanged methylanthrone. No trace of the well-characterised methylnitroanthrone could be detected.

Nitration of Phenylanthranyl Acetate.—When the acetate was nitrated under the usual conditions with concentrated nitric acid (*d* 1.42), the chief product was found to be phenylhydroxyanthrone, although the presence of phenylnitroanthrone was shown by the fact that the partly purified material sintered at 116° and liberated iodine from potassium iodide. By the use of fuming nitric acid (*d* 1.50), the amount of phenylnitroanthrone formed was increased. By repeated crystallisation from a mixture of carbon disulphide and light petroleum, the crude product was separated into two fractions, the less soluble of which contained no nitrogen and melted at 213–214°. The more soluble contained nitrogen, liberated iodine from potassium iodide, and melted at 116°. Both were identified by the method of mixed melting points, the former being phenylhydroxyanthrone and the latter phenylnitroanthrone.

Nitration of Phenylanthranyl Methyl Ether.—When nitric acid (*d* 1.42; 0.7 c.c.) was added to the ether (5.6 grams) suspended in glacial acetic acid (20 c.c.), solution took place rapidly. The crystals that separated after a short time were washed with acetic acid and ether and dried in a vacuum desiccator. They melted at

115–116° and at the same temperature after recrystallisation from a mixture of carbon disulphide and light petroleum (Found : C = 76.1; N = 4.34. $C_{20}H_{13}O_3N$ requires C = 76.2; N = 4.44 per cent.).

Phenylnitroanthrone forms colourless crystals which give a blood-red solution in concentrated sulphuric acid, the colour not being altered by the addition of a drop of nitric acid. When it is boiled with dilute sulphuric acid or glacial acetic acid, oxides of nitrogen are evolved and phenylhydroxyanthrone is produced. After recrystallisation from alcohol, this was identified by the method of mixed melting points.

Summary.

(i) The nitration of some anthrone and anthranol derivatives by nitric acid in acetic acid solution has been studied, and it has been shown that in every case the first action consists in the addition of nitric acid to the "bridge" bond.

(ii) The behaviour of 9-bromoanthrone in the Friedel and Crafts reaction has been studied, and it has been found that this method provides a convenient means for preparing 9-phenylanthrone, but is not of general application.

In conclusion, the authors desire to express their thanks to the Research Fund Committee of the Chemical Society for a grant which has defrayed some of the expenses of this research.

[Received, August 23rd, 1923.]

CCCV.—*The Constituents of Indian Turpentine from Pinus longifolia, Roxb. Part III.*

By JOHN LIONEL SIMONSEN.

IN Part I of this series (T., 1920, 117, 570) it was mentioned that the essential oil from the oleo-resin of *P. longifolia* contained in the high-boiling fraction a sesquiterpene for which the name *d*-longifolene was proposed. This hydrocarbon, which was characterised by the preparation of crystalline derivatives with the halogen acids, was readily obtainable in large quantities, and it appeared of interest to attempt the determination of its constitution. An additional incentive lay in the fact that it was highly desirable to find an economic outlet for this oil, which at the present time forms what is practically a waste product of the Indian turpentine industry.

Recently Ruzicka and his collaborators in a series of important papers (*Helv. Chim. Acta*, 1921, 4, 503 and subsequent papers) have shown that a number of the sesquiterpenes are either derivatives of naphthalene or on dehydrogenation readily yield derivatives of this hydrocarbon. The suggestion that the sesquiterpenes were derivatives of naphthalene had been previously advanced by Wallach (*Annalen*, 1887, 239, 49) and by Semmler (*Ber.*, 1913, 46, 1817), whilst attention may also be directed to an interesting paper by Kay and Morton (*T.*, 1914, 105, 1565), who have commenced synthetic experiments with the object of confirming this suggestion. In view of the publication of these papers, it has appeared to the author desirable to place on record the results so far obtained in the investigation of the constitution of *d*-longifolene.

In his analytical experiments, Ruzicka has made extensive use of a process apparently first introduced by Vesterberg (*Ber.*, 1903, 36, 4200) for the dehydrogenation of resin acids, namely, heating at a high temperature with sulphur and by this method he has, for example, shown that the sesquiterpenes of the cadinene group yield a naphthalene hydrocarbon, cadalene, the constitution of which he has proved by an ingenious synthesis and shown to be 1:6-dimethyl-4-isopropyl-naphthalene (Ruzicka and Seidel, *Helv. Chim. Acta*, 1922, 5, 369).

Prior to the publication of Ruzicka's papers, the author had investigated the action of sulphur on *d*-longifolene and on certain of its derivatives with completely negative results, since, although hydrogen sulphide was evolved in quantity, no trace of a naphthalene hydrocarbon or any other simple hydrocarbon could be isolated from the reaction product. It was therefore necessary to devise other methods for the degradation of this hydrocarbon.

d-Longifolene was found to be extremely resistant to oxidation with potassium permanganate, but on treatment with chromic acid in acetic acid solution or with a mixture of sodium dichromate and sulphuric acid oxidation proceeded smoothly. The main product of the oxidation with chromic acid was a saturated monobasic acid, $C_{14}H_{22}O_2$, melting at 152–153°, for which the name *longifolic acid* is proposed, whilst when a mixture of sodium dichromate and sulphuric acid was employed an isomeric acid, *isolongifolic acid*, melting at 136°, resulted. With both oxidising agents a neutral oil was also obtained which will be referred to in detail below.

Longifolic acid, which was optically inactive, was found to be a weak acid resembling in its properties abietic acid. It was an extremely stable acid and was only slowly attacked by potassium permanganate in alkaline solution at 100°. It dissolved in con-

centrated sulphuric acid and was recovered unchanged on the addition of water, whilst it could be heated to 80° with fuming nitric acid without undergoing oxidation. Although the acid chloride on treatment with bromine at 50° slowly absorbed the bromine with evolution of hydrogen bromide, the reaction proceeded apparently in a complex manner and the greater part of the acid was isomerised, being converted into *isolongifolic* acid. In *longifolic* acid, therefore, the carboxyl group would appear to be attached to a tertiary carbon atom and support was lent to this view by the very great difficulty experienced in esterifying the acid and the slowness with which the ester underwent hydrolysis. The acid was not esterified by prolonged treatment with alcohol and sulphuric acid, although the *methyl* ester was readily obtained in a quantitative yield by the action of methyl sulphate in the presence of alkali.

It was mentioned above that when *d*-*longifolene* was oxidised with a mixture of sodium dichromate and sulphuric acid, in place of *longifolic* acid an isomeric acid, *isolongifolic* acid, formed the main product of the reaction. This acid closely resembled *longifolic* acid in its properties and it was readily prepared from the latter acid by the action of mineral acids. The isomerisation was effected by the action of hydrogen bromide at 200°, by the action of concentrated sulphuric acid at 140°, and by boiling with sulphuric acid (*d* 1.6). The change was never complete, and separation of the mixture of the two acids by fractional crystallisation afforded considerable difficulty; if, however, the mixture of acids was converted into the methyl ester, separation was readily effected, since the methyl ester of the *iso*-acid had a slightly higher boiling point and crystallised well, whereas the methyl ester of *longifolic* acid was an oil. No evidence has so far been obtained which has enabled the author to determine whether these two acids are structural or stereoisomerides, since it has not proved possible to reconvert *isolongifolic* acid into *longifolic* acid, but it would appear probable that they are *cis*- and *trans*-isomerides.

A large number of experiments have been made with the object of degrading *longifolic* acid to simpler acids in order to determine the nature of the ring structure present. When it was oxidised with potassium permanganate in alkaline solution at 100°, the oxidation product was a viscid, resinous oil. The greater portion of the oil could not be induced to crystallise and evidently consisted of an extremely complex mixture of acids. It was found possible to separate only two acids in a pure state. One of these was readily identified as *as*-dimethylsuccinic acid, whilst the second acid, which was obtained in very small quantity only (0.1 gram from 50 grams of *longifolic* acid), was apparently an acid of the

formula $C_{10}H_{14}O_2$. This acid, which crystallised in magnificent prisms melting at $242-244^\circ$, was isomeric with teresantalinic acid (Semmler, *Ber.*, 1910, **43**, 1896) and it would appear closely to resemble this acid in its properties. Owing to the small yield of this acid, it was not possible to examine it in any detail and all efforts to improve the yield were unsuccessful.

When longifolic acid was treated with nitric acid, similar oxidation products were obtained, an uninviting viscid oil resulting, from which only oxalic acid and *as*-dimethylsuccinic acid could be separated.

Although the evidence afforded by these experiments is meagre, it would appear possible to devise a satisfactory formula for longifolene. The formation of a saturated monobasic acid, $C_{14}H_{22}O_2$, by the oxidation of the hydrocarbon definitely proves the presence of a tricyclic ring structure with an unsaturated side-chain and therefore the formula can be written $C_{13}H_{21}-CH:CH_2$. Further, since longifolic acid yields *as*-dimethylsuccinic acid, the presence of the group $-CMe_2-\dot{C}H-$ as part of the ring structure may be regarded as established.

Cogent reasons have been advanced (compare Ruzicka and Stoll, *Helv. Chim. Acta*, 1922, **5**, 923) for considering all sesquiterpenes as built up of three isoprene molecules. With this view the author is in accord. According to Ruzicka and Stoll, in the case of the sesquiterpenes of the cadinene group the relationship is shown by formula I, the naphthalene hydrocarbon, cadalene, being represented by II. The eudesmene group of sesquiterpenes is regarded as derived from III, yielding eudalene (IV), a methyl group being eliminated on formation of the naphthalene ring.*

It at once became obvious that it was not possible to regard longifolene as being derived from either of these "types," since they did not allow for the presence of an unsaturated side-chain $-CH:CH_2$. If, however, the three isoprene molecules are considered to be combined as in the skeleton formula V, then it becomes

* From the eudesmene "type," sesquiterpenes of the camphane group can be considered to be derived (*loc. cit.*, p. 929). The dotted lines in the formula indicate the isoprene molecules,

possible to devise what would appear to be a satisfactory formula for *d*-longifolene (VI).

In putting forward this formula for *d*-longifolene the fact must be emphasised that no definite evidence has been obtained regarding the nature of the ring structure present, and the formula can only be regarded as tentative. In view, however, of the very great stability of the hydrocarbon and also of longifolic acid, for which formula VII is suggested, it cannot be considered as probable that a cyclopropane ring is present in the molecule.* The proposed constitution for longifolic acid would agree well with the ascertained properties of this acid and it is clear that it would prove extremely difficult to obtain from it degradation products containing a simpler ring structure. Examination of the literature shows few cases of the successful oxidation of tricyclic acids of the terpene group. Apparently the only satisfactory observation was that made by Buchner (*Ber.*, 1913, 36, 767), who obtained from the condensation product of camphene and ethyl diazoacetate (VIII) cyclopropane-1 : 1 : 2-tricarboxylic acid (IX).

If VII be accepted as the formula of longifolic acid, the oxidation acid, $C_{10}H_{14}O_2$, m. p. 244° , referred to above, would probably be

* It is possible, although in the author's opinion not probable, that *d*-longifolene is represented by formula VI(a), in which case longifolic acid would have formula VII(a) and the isomerisation to *isolongifolic acid* might be due to an intramolecular rearrangement, the latter acid having formula VII.

represented by either formula X or XI. In view of the very weak acidic properties of this acid, formula XI would appear to be the more likely representation.

d-Longif-1 : 2-dione.

As was mentioned on page 2643, in addition to longifolic and isolongifolic acids a considerable quantity of a neutral oil was obtained from the oxidation of *d*-longifolene with either chromic acid or sodium dichromate and sulphuric acid. When this oil was carefully fractionated under diminished pressure, in addition to unchanged hydrocarbon, a sulphur-yellow, crystalline solid was separated which melted at 94–95°. Unfortunately the yield of this interesting substance was extremely small, rarely exceeding 2 grams from 100 grams of the hydrocarbon, and all attempts to increase it were unsuccessful. It has not, therefore, proved possible to investigate this substance in as great a detail as was desired.

On analysis, the substance was found to have the formula $C_{15}H_{22}O_2$ and since it reacted with the usual ketonic reagents yielding mono-derivatives, it therefore contained one carbonyl group. On reduction, an *alcohol*, $C_{15}H_{24}O_2$, resulted, whilst on acetylating reduction the *acetyl* derivative of the alcohol was formed. From its bright yellow colour—in appearance it closely resembled camphor-quinone—it appeared probable that the substance under examination was an ortho-diketone (orthoquinone), but for a long time experiments made with the object of establishing this were unsuccessful. It did not react with *o*-phenylenediamine under the ordinary conditions, but when the ketone was dissolved in acetic acid and heated for several hours with *o*-phenylenediamine hydrochloride, it was found to yield a *quinoxaline*. There can therefore be no doubt that this substance is an ortho-diketone and it is proposed to call it *d*-longif-1 : 2-dione or *d*-longifquinone.*

d-Longif-1 : 2-dione is a substance of considerable stability and has yielded a number of interesting derivatives.

* The rotation of the ketone itself was not determined, but the alcohol was dextrorotatory.

It was shown by Holleman (*Proc. K. Akad. Wetensch. Amsterdam*, 1904, 6, 715; compare Perkin, P., 1907, 23, 166) that when *o*-quinones were treated with hydrogen peroxide, especially in acetic acid solution, they underwent oxidation to the corresponding dibasic acid. It was found that *d*-longif-1:2-dione was not attacked by this reagent and even after prolonged digestion on the water-bath the whole of the ketone was recovered unchanged. When, however, the quinone was treated with a mixture of nitric and sulphuric acids under the conditions described on page 2661, a levorotatory dibasic acid, $C_{15}H_{24}O_4$, was obtained which melted at 225–227° and readily yielded an anhydride. For this acid the name *1- α -longiforic acid* is proposed. Like the quinone, this acid is extremely stable and has so far resisted all attempts to degrade it. When heated with hydrogen bromide, it was converted into an isomeric levorotatory acid melting at 197–198°, for which the name *1- β -longiforic acid* is suggested. This acid did not yield an anhydride when treated with acetyl chloride and therefore it would appear to be the *trans*-form of the acid melting at 225–227°. An attempt was therefore made to convert the β -acid into the anhydride of the α -acid by treatment with acetic anhydride (see p. 2662); the β -acid was, however, recovered unchanged and therefore there is at present no experimental evidence to support the view that these two acids are *cis*- and *trans*-isomerides.

The α -acid was also converted into the β -acid, together with an amorphous purple substance, when the acid chloride was treated with bromine at 100°. The mechanism of this reaction is obscure, but the β -acid was doubtless formed by the action of the hydrogen bromide liberated.

When the quinone was heated at 160° with an acetic acid solution of hydrogen bromide, a complex mixture of substances was obtained from which a small quantity of a *keto*-acid, $C_{15}H_{26}O_3$, melting at 88–90° was separated. This acid had been formed by the simple addition of water to the quinone, but the acid was not, as appeared probable at first, an aldehyde, since it was found to be stable to potassium permanganate in alkaline solution. The formation of a *keto*-acid would obviously involve a molecular rearrangement and on considering the nature of the reaction it is of interest to note that Manasse and Samuel (*Ber.*, 1897, 30, 3157; 1902, 35, 3831) showed that when camphorquinone was treated with concentrated sulphuric acid simple addition of water took place with the formation of a *keto*-acid of the formula $C_{10}H_{16}O_3$. This acid was fully characterised by the preparation of derivatives, but it would not appear to have been further investigated and its constitution has not been elucidated. In the hope of obtaining a larger yield

of the keto-acid, the action of sulphuric acid on *d*-longif-1 : 2-dione was tried, when it was found that the bulk of the quinone underwent sulphonation; no acid was formed and only a small quantity of a colourless, crystalline substance decomposing at 142° was separated. This substance has not yet been examined. It is proposed to examine the action of hydrogen bromide on camphor-quinone and also to investigate Manasse's acid, since the determination of the constitution of this acid may throw some light on the nature of the acid derived from longifquinone.

Results of some interest were obtained when longifquinone-monoxime was treated with benzenesulphonyl chloride in pyridine solution (compare Werner and Piguet, *Ber.*, 1904, 37, 4295; Beckmann and Liesche, *Ber.*, 1923, 56, [B], 1). The main product of the reaction was a beautifully crystalline substance of the formula $C_{30}H_{46}O_4N_2$ which melted at 182–183°, whilst in addition a cyano-acid, $C_{15}H_{23}O_2N$, was also isolated. The substance melting at 182–183° was insoluble in cold alkali, but yielded on treatment with alcoholic potassium hydroxide solution the cyano-acid referred to above and *d*-longifquinoneoxime. A clue to the nature of this substance was furnished by the work of Forster on the action of benzenesulphonyl chloride on isonitrosocamphor in pyridine solution (T., 1905, 87, 240). He obtained as the main product of the reaction an anhydride, $C_{20}H_{28}O_3N_2$, a substance which he had previously prepared from the isomeric benzoyl derivatives of isonitrosocamphor (T., 1903, 83, 530; 1904, 85, 907).^{*} This anhydride was considered to be best represented by formula XII, since when heated above its melting point it yielded the anhydride (XIII), whilst on treatment with alcoholic potassium hydroxide solution the cyano-acid (XIV) was formed.

The substance $C_{30}H_{46}O_4N_2$ would appear to have been formed in a somewhat similar manner, and may be regarded as the "N-ester" represented by formula XV, which would explain the formation

of the cyano-acid and oxime on hydrolysis with alcoholic potassium hydroxide solution. If this be the case, the correct formula for the substance would be $C_{30}H_{44}O_3N_2 \cdot H_2O$, the ester crystallising with

^{*} The author is much indebted to Dr. M. O. Forster, F.R.S., for directing attention to these papers, and also for the many other valuable suggestions he has made during the progress of this research.

2880 SIMONSEN: THE CONSTITUENTS OF INDIAN TURPENTINE

one molecule of water of crystallisation. Evidence in support of this was obtained, for when the ester was dried at 120° loss of weight took place and the resulting product gave analytical figures agreeing fairly closely with those required for the anhydrous substance $C_{30}H_{44}O_3N_2$.

The cyano-acid was extremely resistant to hydrolytic agents and could not be converted into the corresponding dibasic acid, but from its method of formation it was doubtless the half nitrile of longiforic acid.

It now remains to consider the constitution which should be accorded to the quinone. Owing to the limited quantity of material available and the great stability of all the substances which have been prepared, it has not proved possible to separate products throwing any light on the nature of the ring structures present and therefore the following formulæ are suggested with reserve. It has been assumed that longifquinone is formed from longifolene, for which the constitution represented by formula VI has been suggested, but the possibility cannot be ignored, in view of the small yield of the product, that it may originate from a small amount of an isomeric terpene present in the oil.

In the formation of the quinone, fission of one of the rings present in the terpene must have taken place, since both the terpene and the quinone are tricyclic. It would appear to be most probable that it is the cyclobutane ring which has undergone disruption with formation of an intermediate substance represented by formula XVI. This substance in the presence of water could then undergo

condensation, yielding either XVII or XVIII, which on oxidation would give the quinones represented by formulæ XIX and XX. If these formulæ be examined on the models, it will be observed that XX involves a very strained ring structure, whilst XIX is comparatively free from strain and in addition the carbon atoms (1) and (2) (XVI) are in close juxtaposition to one another. It may legitimately be urged against formula XIX that it contains the very unusual structure of a *cyclobutane-1:2-dione*. So far as the author is aware, 1:2-diketones of the *cyclobutane* series have not been prepared; on the other hand, the 1:3-diketones are readily formed as polymerisation products of the ketens (Staudinger, "Die Ketene," p. 46), and some of these have been shown to be substances of very considerable stability. From our knowledge of the properties of the *cyclobutane* ring it is likely that *cyclobutane-1:2-diones* of the general formula XXI would be stable when once formed.

The observed properties of the quinone would be satisfactorily accounted for by formula XIX and the non-reactivity of one of the keto-groups (3, XIX) is explained by its attachment to a tertiary carbon atom. Accepting formula XIX for the quinone, the alcohol formed on reduction would be represented by XXII and longiforic acid by XXIII.

It is hoped that the further experiments which are in progress may throw light on the constitution of this interesting sesquiterpene.

EXPERIMENTAL.

Although longifolene is an unsaturated hydrocarbon, it is extremely resistant to oxidation with potassium permanganate. Even when heated on the water-bath with excess of an alkaline solution of this reagent for some days, nearly the whole of the hydrocarbon was recovered unchanged, whilst no better results were obtained when acetone was used as a solvent. The hydrocarbon reacted vigorously with nitric acid, the reaction tending to proceed with explosive violence, but although various strengths of acid were employed, it was not found possible to separate any homogeneous products. Much more satisfactory results were obtained when either chromic acid in acetic acid solution or a mixture of sodium dichromate and

sulphuric acid was allowed to react with the hydrocarbon. Since the products formed were different, both methods of oxidation are described below.

I. *Oxidation of d-Longifolene with Chromic Acid. Longifolic Acid,*
 $C_{14}H_{22}O_2$.

To the hydrocarbon * (100 grams), mixed with acetic acid (500 c.c.), chromic acid (200 grams) dissolved in water (200 c.c.) was gradually added. The oxidation proceeded with considerable evolution of heat and it was found desirable to cool the mixture from time to time, care being taken, however, that the oxidation did not cease, as otherwise the yield was impaired. During the early stages of the oxidation a viscid, red oil separated, and redissolved as the reaction proceeded. When all the chromic acid solution had been added, the reaction mixture was heated on the water-bath, the clear green solution obtained was cooled, water (1 litre) added, and the oil which separated extracted with ether. The extract was well washed with water and evaporated, and the residual viscid green oil was digested with an excess of sodium hydroxide solution, filtered, and once more extracted with ether. During the extraction three layers formed, an ether layer surmounting a deep brown solution of the sodium salts of the oxidation acids and below this a clear aqueous solution. The two lower layers were drawn off, and the yellow, ethereal solution was shaken repeatedly with sodium hydroxide solution and water to remove all traces of acids (the washing was continued until the aqueous solution no longer became turbid on acidification), dried over potassium carbonate, and evaporated, when a pale yellow oil remained the investigation of which is described on p. 2659.

The combined alkaline extracts were acidified, when a viscid, brown oil separated which slowly partly crystallised. The oil was taken up with ether, the ether dried and evaporated, and the brown, semi-solid residue (70—80 grams) was mixed with an equal weight of hot formic acid (d 1.22) and kept for some days in the ice-chest, when the greater part of the acid separated as a hard, colourless, crystalline cake.† This, after draining on porous porcelain, melted somewhat indefinitely, softening at 133° and melting at 141 — 143° . The acid was purified by repeated crystallisation from either alcohol (90 per cent.) or light petroleum, in both of which

* All the *d*-longifolene used in the experiments described was purified by distillation over sodium under diminished pressure.

† The formic acid filtrate yielded on evaporation an oily mixture of longifolic acid, longif-1:2-dione, and liquid acids which have not up to the present been examined.

solvents it was so very readily soluble that purification was attended with considerable loss of material.

Longifolic acid was ultimately obtained in large, glistening prisms which softened at 149° and melted at $152\text{--}153^{\circ}$ (Found : C = 75.6; H = 9.9. $C_{14}H_{22}O_2$ requires C = 75.6; H = 10.0 per cent.). The acid, which was optically inactive, was quite insoluble in water, but extremely readily soluble in all the ordinary organic media with the exception of formic acid, in which it was very sparingly soluble even on boiling. When titrated in alcoholic solution with a standard alcoholic solution of potassium hydroxide, 0.12 gram neutralised 0.00297 gram of the alkali, whereas a monobasic acid of the formula $C_{14}H_{22}O_2$ should neutralise 0.00303 gram. In small quantities, longifolic acid distilled unchanged at the ordinary pressure; it boiled at about $234^{\circ}/55$ mm. In its general properties, longifolic acid resembled the higher fatty acids and abietic acid. It was a weak acid and could readily be extracted by ether from an aqueous solution of its salts, that property rendering its separation from neutral products very tedious. When it was mixed with sodium hydroxide solution, an oily sparingly soluble *sodium* salt separated which could not be obtained crystalline. The *calcium*, *barium*, *copper*, and *lead* salts were obtained as sparingly soluble, amorphous solids, whilst the *silver* salt separated from a faintly alkaline solution of the *ammonium* salt in alcohol as a caseous, white precipitate (Found : Ag = 32.7. $C_{14}H_{21}O_2Ag$ requires Ag = 32.8 per cent.).

An alkaline solution of longifolic acid was stable to potassium permanganate in the cold, but the warm solution was slowly oxidised; in acid solution, no action took place even on boiling. In chloroform solution, it did not absorb bromine and all attempts to obtain bromo-derivatives by the action of bromine on the acid chloride were unsuccessful. The great stability of the acid was shown by the fact that after fusion with potassium hydroxide at 300° for half an hour it was recovered unchanged. It could be recrystallised from nitric acid (d 1.4) and was only slowly oxidised by this acid at 100° . In concentrated sulphuric acid, longifolic acid dissolved, yielding a colourless solution from which the acid was precipitated unchanged on the addition of water.

Methyl Longifolate.—This ester was readily obtained in a quantitative yield when the sodium salt of the acid was treated with methyl sulphate. It was a colourless, mobile oil which distilled at $170\text{--}173^{\circ}/14$ mm. and did not crystallise when cooled to -15° (Found : C = 76.6; H = 10.2. $C_{15}H_{24}O_2$ requires C = 76.3; H = 10.2 per cent.).

II. Oxidation of d-Longifolene with Sodium Dichromate and Sulphuric Acid. isoLongifolic Acid.

In carrying out this oxidation, the following method was found to yield the most satisfactory results. The terpene (100 grams), mixed with acetic acid (500 c.c.), was treated with sodium dichromate (298 grams) in water (700 c.c.), and sulphuric acid (196 c.c.) gradually added. During the earlier stages of the oxidation the temperature was kept at about 50° by cooling, but towards the end of the reaction the mixture was heated on the water-bath until a clear green solution was obtained. Water (800 c.c.) was then added and after remaining over-night a mass of crystals permeated with a viscid oil had separated. The oxidation product was worked up as described above (p. 2652) and the resulting acid after crystallisation from formic acid melted at 110–130°.

The purification of the acid mixture was best carried out by means of the *methyl* ester, which was readily obtained by treatment of the sodium salt with methyl sulphate. The ester distilled between 174–185°/25 mm. and three fractions, 174–177°, 177–180°, and 180–185°, were taken. On keeping for some days in a cool place, the latter two fractions gradually crystallised in fine needles. These were collected and the liquid ester refractionated, when a further quantity of the solid ester was obtained.*

Methyl isolongifolate crystallised from methyl alcohol in long, thin, colourless prisms which melted at 54–55° (Found : C = 76.7; H = 10.5. $C_{15}H_{24}O_2$ requires C = 76.3; H = 10.2 per cent.).

isoLongifolic acid was obtained when the crystalline ester was hydrolysed with alcoholic potassium hydroxide solution. The hydrolysis took place extremely slowly and at least twelve hours' boiling on the water-bath was required for its completion.†

isoLongifolic acid crystallised from acetic acid in glistening, prismatic needles which melted at 136° (Found : C = 75.6; H = 10.1. $C_{14}H_{22}O_2$ requires C = 75.6; H = 10.0 per cent.). On titration with standard potassium hydroxide solution, 0.1465 gram neutralised 0.00365 gram KOH, whereas this amount of a monobasic acid of the formula $C_{14}H_{22}O_2$ should neutralise 0.00369 gram.

In its general properties, *isolongifolic acid* was indistinguishable from *longifolic acid* except that it was somewhat more sparingly soluble in the ordinary organic media. When mixed in equimolecular proportions, the acids are deposited from solvents as an oil

* From the liquid ester nearly pure *longifolic acid* was obtained on hydrolysis.

† Methyl *longifolate* is hydrolysed less readily than methyl *isolongifolate*, and it is probable that this property might be used for the separation of a mixture of these acids.

and the separation by crystallisation of a mixture of the two acids affords considerable difficulty.

Reduction of Methyl isoLongifolate. isoLongifolol, C₁₄H₂₄O.

In one experiment, the methyl ester (10 grams), dissolved in alcohol (50 c.c.), was gradually added to sodium (20 grams), the flask being kept on a boiling water-bath. When all the sodium had passed into solution (a further quantity of alcohol being added if necessary), the reduction product was poured into water and the alcohol isolated by means of ether in the usual manner. On removal of the ether, *isolongifolol* remained as a crystalline solid (yield 6 grams). It separated from light petroleum, in which it was somewhat sparingly soluble in the cold, in silky needles which melted at 112–114° (Found: C = 81.0; H = 11.7. C₁₄H₂₄O requires C = 80.8; H = 11.5 per cent.).

The *phenylurethane*, which was prepared by heating the alcohol with the calculated quantity of phenylcarbimide in light petroleum solution, separated on evaporation of the solvent as an extremely viscid oil, which after standing for some weeks crystallised. It was purified by recrystallisation from dilute methyl alcohol, from which it was obtained in fine needles melting at 91–92°. It was extremely readily soluble in all the ordinary solvents (Found: N = 4.6. C₂₁H₂₉O₂N requires N = 4.2 per cent.).

The *methyl xanthate* could not be obtained crystalline and all attempts to convert it into the hydrocarbon by distillation were unsuccessful.

isoLongifolaldehyde, C₁₄H₂₂O.

A solution of the alcohol (9.2 grams) in benzene (80 c.c.) was gradually treated with a mixture of potassium dichromate (7.4 grams), sulphuric acid (9.2 grams), and water (100 c.c.). Oxidation proceeded slowly and was completed by warming on the water-bath. On distillation in steam after the benzene had passed over, a small quantity of a pale yellow oil distilled. This was collected separately, extracted with ether, and, after removal of the solvent, distilled under diminished pressure, when the whole passed over at about 170°/35 mm. (yield 2 grams). Owing to the small quantity of material available, it could not be further purified and therefore it was converted into the *semicarbazone*, which crystallised from alcohol in rosettes of glistening needles decomposing at 210° (Found: C = 68.6; H = 9.7. C₁₅H₂₅ON₃ requires C = 68.4; H = 9.5 per cent.).

The residue remaining in the flask after the steam distillation of the aldehyde yielded *isolongifolic acid* melting at 136° (yield 4.1 grams).

Conversion of Longifolic Acid into isoLongifolic Acid.

On treatment with mineral acids, longifolic acid was converted into isolongifolic acid. The following method was found to be the most convenient. A mixture of longifolic acid (5 grams) with hydrogen bromide dissolved in acetic acid (saturated at 0°; 15 grams) was heated in a sealed tube at 200° for four hours. On the addition of water, a viscid oil separated which rapidly became pasty. The aqueous solution was decanted and the semi-solid residue dissolved in hot formic acid, when, on keeping, a crystalline acid was slowly deposited. This was purified by repeated crystallisation from acetic acid, when pure isolongifolic acid was ultimately obtained melting at 136°. The identity of the acid was confirmed by the method of mixed melting point and by analysis (Found: C = 75.6; H = 10.1. Calc., C = 75.6; H = 10.0 per cent.).

isoLongifolic acid was also formed when longifolic acid was heated with concentrated sulphuric acid at 130° for a short time or boiled with sulphuric acid (*d* 1.6). Considerable carbonisation took place during these experiments and therefore the process was not suitable for the preparation of the acid.

Longifolamide.

A mixture of longifolic acid (15 grams), dissolved in benzene (150 c.c.), and phosphorus pentachloride (15 grams) was heated on the water-bath for half an hour. The cooled reaction mixture was saturated with dry ammonia and kept for some hours, ammonia being passed into the liquid from time to time. After remaining over-night, water was added and the benzene was separated and repeatedly washed with dilute sodium hydroxide solution to remove unchanged acid, dried, and evaporated, when a viscid oil remained which on trituration with light petroleum crystallised. The amide was collected, drained on porous porcelain to remove a little adherent oil, and purified by crystallisation from light petroleum. The yield was very poor and a considerable quantity of acid was recovered.

Longifolamide crystallised in rosettes of glistening needles which melted sharply at 133° (Found: N = 6.4. $C_{14}H_{23}ON$ requires N = 6.3 per cent.). In view of the low melting point of the amide it appeared probable that it was a mixture of the amides of longifolic and isolongifolic acids. Attempts to separate these by fractional crystallisation were unsuccessful, but that the amide was a mixture was confirmed by the fact that on hydrolysis by the Bouveault method a mixture of longifolic and isolongifolic acids resulted. A small quantity of the amide recovered from the hydrolysis had the original melting point, and therefore preferential hydrolysis had

not taken place. An attempt to convert the amide into the amine by the Hoffmann reaction was unsuccessful, the greater portion of the amide being recovered unchanged.

From longifolamide a *urethane* was obtained by Jeffreys's method (*Amer. Chem. J.*, 1899, 22, 14). The amide (5 grams), dissolved in methyl alcohol (15 c.c.), was cooled in a freezing mixture, sodium methoxide (methyl alcohol 25 c.c.; sodium 1.04 grams) added, and the mixture treated immediately with bromine (3.62 grams). After warming on the water-bath for ten minutes, the solution was neutralised with acetic acid and the alcohol removed, when a viscid oil remained. This was taken up with ether, the ether dried and evaporated, and the residual oil distilled under diminished pressure (46 mm.), when the greater portion passed over at 223–225°. The *urethane* was an extremely viscid oil which, after keeping for some months, solidified. It was excessively soluble in all organic solvents and could not be recrystallised. It melted somewhat indefinitely at about 60°, a value which is subject to revision, since the substance was evidently not quite pure (Found: N = 5.3. $C_{15}H_{25}O_2N$ requires N = 5.6 per cent.).

isoLongifolanilide.—*isoLongifolic acid* (1 gram) was treated with a slight excess of phosphorus trichloride at 30°. When the reaction was complete the excess of the trichloride was removed in a vacuum, and the residual oil was dissolved in benzene, decanted from the phosphorous acid, and mixed with a slight excess of aniline in benzene solution. After remaining over-night, the solvent was removed and the residual solid triturated with dilute hydrochloric acid and collected. It was purified by crystallisation from benzene, in which it was only sparingly soluble in the cold, when *isolongifolanilide* separated in fine needles which melted at 197° (Found: N = 4.9. $C_{20}H_{27}ON$ requires N = 4.7 per cent.).

When longifolic acid was subjected to the same series of reactions, an anilide was obtained which melted at about 120°. Fractional crystallisation resulted in the separation of a small quantity of the pure anilide of *isolongifolic acid* melting at 197°, but all attempts to separate the anilide of longifolic acid in a pure state were unsuccessful, the two anilides forming apparently a eutectic mixture.

Oxidation of Longifolic Acid with Potassium Permanganate.

A large number of experiments were made with the object of devising a satisfactory method for the oxidation of longifolic acid with potassium permanganate. As has already been mentioned, the main product of the oxidation was in all cases a viscid, uninviting resinous oil which could not be induced to crystallise and from which

crystalline derivatives could not be obtained on treatment with a variety of reagents. A brief account is given of the separation of *as*-dimethylsuccinic acid and of the crystalline acid of the formula $C_{10}H_{14}O_2$.

In one experiment, a solution of longifolic acid (25 grams) in aqueous sodium carbonate (10 grams Na_2CO_3) was heated on the water-bath and potassium permanganate solution (5 per cent. $KMnO_4$) gradually added. The oxidation, which proceeded fairly rapidly at first, became very slow after the addition of about half of the permanganate solution, and at least twelve hours were required for its completion. The manganese dioxide was separated and the clear golden-yellow solution concentrated to a small bulk on the water-bath. On acidification, a viscid oil separated, which was taken up with ether, the ether dried and evaporated (yield 25 grams). The brown resinous acid, which on cooling in a freezing mixture set to the consistency of colophony and was somewhat hygroscopic, was dissolved in excess of ammonia, and the solution, filtered from a little insoluble oil, was concentrated on the water-bath. A crystalline solid was slowly deposited and after remaining over-night in the ice-chest was collected (yield 0.05 gram). The acid was purified by repeated crystallisation from acetic acid, from which solvent it was obtained in large, striated, iridescent prisms which melted at 244° (Found: C = 72.5, 72.4; H = 8.2, 8.5. $C_{10}H_{14}O_2$ requires C = 72.3; H = 8.4 per cent.). This acid, the constitution of which is discussed on p. 2646, was found to be a very weak acid, being readily deposited from an aqueous solution of the ammonium salt on warming. It was insoluble in water, very sparingly soluble in ether or benzene, and more readily so in ethyl acetate or acetic acid. It did not yield any characteristic salts.

The ammoniacal solution from which this acid had been separated was acidified and the recovered acid converted into the ethyl ester by treatment with alcohol and sulphuric acid in the usual manner. On fractionation of the ester under diminished pressure (29 mm.) after a small fraction had passed over below 200° , the remainder of the oil distilled irregularly between 200 — 270° , yielding no homogeneous fraction.

The fraction which boiled below 200° had a pleasant fruity odour. It was hydrolysed with alcoholic potassium hydroxide solution and the resulting acid, which was extracted with ether, crystallised completely on removal of the solvent. It was purified by conversion into the sparingly soluble calcium salt, which separated from the boiling solution. After crystallisation from benzene, the acid melted sharply at 139 — 140° and was identified as *as*-dimethyl

succinic acid by analysis (Found: C = 48.9; H = 6.9. Calc., C = 49.3; H = 6.9 per cent.) and by the preparation of the anilic acid melting at 189–190° and the anil melting at 85–87° (compare Perkin, T., 1898, 73, 842). The filtrate from which the sparingly soluble salt of *as*-dimethylsuccinic acid had been separated yielded a small quantity of an acid which melted at about 127°, but it was not obtained in sufficient quantity for purification.

d-Longif-1 : 2-dione (Longifquinone), $C_{15}H_{22}O_2$.

The ether extract containing the neutral oil from the oxidation of longifolene (see p. 2652) was well washed with sodium hydroxide solution to remove all traces of acid and with water and dried over potassium carbonate. The pale yellow viscid oil remaining after the removal of the ether was repeatedly distilled under diminished pressure (43 mm.), when ultimately two main fractions resulted, boiling at 140–160° and 210–240°. The first fraction consisted essentially of unchanged hydrocarbon, whilst the second, which was sulphur-yellow in colour and exhibited a strong greenish-yellow fluorescence when viewed in a thin film, partly crystallised on keeping. The solid was collected, drained on porous porcelain, and recrystallised from alcohol, when the *quinone* separated in sulphur-yellow needles which melted at 93–94°. If a dilute alcoholic solution of the *quinone* was allowed to evaporate slowly, the *quinone* was obtained in massive rhombohedra (Found: C = 76.8, 77.1; H = 9.5, 9.7. $C_{15}H_{22}O_2$ requires C = 76.9; H = 9.4 per cent.).

d-Longif-1 : 2-dione was readily soluble in all the ordinary organic media with the exception of alcohol, in which it was somewhat sparingly soluble in the cold. It was quite insoluble in water or in alkalis. In small quantities it distilled unchanged at the ordinary pressure. It dissolved in nitric acid (*d* 1.4) and was precipitated unchanged on the addition of water. It was not attacked by potassium permanganate solution in either acid or alkaline solution even on boiling, and it did not react with bromine at the ordinary temperature. As has already been mentioned, it was not oxidised by hydrogen peroxide when heated with this reagent in acetic acid solution. It did not react with benzaldehyde or piperonal in alkaline solution nor with amyl nitrite in acid solution.

The *monosemicarbazone*, prepared in the usual manner, crystallised from dilute acetic acid in rosettes of very pale yellow needles which softened at 188° and decomposed at 214–216° (Found: N = 14.6. $C_{16}H_{25}O_2N_3$ requires N = 14.6 per cent.). An examination of the mother-liquor from which the *semicarbazone* had been separated indicated the presence of a second *semicarbazone* which has not up to the present been investigated.

The *monophenylhydrazone* was precipitated as a sparingly soluble, yellow, crystalline powder when the quinone was warmed on the water-bath with a solution of phenylhydrazine in acetic acid. It crystallised from alcohol in thin, iridescent plates which melted at 129–130° (Found: C = 77.5; H = 8.4; N = 9.1. $C_{21}H_{23}ON_2$ requires C = 77.8; H = 8.6; N = 8.6 per cent.).

The *mono-p-bromophenylhydrazone* crystallised from acetic acid in long, yellow, prismatic needles which melted at 159° (Found: Br = 20.0. $C_{21}H_{27}ON_2Br$ requires Br = 19.9 per cent.).

The *monoxime* was obtained in quantitative yield when the quinone was heated on the water-bath in alcoholic solution with a slight excess of hydroxylamine hydrochloride for some hours. It was purified by crystallisation from light petroleum, in which it was only sparingly soluble, when it was obtained in rosettes of needles which decomposed at 226–227° (Found: C = 72.6; H = 9.2; N = 5.7. $C_{15}H_{23}O_2N$ requires C = 72.3; H = 9.2; N = 5.6 per cent.). A careful examination of the mother-liquors from which the oxime had been separated revealed the presence of a second oxime, which melted at about 180°. The quantity obtained was too small for further investigation.

The monoxime dissolved in dilute sodium hydroxide solution, yielding a yellow solution from which it was precipitated by carbon dioxide. It was insoluble in mineral acids and its alcoholic solution gave no colour with ferric chloride. In alcoholic solution it was strongly dextrorotatory, $[\alpha]_D^{20} + 121.3^\circ$ being observed.

The *acetyl* derivative crystallised from methyl alcohol in thin prisms melting at 127°.

Action of o-Phenylenediamine on d-Longif-1:2-dione.

The quinone was found to react very tardily with *o*-phenylenediamine. In one experiment, the quinone was dissolved in acetic acid and boiled for four hours with an excess of *o*-phenylenediamine hydrochloride. When the solution was cooled and poured into water, an oil separated which rapidly crystallised. The solid was collected and purified by crystallisation from methyl alcohol, being obtained in colourless, glistening needles which melted at 134°. The *quinoxaline* derivative of the quinone was insoluble in alkali but dissolved in concentrated hydrochloric acid, yielding a yellow solution, and was reprecipitated on dilution with water (Found C = 82.7; H = 8.8. $C_{21}H_{26}N_2$ requires C = 82.3; H = 8.5 per cent.).

Reduction of d-Longif-1:2-dione. d-Longif-1-cl-2-one.

When zinc dust was gradually added to the boiling solution of the quinone (1 gram) in acetic acid (25 c.c.), the yellow colour di-

appeared, and on heating for fifteen minutes a colourless solution was obtained. After filtering from unchanged zinc dust, the acetic acid solution was diluted with water, when *d-longif-1-ol-2-one* slowly crystallised in colourless needles. After crystallisation from dilute alcohol, it melted at 115–117° (Found: C = 76.7; H = 10.2. $C_{15}H_{24}O_2$ requires C = 76.5; H = 10.2 per cent.). In alcoholic solution, $[\alpha]_D^{20} + 100.8^\circ$ was observed.

The alcohol was found to be very readily soluble in all the ordinary organic solvents and quite insoluble in water. Both in solution and in the dry state it was very readily oxidised by the air with regeneration of the quinone. In alcoholic solution it gave no colour with ferric chloride. In dry chloroform solution it was not attacked by bromine, but in presence of moisture oxidation to the quinone took place.

The same product was also formed when the quinone was reduced with zinc dust in alcoholic ammonia solution or by sodium in amyl-alcoholic solution. It was not found possible to reduce the second keto-group.

When boiled with acetic anhydride, the alcohol was readily acetylated with formation of *d-acetyl-longif-1-ol-2-one*. This substance was, however, much more readily prepared by the reduction of the quinone with zinc dust in the presence of acetic anhydride. The acetyl derivative crystallised from either dilute acetic acid or dilute alcohol in colourless prisms which melted at 90–91° (Found: C = 73.0; H = 9.7. $C_{17}H_{26}O_3$ requires C = 73.4; H = 9.3 per cent.).

1- α -Longiforic Acid.

The quinone was readily oxidised by a mixture of nitric and sulphuric acids. In one experiment, the quinone (8 grams) was added gradually to a mixture of nitric acid (*d* 1.4; 10 c.c.) and sulphuric acid (*d* 1.84; 2 c.c.); the ketone rapidly passed into solution, the temperature being kept at about 10° by cooling in ice. The clear yellow solution was kept for about thirty minutes and then poured on to ice, when a caseous, white, crystalline precipitate separated. This was collected, well washed with water, and dissolved in an excess of barium hydroxide solution, when a small quantity of a sparingly soluble red barium salt remained undissolved. This was removed, the clear filtrate acidified, and the acid collected and recrystallised from ethyl acetate, from which it separated in glistening, iridescent rhombohedra (Found: C = 67.1, 66.9; H = 8.8, 9.2. $C_{15}H_{24}O_2$ requires C = 67.1; H = 8.9 per cent.). In alcoholic solution, $[\alpha]_D^{20} - 23.47^\circ$.

1- α -Longiforic acid sintered at 217° and melted with slight decomposition at 225–227°. It was very readily soluble in methyl or
4 U*

ethyl alcohol, acetone, or acetic acid, somewhat readily soluble in hot ethyl acetate, but very sparingly soluble in other solvents. Its alkaline solution was stable to potassium permanganate, and in acetic acid solution it did not absorb bromine, nor was it attacked by chromic acid in the same solvent even in boiling solution.

When the acid was heated on the water-bath with acetyl chloride for a short time and the excess of acetyl chloride removed under diminished pressure, a viscid oil remained which on keeping slowly crystallised in fine needles. Owing to its excessive solubility in all solvents, attempts to purify this substance were unsuccessful, but there can be little doubt that it was the *anhydride* of the acid. It was insoluble in cold alkalis, but on boiling with water it was reconverted into 1- α -longiforic acid. On treatment of the anhydride with aniline in benzene solution the *anilic acid* was obtained as an amorphous, white powder which could not be obtained crystalline.

The *methyl ester*, prepared from the silver salt by treatment with methyl iodide in the usual manner, crystallised from alcohol in bayonet-shaped needles which melted at 94–95° (Found : C = 69.0; H = 9.6. $C_{17}H_{28}O_4$ requires C = 68.9; H = 9.5 per cent.).

Action of Hydrogen Bromide on 1- α -Longiforic Acid. 1- β -Longiforic Acid.

The α -acid (1 gram) was mixed with a solution of hydrogen bromide in acetic acid (saturated at 0°, 5 c.c.) and heated in a sealed tube at 140° for three hours. The clear brown solution was poured into water, when an acid rapidly crystallised. It was purified by recrystallisation from dilute alcohol, when it was obtained in well formed, prismatic needles (Found : C = 67.1; H = 8.5. $C_{15}H_{24}O$ requires C = 67.1; H = 8.9 per cent.). In alcoholic solution, it was laevorotatory, $[\alpha]_D^{20}$ –49.3°.

1- β -Longiforic acid melted at 197–198°, sintering slightly below this temperature. It was very readily soluble in the ordinary organic solvents with the exception of cold formic acid, in which it was very sparingly soluble. The *calcium salt*, which was amorphous, was characterised by the fact that it was readily soluble in cold water, but only sparingly soluble in hot.

On titration with standard alkali, 0.1652 gram neutralised 7.8 c.c. of a standard solution of potassium hydroxide, whereas a dibasic acid, $C_{15}H_{24}O_4$, should neutralise 7.7 c.c.

Unlike the α -acid, 1- β -longiforic acid did not yield an anhydride when treated with acetyl chloride. An attempt was made to reconvert it into the α -acid by treatment with acetic anhydride but the acid was recovered unchanged after having been heated with this reagent for six hours at 220° in a sealed tube.

Like the α -acid, the β -acid was stable to potassium permanganate in alkaline solution and in chloroform solution it did not absorb bromine. The *methyl ester*, prepared from the silver salt, was a viscid oil which was not further examined.

Action of Bromine on 1- α -Longiforic Acid.

In one experiment, the acid (1.6 grams) was mixed with phosphorus pentachloride (2.7 grams) and after the formation of the acid chloride was complete, bromine (2 grams) was added and the mixture heated in a sealed tube at 100°. The bromine rapidly disappeared and after two hours the cooled bromination product was poured into formic acid. A deep purple solution resulted and after warming on the water-bath until the acid chloride was completely decomposed the solution was kept over-night, when a hard, black, crystalline cake had separated. This was collected, ground up with dilute sodium carbonate solution, and the deep purple solid which remained undissolved was removed. On acidification, the colourless alkaline solution deposited a caseous, white precipitate, which after drying on porous porcelain melted at 196°. It was recrystallised from formic acid, when it melted at 197–198° and was identified as β -longiforic acid. The purple solid which was insoluble in alkali could not be obtained crystalline and was not further examined.

Action of Hydrogen Bromide on d-Longif-1 : 2-dione.

The quinone (5 grams) was mixed with an acetic acid solution of hydrogen bromide (saturated at 0°; 15 c.c.) and heated in a sealed tube at 160° for ten hours. The pale brown solution was evaporated on the water-bath to remove the volatile acids, when a viscid, brown oil remained. The oil was dissolved in ether and the ethereal extract well washed with sodium carbonate solution, dried, and evaporated. The residual oil, which could not be induced to crystallise, was a mixture of unattacked quinone, which was identified by its characteristic phenylhydrazone, and a substance containing bromine. The latter substance could not be obtained pure.

On acidification, the alkaline solution deposited a brown oil; this was taken up with ether, the ether dried and evaporated, and the residual oil dissolved in ammonia. On treatment of the boiling, slightly alkaline solution with calcium chloride, a sparingly soluble, resinous, brown calcium salt separated. This was removed and, on standing, the filtrate deposited a colourless, crystalline calcium salt (yield 1 gram). On decomposition of the crystalline calcium salt with hydrochloric acid, an oily acid separated which slowly crystallised. The purification of the acid was attended with considerable difficulty owing to its ready solubility in solvents and its

tendency to be deposited as an oil. The following method was ultimately adopted, although not altogether satisfactory and involving considerable loss of material.

After draining on porous porcelain, the crude acid, which contained a viscid, oily impurity, was dissolved in dry ether and the solution allowed to evaporate slowly, when the acid crystallised in glistening prisms which were, however, still contaminated with a trace of oil. After two further crystallisations from ether, the acid was finally twice recrystallised from dilute acetic acid, when it was obtained in prisms melting at 88–90° (Found: C = 71.6, 71.3; H = 9.7, 9.7. $C_{15}H_{24}O_3$ requires C = 71.4; H = 9.5 per cent.). This new acid, which was quite stable to potassium permanganate in alkaline solution, reacted readily with semicarbazide acetate to yield a semicarbazone which decomposed at about 207°. Owing to the very small quantity of material available, it could not be further investigated.*

*Action of Benzenesulphonyl Chloride on d-Longif-1:2-dione-
monoxime.*

In one experiment, the oxime (7.3 grams) was dissolved in pure dry pyridine (25 c.c.) and to the solution benzenesulphonyl chloride (7.3 grams) was added all at once. The reaction mixture became warm and the colour slowly changed from brown to purple. After thirty minutes, a further quantity of pyridine (25 c.c.) was added to the mixture, which was then heated for one hour on the water-bath, the purple colour disappearing and a dirty brown solution being obtained. The cooled liquid was poured into dilute sulphuric acid (25 per cent.; 200 c.c.), when a viscid, reddish-brown oil separated. The clear acid solution was decanted, and the oil extracted with ether, when a crystalline solid (A) remained undissolved (yield 6 grams).

The ether, which was deep red in colour, was evaporated and the

* In view of the possible relationship of this keto-acid to the keto-acid, $C_{15}H_{24}O_3$, prepared by Manasse (*loc. cit.*) (see p. 2648) from camphorquinone, the action of sulphuric acid on *d*-longif-1:2-dione was investigated, since it was hoped that the above-mentioned keto-acid might be obtained in a better yield. At the ordinary temperature, the quinone dissolved in sulphuric acid, yielding a yellow solution, which became red on keeping and on pouring into water deposited a purple solid. When the reaction was allowed to proceed at 0° and the acid solution was poured on to ice, a pink solution resulted from which a small quantity of a neutral colourless solid separated. This crystallised from alcohol in serrated prisms melting at 142° with vigorous evolution of gas. The amount obtained was too small for analysis. The greater part of the quinone appeared to be sulphonated and no trace of the keto-acid melting at 88–90° was formed.

residual red oil triturated with dilute potassium hydroxide solution, the portion remaining undissolved being added to A. The alkaline filtrate was saturated with carbon dioxide, when a small quantity of a colourless solid separated which was identified as unattacked oxime.

On acidification of the potassium carbonate solution a crystalline acid separated. This was collected and recrystallised from a mixture of benzene and light petroleum, when it was obtained in glistening leaflets which melted at 127° and was identified as the *cyno-acid* described below.

The main product of the reaction (A) was purified by repeated crystallisation from alcohol (90 per cent.), when it was ultimately obtained in faintly brown, glistening, prismatic needles which melted at $182-183^{\circ}$ and decomposed slightly above this temperature. For analysis, it was dried at 100° [Found: C = 72.4; H = 9.2; N = 5.9; *M*, in freezing benzene, = 492 (mean). $C_{30}H_{44}O_3N_2 \cdot H_2O$ requires C = 72.3; H = 9.2; N = 5.6 per cent.; *M* = 498].

When dried at 120° until constant in weight, the substance gave figures approximating to those required for the anhydrous substance, but slight decomposition appeared to have taken place, although the melting point was unaltered (Found: C = 75.9; H = 9.2. $C_{30}H_{44}O_3N_2$ requires C = 75.0; H = 9.2 per cent.). In benzene solution, $[\alpha]_D^{25} + 81.67^{\circ}$ was observed. The probable constitution of this substance has already been discussed (p. 2649).

The anhydride, which was quite insoluble in cold alkalis, was not attacked by hot alcoholic ammonia, but when warmed for a short time with alcoholic potassium hydroxide solution it was rapidly decomposed. The solution, which was pale yellow in colour, was diluted with water, when a very small quantity of an oil separated; this was taken up with ether (A) and the alkaline liquid evaporated on the water-bath until free from alcohol. The cold solution was saturated with carbon dioxide and the solid which separated was collected. After crystallisation from light petroleum, it melted at $225-227^{\circ}$ and was identified as *d*-longif-1:2-dionemonoxime by conversion into the acetyl derivative melting at 127° .

On acidification of the potassium carbonate solution with acetic acid, a crystalline solid separated. This was collected and purified by crystallisation from either dilute methyl alcohol or light petroleum, from both of which solvents it was obtained in glistening leaflets melting at 127° .

The *cyno-acid*, the constitution of which has already been discussed (p. 2649), was insoluble in water, but very readily soluble in all the ordinary organic solvents except light petroleum. It yielded sparingly soluble, but amorphous, barium, calcium, and copper salts.

On titration it was found to be a monobasic acid (Found: C = 72.4; H = 9.2; N = 5.8; $M = 249.2$. $C_{15}H_{23}O_2N$ requires C = 72.3; H = 9.2; N = 5.6 per cent.; $M = 249$).

All attempts to hydrolyse the cyano-acid to the corresponding dibasic acid were unsuccessful.

The ether extract (A) yielded on evaporation a viscid, yellow oil, which, when boiled for a short time with hydrochloric acid, was converted into the cyano-acid. There can therefore be little doubt that it was the *methyl* ester of this acid.

It may be mentioned that the cyano-acid was also formed from the anhydride when the latter was heated with sodium carbonate solution or with acetic anhydride. When acetic anhydride was used, the cyano-acid was accompanied by the acetyl derivative of the oxime.

The author wishes to express his indebtedness to Mr. P. H. Guest, Manager, the Turpentine Factory, Jallo, for supplying him with large quantities of the sesquiterpene, and to his assistants, Messrs. Gopal Rau and Ghose, for the care with which they made the numerous analyses required during the progress of the work.

CCCVI.—*Studies on Starch. Part I. The Nature of Polymerised Amylose and of Amylopectin.*

By ARTHUR ROBERT LING and DINSHAW RATTONJI NANJI.

Introduction.

THE object of the work now presented is to throw further light on the vexed question of the chemical nature of starch, and so arrive at some definite conclusions regarding the constitution of that polysaccharide.

Our knowledge concerning the chemistry of the polysaccharides, to which class starch—the most important reserve carbohydrate in the vegetable kingdom—belongs, despite the fact that it has occupied the attention of chemists for upwards of a century, is far less precise than that of most compounds in the domain of so-called organic chemistry. Nor is the reason far to seek. The polysaccharides as we know them in nature mostly occur in the colloidal state, and they fail to respond to methods of attack which have proved so fruitful in the case of the simpler compounds. The number of memoirs which have been published containing an account

of investigations carried out to solve the chemical nature of starch—counting only those of the first order—amounts to many hundreds. Indeed if cellulose be excepted (with which starch is closely related in a chemical though not in a physiological sense), the literature of starch is perhaps more voluminous than that of any other chemical substance.

The greater part of the knowledge we possess of starch has been derived from a study of its hydrolytic products under the influence of acids and of enzymes, and in the majority of cases the enzyme employed has been malt diastase. In view of what we now know, however, it is not surprising that in these circumstances abortive conclusions have been arrived at, for it has been established with certainty that starch consists of at least two constituents, each of which is attacked by malt diastase, giving rise to products which are very difficult to separate. That the problem has not been solved earlier is largely due to the failure of workers to recognise these facts. Yet researches such as those of C. O'Sullivan and of Horace T. Brown will always stand out as classics in chemical literature, and the experimental data brought forward in them are not without value. Indeed we owe an immense debt to these pioneer workers for the methods they devised of attacking the problem.

In ordinary works on chemistry starch and other cognate polysaccharides are usually represented by the formula $(C_6H_{10}O_5)_n$ or they are regarded as mixtures of substances of different degrees of hydration, $(C_6H_{10}O_5)_n + H_2O$, the limiting formula being reached when n is of infinite magnitude.

The fact that starch as we know it in the form of granules consists of more than one substance was first pointed out by C. Nägeli ("Die Stärkekörner," Zurich, 1858), who believed that starch granules are formed in the plastids of plants by intussusception and that the outer layer of the granules is the older and the poorer in the elements of water. He brought forward experimental evidence showing that this outer layer consists of a substance to which he gave the name starch cellulose, whilst he furnished other evidence showing that the inner portion is composed of a substance to which he gave the name granulose, the latter being that constituent of the granules which when dissolved in water gives a clear blue solution on addition of iodine. A. Meyer ("Untersuchungen über die Stärkekörner," Jena, 1895) maintains that starch granules are formed in the same manner as crystals, by apposition. Again, however, Meyer emphasises the view that the granules consist of two substances, α -amylose—the outer portion—and β -amylose the inner portion. These two substances he believed to differ from one another in their degree of hydration.

The most definite observations of the constituents of starch granules are those of the French workers, notably Maquenne and Roux, Mme Gatin-Gruzewska, and Fouard. Maquenne and Roux (*Ann. Chim. Phys.*, 1904, [viii], 2, 109; 1906, [viii], 9, 179) state that the inner portion of the granules consists of a substance which they call "amylocellulose" or "amylose." It is the granulose of Nägeli and is said to be completely converted into maltose in presence of malt diastase. They state that it is present in starch granules to the extent of 80 per cent. in different degrees of hydration, its solubility in water varying *pari passu* with the latter. The second constituent is that forming the external portion of the granules, and for this they propose the name "amylopectin." It gives a viscous paste when heated with water. The property of starch granules of forming a paste with water is indeed ascribed to amylopectin. Mme Gatin-Gruzewska (*Compt. rend. Soc. biol.*, 1908, 64, 178; *Compt. rend.*, 1908, 146, 540) described two methods of isolating amylopectin consisting in treating starch granules with alkali (see p. 2674). The amylose is dissolved, leaving the amylopectin. Amylopectin is said to form 40—45 per cent. of the substances contained in the granules. Maquenne (*Compt. rend.*, 1908, 146, 542) suggests that Mme Gruzewska's values for the percentage of amylopectin are too high.

Fouard has published a series of papers on the colloidal properties of starch (*Compt. rend.*, 1907, 144, 501, 1366; 1908, 146, 285, 978; 1908, 147, 813, 931; 1909, 148, 502). In the first place, he shows that acids extract a certain quantity but not all of the phosphate content of starch granules. The remainder of the phosphate he believed to be in organic combination. We shall have occasion to deal with this matter later on in the present paper. He shows also that coagulation of a solution of so-called soluble starch is conditioned by hydrogen-ions and the formation of a solution by hydroxyl-ions. It is calculated that the concentration of hydrogen-ions required to disturb the equilibrium of a 5 per cent. starch solution is represented by $p_H = 13.5$. It is shown that a solution of starch may be filtered through a collodion membrane and that in this way 55 per cent. of the original starch can be obtained in the form of a clear true solution giving an intensely blue homogeneous solution and not a precipitate with iodine. When such a clear solution of starch is boiled, the specific rotatory power is increased from $[\alpha]_D + 186.1^\circ$ to $+193.6^\circ$.

A great advance was made in the chemistry of starch in 1904 when F. Schardinger obtained so-called crystalline dextrins (*Wiener Klin. Wochens.*, 1904, Nr. 8; *Zentr. Bakt. Parasitenk.*, 1908, [ii], 22, 98) by the action of an organism isolated from a retting

vat which he named *Bacillus macerans*. In this way he obtained three crystalline dextrans, the yield being 25 per cent. of the starch employed. The two chief products were denoted by Schardinger dextrin- α and dextrin- β , and of these the α -derivative preponderated. The third dextrin was obtained by dissolving the slime, left after separating the α - and β -dextrans, in dilute alcohol. Pringsheim and Langhans (*Ber.*, 1912, 45, 2533) and Pringsheim and Eissler (*ibid.*, 1913, 46, 2959) submitted these dextrans to a critical examination. They propose to call them amyloses and they find that the dextrin- α of Schardinger has a molecular weight represented by the formula $(C_6H_{10}O_5)_4$. It is therefore a tetra-amylose. When heated with acetic anhydride and zinc chloride, it undergoes acetylation and depolymerisation, being converted into the acetyl derivative of a diamylose. It is also shown that dextrin- β , when heated with acetic anhydride and zinc chloride, is converted into the acetyl derivative of a triamylose. Dextrin- β is regarded therefore as a hexa-amylose. The amylose from the slime is found also to be a hexa-amylose. It belongs to the α -series.

The amyloses isolated by Pringsheim and his collaborators from potato starch are regarded as belonging to two series of α - and β -derivatives. They are shown in the following table, the basal molecules being within the round brackets, whilst the polymeric molecules are within the angular brackets.

	α -Series.	Specific rotation.
		$[\alpha]_D$.
Hexa-amylose (from the slime)	$[(C_6H_{10}O_5)_6]_3$	139°
Tetra-amylose (from dextrin)	$[(C_6H_{10}O_5)_4]_2$	136.8
Diamylose	$(C_6H_{10}O_5)_2$	136.6
	β -Series.	
Hexa-amylose (from dextrin)	$[(C_6H_{10}O_5)_6]_2$	157.9
Triamylose	$\cdot (C_6H_{10}O_5)_3$	151.8

This table is quoted from "*Die Polysaccharide*" (Pringsheim, 1923, p. 167). The letters α and β affixed to the amyloses were not intended by Pringsheim to denote their respective constitutions but only to distinguish the members of the two series. By a happy coincidence, however, the members of the α -series are those to which α -hexa-amylose belongs, whilst the members of the β -series are those to which $\alpha\beta$ -hexa-amylose belongs.

In the light of these observations, it is suggested by Pringsheim and his collaborators that starch and the amyloses consist of basal units polymerised to different degrees, the units being held together by subsidiary valencies. The polymeric substances may therefore be regarded as co-ordination compounds.

It will be noticed that in the above table the final units are of two

kinds, a diamylose and a triamylose, a point of special significance in connexion with our own observations.

Attention may here be directed to the fact that Karrer and his collaborators differ from Pringsheim's views on the constitution of starch and the amyloses. Thus Karrer and Burklin (*Helv. Chim. Acta*, 1922, 5, 181) believe that α -hexa-amylose consists of maltose anhydride molecules, $(C_{12}H_{20}O_{10})_3$, and they regard starch as polymerised maltose anhydride. Support for this view is afforded by the observation of Karrer and Nägeli (*Helv. Chim. Acta*, 1921, 4, 169) that by the action of acetyl bromide on the polyamyloses in presence of a little glacial acetic acid hepta-acetylbromomaltose is produced, from which maltose can be obtained when it is shaken with silver carbonate and subsequently hydrolysed.

In 1894 Tanret (*Compt. rend.*, 119, 158) obtained a substance, which he named levoglucosan, by heating picein, a glucoside, with barium hydroxide at 100° for several hours. Pictet and Sarasin (*Compt. rend.*, 1918, 166, 38) prepared the same substance by distilling starch or cellulose under diminished pressure. Karrer (*Helv. Chim. Acta*, 1920, 3, 258) showed that it is formed by heating β -glucose. Irvine and Oldham (T., 1921, 120, 1744) therefore call it β -glucosan.

Pictet and Cramer (*Helv. Chim. Acta*, 1920, 3, 649) believe β -glucosan to have the following constitution:

This constitutional formula $<1, 4> - (1, 6)$ anhydroglucose has been established by Irvine and Oldham (*loc. cit.*), who employed the methylation method.

Whether β -glucosan may be regarded as a basal unit of polymerised starch or cellulose seemed doubtful, seeing that its mode of preparation is such as to render intramolecular changes by no means improbable.

It is interesting, however, to note that another anhydroglucose (glucosan) was obtained by Gelis (*Compt. rend.*, 1860, 51, 331) by heating dextrose at 170° . Pictet and Castan (*Helv. Chim. Acta*, 1920, 3, 645) obtained the same substance by heating glucose in a partial vacuum at 150° . On account of its labile properties, they believe it to contain an ethylene-oxide ring and suggest that it has the constitution

or $<1, 4> - (1, 2)$ anhydroglucose.

By heating together equimolecular proportions of β -glucosan and Gelis's glucosan, Pictet (*Bull. Soc. chim.*, 1920 [iv], 27, 650) obtained a dextrin which when boiled with oxalic acid yielded a syrup from which maltose was isolated in the form of its octanitate.

Of other recent work on the polysaccharides, that of Irvine and his school deserves special mention. This has been summarised in an address to Section B of the British Association (1922) and also in a lecture to the Chemical Society (this vol., p. 898).

The Constituents of Starch Granules.

It has been stated already that starch granules consist of at least two substances, amylose and amylopectin, which together constitute the major portion of the granules. In the case of the starches of potato and arrowroot, amylose and amylopectin are practically the sole constituents. It will be shown later that these two constituents give rise to different intermediate products when hydrolysed in the presence of enzymes. Both, however, give the same ultimate product, glucose, when hydrolysed in presence of acids.

It should here be mentioned that Professor Schryver, in a private communication, has informed us that he has isolated a hemicellulose from wheat starch, but at present we are without details of his work. They are contained, we understand, in a paper now in the press.* We may say that we find that certain starches, notably those of barley, wheat, and rice, contain besides amylose and amylopectin other carbohydrates and as a result of a general examination of these substances they would appear to be of the nature of hemicelluloses. They can be separated by treating starch paste with certain enzymes. We are concerned here, however, more particularly with potato starch, and arrowroot starch, the granules of which consist almost entirely of amylose and amylopectin. As a result of work we have carried out on other starches, namely, those of wheat, barley, rice, and maize, we are able to state that the ratio of amylose to amylopectin is constant in all these starches, namely, 2:1, and there is no fundamental difference so far as these two constituents are concerned in any of the starches we have examined. However, the absolute percentages of these constituents may vary widely according to the quantity present of the other constituents above referred to.

When starch is incinerated, the ash is found to consist principally of silica and phosphates, both of which play an important rôle in plant metabolism. The straws of the *Gramineæ* contain as much as

* Papers on this subject by Claysen and Schryver and by Schryver and Thomas have appeared since this paper was sent in for publication (*Biochem. J.*, 1923, 17, 493, 497).

2 per cent. of silica, whilst in the case of rice straw the quantity is as much as 6 per cent.

As regards phosphoric acid, we have already referred to Fouard's observations (*loc. cit.*) on the presence of phosphate in starch granules, but so far as we are aware no one has up to the present directed attention to the presence of silica. Bearing in mind the fact that phytin is a phosphoric ester of inositol, it seems highly probable, arguing by analogy, that the phosphate present in one of the substances which forms the outer layer of starch granules, namely, amylopectin, is also combined as an ester, and to this is probably to be ascribed the property of forming a jelly which is one of the characteristics of amylopectin. In support of this view, we find that in the well-known method of preparing so-called soluble starch according to Lintner's instructions, namely, treating starch granules with 7 per cent. hydrochloric acid for a week, the acid liquid contains phosphoric acid. In all probability the silica is also removed, but it would be deposited in an insoluble condition. This deposition of silica is indeed to be observed when the starches of rice, wheat, and barley are hydrolysed with acids. In the case of the starches of potato and arrowroot, the quantity of silica is so small that it is not noticeable, and clear solutions are obtained. The phosphoric acid appears, then, to be associated with amylopectin, whilst the silica is in all probability associated with other substances of the nature of hemicelluloses. It has been shown previously by Fernbach and Wolff (Seventh Internat. Cong. Appl. Chem., 1909, Sect. VI, B, 124) that when a 5 per cent. starch paste is heated with hydrogen peroxide and ammonia solution or traces of certain salts, the paste rapidly liquefies. In all probability, under these conditions the phosphoric acid group is split off and liquefaction ensues. Samec (*Koll. Chem. Beihefte*, 1914, 6, 23) has shown that amylopectin contains phosphorus, whilst amylose is free from phosphorus. Northrop and Nelson (*J. Amer. Chem. Soc.*, 1916, 38, 472), dealing with the question of phosphoric acid in starch, isolated an ester containing 5.3 per cent. of phosphorus. This observation has an important bearing on our own work, as will be seen later. Kerb (*Biochem. Z.*, 1919, 100, 8) describes the preparation of phosphoric esters from ordinary soluble starch, and he finds that the phosphoric group is not easily removed from these esters. Thus their solutions do not give a precipitate with magnesia mixture or with molybdic acid unless they have been previously treated with hydrogen peroxide and a little nitric acid in presence of a trace of iron salts according to the method of Mendel and Neuberg (*Biochem. Z.*, 1915, 71, 196).

Even polymerised amylose, the substance forming the interior portion of starch granules, may be to some extent esterified with

phosphoric acid. Fernbach (*Compt. rend.*, 1904, **138**, 428) has shown that potato starch granules, especially the lighter ones, contain a nucleus relatively rich in phosphorus, on which is superposed so as to form the larger granular, layers of starch free from phosphorus.

Separation of Polymerised Amylose and Amylopectin.

At the outset of our experiments we discovered that the dextrin obtained by Baker (T., 1902, **81**, 1177) by the action of the diastase of ungerminated barley on soluble starch and named by him α -amylodextrin is a derivative of amylopectin. It is this discovery which first gave us the clue to devising methods for the separation of the two constituents with which we are now dealing. This part of the subject will, however, be discussed in detail in another part of this communication.

Physical Methods.—Polymerised amylose as it exists in starch granules is for the most part soluble in water, whilst amylopectin is not. We are not able, however, to avail ourselves of this difference in solubility for the separation of these two substances, since the amylose of the granules is surrounded by an outer insoluble coating. This difficulty may, however, be overcome completely by dealing with starch paste instead of starch granules. When starch paste is submitted to the temperature of a mixture of ice and salt in an ice-chest for ten to twelve hours, it is found that the starch is precipitated from solution as a fibrous mass resembling cotton wool. Examination under the microscope shows the presence of the small, disintegrated sacks described by Mme Gatin-Gruzewska (*loc. cit.*). After the mass has been brought to the temperature of the room, it is kept at a point a little below the gelatinising point of the starch used. Thus in the case of potato starch this temperature should be about 60°. After some time the amylose will have passed into solution, leaving the amylopectin undissolved, which latter may then be collected by centrifuging and repeated washing with water at 60°. If it be desired to prepare pure amylopectin, the leaching with water at 60° must be repeated several times until the final washing no longer gives a blue coloration with iodine. Amylopectin thus prepared may be dried at a low temperature, when it presents the appearance of white, transparent scales. In this form, however, a paste can be obtained from it with hot water only after it has been finely powdered. These physical methods are only available in the case of those starches such as potato and arrowroot not containing the hemicellulose constituents.

The amylose solution comprising the supernatant liquid and washings may be concentrated on a water-bath and precipitated with alcohol.

Amylopectin, when made into a paste with hot water, gives a bluish-black coloration and precipitate with iodine, whilst amylose gives a clear bright blue solution and no precipitate.

A second physical method applicable in the case of starches of high gelatinising point such as those of barley, wheat, and rice, is to keep the granules in suspension at a temperature just below the gelatinising point, when the amylose will pass into solution, leaving the amylopectin and the hemicellulose constituent undissolved. The insoluble constituents cannot be completely freed from amylose by this method.

The method of obtaining amylose by ultra-filtration described by Fouard (*loc. cit.*) has been already dealt with in the introduction.

We have also made use of the adsorptive power of certain colloids such as alumina and dialysed iron. When to a starch paste aluminium sulphate is added and subsequently an equivalent quantity of barium hydroxide so as to produce an alumina sol within the paste, most of the starch flocculates, leaving a clear supernatant liquid containing amylose together with a little amylopectin. The precipitate may be collected and washed in a centrifuge. Dialysed iron produces a similar result. The behaviour of these colloids is influenced considerably by the hydrogen-ion concentration of the mixture.

Obviously this method is not available for the separation of amylose and amylopectin in the pure state.

Chemical Methods.—It is only right to state here that credit must be accorded to Mme Gatin-Gruzevska (*loc. cit.*) as being the first to separate by chemical methods amylose and amylopectin. Her first method consists in adding to a 3 per cent. starch paste a quarter of its volume of a hot 40 per cent. solution of potassium or sodium carbonate and treating the mixture with one-third of its volume of 95 per cent. alcohol. The filamentous precipitate of amylopectin produced is washed, caused to swell in water, neutralised, and purified by dialysis or by washing by decantation. Another method, which enables the two substances to be separated almost in their natural state, depends on the fact that when starch in the form of granules is treated with 1 per cent. caustic alkali, the envelopes, consisting of amylopectin, swell up and the contained amylose passes into solution. The liquid is neutralised with acetic acid, when the envelopes contract. The mixture is then kept for twenty-four hours, when the amylopectin is found in the form of empty sacks at the bottom of the vessel. Operating in this way, Mme Gruzevska separated 40—45 per cent. of amylopectin from potato starch. As already observed, Maquenne (*loc. cit.*) believes this percentage of amylopectin is too high and our own observations have confirmed this.

Neither of these methods in our hands has given satisfactory

results for the preparation of large quantities of polymerised amylose and amylopectin. We find that when frozen starch paste is treated with 0.5–1 per cent. sodium carbonate solution, the amylose is leached out more readily than by plain water. It may then be separated from amylopectin as already described. It should be pointed out, however, that the amylopectin obtained by alkaline extraction gives a violet coloration with iodine instead of the bluish-black precipitate obtained with the substance prepared with the use of plain water. It would therefore seem that under the influence of alkalis some depolymerisation takes place, and this we might expect from Fouard's results (*loc. cit.*).

When starch paste is treated at the ordinary temperature with one molecular proportion of calcium, strontium, or barium hydroxide, the starch is completely thrown down in the form of a white, flocculent or gelatinous precipitate according to the concentration of the starch paste. The supernatant liquid immediately after precipitation gives no coloration with iodine. If, however, the precipitate be kept under water for some time and well agitated, the amylose will pass into solution, leaving the amylopectin precipitate undissolved. This separation may be even more readily accomplished by drying the alkaline-earth precipitate to a pulverulent form from which amylose can be extracted with water. From these facts it would seem that amylopectin forms a definite, insoluble compound with the alkaline earths which does not dissociate with water at the ordinary temperature. Whether amylose also forms a definite, insoluble compound with the alkaline earths cannot be decided, but it appears more probable that it is coprecipitated with the alkaline earth compound of amylopectin by adsorption.

Biochemical Methods.—The method we have adopted consists in treating starch paste at 50° with precipitated barley diastase which has been dried by treatment with strong alcohol. In this way, the amylose is converted completely into maltose in about twelve hours, whilst the amylopectin is scarcely attacked. The rate of hydrolysis, as we shall show in a later paper, is accelerated by the presence of certain electrolytes. When this biochemical method is adopted, the maltose may be removed by dialysis, when a solution of amylopectin is obtained from which that substance can be isolated by any of the methods already described, or it may be precipitated by alcohol.

It should be pointed out here that when barley grist or barley extract, or freshly precipitated barley diastase dissolved without drying [as was employed by Baker (*loc. cit.*)], is used as converting agent, the amylopectin is attacked, the final product being Baker's α -amylodextrin.

Hydrolysis of Starch.

Although it will be quite unnecessary for us to deal exhaustively with the voluminous literature of this portion of the subject, in order to make our thesis quite clear we shall have to refer to some of the memoirs dealing with studies which have furnished evidence from which conclusions have been deduced as to the constitution of starch. Most of these conclusions are erroneous owing to the fact that starch has been regarded as a homogeneous substance and not, as indeed it is, a mixture of at least two substances.

The one fact that has been established beyond all doubt is that the two chief constituents of starch, namely, polymerised amylose and amylopectin, are hexosans which by complete hydrolysis in presence of acids are converted quantitatively into glucose.

The particular phase of the subject to which it is necessary for us to refer in the first place is that dealing with the hydrolysis of starch in presence of the diastase of germinated barley. We may pass over the earlier work of Payen and Persoz and of Musculus and mention the researches of C. O'Sullivan, who, in 1872 (T., 25, 579), established the fact that the sugar obtained was maltose, thus confirming the observations of de Saussure in 1819 and of Dubunfant in 1849. The papers published by O'Sullivan on this subject from 1872 to 1879 mark a distinct advance in our knowledge of the dextrins formed by the hydrolysis of starch, and his work was continued and considerably extended by H. T. Brown and his collaborators. In 1885, Brown and Morris (T., 47, 527) confirmed Herzfeld's observation (*Inaug. Diss.*, Halle, 1879) of the existence of a reducing substance intermediate between maltose and the dextrins among the hydrolytic products of starch and they adopted for it Herzfeld's name, maltodextrin; it was found to be unfermentable by *Saccharomyces cerevisiæ*. The next important advance was made by C. J. Lintner, who, in 1891, announced the discovery of an isomaltose in malt wort and in beer (*Z. ges. Brauw.*, 1891, 284). In a subsequent paper, Lintner and Düll (*Z. angew. Chem.*, 1892, 5, 268) stated that the same sugar is invariably present as a product of the hydrolysis of starch in presence of malt diastase. Ling and Baker (T., 1895, 67, 702, 739) drew the conclusion that the isomaltose of Lintner was a mixture of maltose and a simple dextrin, $C_{12}H_{20}O_{10} + H_2O$, whilst Brown and Morris (*ibid.*, 1895, 67, 709) deny entirely the existence of isomaltose, and Ost (*Chem. Ztg.*, 1895, 19, 1501) drew similar conclusions. Ling and Baker (T., 1897, 71, 509) describe the preparation and properties of maltodextrin- α and maltodextrin- β , whilst from the unfermentable residue of the particular fractions from which Lintner isolated his

isomaltose they obtained a substance which, in accordance with their former views, they regarded as a simple dextrin. Inasmuch as it gave a small quantity of osazone, they suggested that it may have contained a little maltose. Syniewski (*Annalen*, 1900, 309, 282; 1902, 324, 212) came nearer than perhaps any previous investigator towards solving the constitution of starch. Among other facts, his work leaves little doubt as to the existence of Lintner's isomaltose, to which he gave the name dextrinose. Although he regarded the isomaltose as a β -disaccharide, it is remarkable that he failed to discover methods of proving this point.

We have already stated that Baker's α -amylodextrin is derived from amylopectin. When barley grist or barley extract or a solution of freshly precipitated barley diastase which has not been dehydrated with strong alcohol is allowed to act on a paste of amylopectin, the amylopectin is broken down into a simpler substance, which is, in fact, the substance referred to by Baker as α -amylodextrin. When this product is repeatedly extracted with boiling 80 per cent. alcohol, it may be obtained devoid of cupric-reducing power. A better method of removing the reducing substance from this product is to dry it, grind it to a very fine powder, and extract it with boiling 80 per cent. alcohol. It is therefore not a dextrin, but a derivative of amylopectin similar to the polymerised amyloses. We regard it as polymerised $\alpha\beta$ -hexa-amylose and therefore in future for the sake of brevity we shall refer to it as $\alpha\beta$ -hexa-amylose. According to Mme Gruzewska, the specific rotatory power of amylopectin is $[\alpha]_D + 221^\circ$, whilst we find that that of polymerised $\alpha\beta$ -hexa-amylose is $[\alpha]_D + 193^\circ$, a number which agrees fairly closely with that observed by Baker.

Precipitated diastase which has been dehydrated with alcohol and dried does not possess the power of attacking amylopectin to any extent, which is recovered almost unchanged, having a specific rotatory power of about $[\alpha]_D + 221^\circ$. $\alpha\beta$ -Hexa-amylose may be produced from amylopectin by a process of depolymerisation, but in a sense it may be regarded as a hydrolytic product, since it involves the removal of the phosphoric acid groups in the amylopectin. The same change occurs to some extent when amylopectin is treated with dilute alkali (see p. 2675). $\alpha\beta$ -Hexa-amylose, although containing β -linkings, is not hydrolysed by the very active β -glucosidic enzyme obtained from bitter almonds. To prepare this enzyme, bitter almonds (100 grams) were extracted at a low temperature and to the clear filtrate were added a few drops of dilute acetic acid to coagulate the proteins. The filtrate from the coagulum was treated with 3 vols. of 95 per cent. alcohol, the precipitate collected and dissolved in 33 c.c. of water, and a few drops of toluene were

added. The solution thus obtained was extremely active compared with the dry preparation.

By the action of yeast maltase, however, the $\alpha\beta$ -hexa-amylose is slowly hydrolysed, giving, after incubating at 38° with the enzyme for a week in presence of toluene, a mixture of glucose and isomaltose.

Hydrolysis of Amylopectin in presence of Malt Diastase.—Amylopectin was hydrolysed in presence of unrestricted malt diastase at 50° . It was then found to be broken down rapidly, and in a few minutes the solution no longer gave a coloration with iodine. After two hours the specific rotatory power of the liquid was found to be $[\alpha]_D + 139^\circ$ and the presence of a little glucose was detected. The action is slower if the diastase solution has been previously heated at 65° and the reaction allowed to proceed at the same temperature. In an experiment carried out under these conditions, the specific rotatory power after six hours was $[\alpha]_D + 126^\circ$, and glucose in considerable quantity was present in the solution.

Preparation of Hexatriose (α -Glucosidoisomaltose or β -Glucosidomaltose).

A solution of $\alpha\beta$ -hexa-amylose containing 3—4 grams per 100 c.c. was treated with 10 c.c. of precipitated malt diastase solution containing 0.001 gram of the enzyme per c.c. under the following conditions. The enzyme solution was previously heated at 70° and the conversion allowed to proceed at the same temperature. At the end of every half hour, fresh 10 c.c. portions of diastase solution restricted as before were added. In three to three and a half hours the solution no longer gave the iodine reaction. At this point the solution was rapidly raised to the boiling point. The specific rotatory power of the solid matters in the solution was $[\alpha]_D + 165^\circ$ and the reducing power R 66 and these values have been confirmed for the pure substance in a number of experiments. No glucose was present. We find, however, that unless extreme care is taken to keep the temperature from falling below 70° glucose is formed. Cryoscopic determinations showed that the dissolved matter in the conversion carried out at 70° had the molecular weight of a hexatriose.

The hexatriose was isolated by evaporating the solution at a low temperature to a syrup, which was treated with alcohol, and filtering off the precipitate resulting from the diastase. The alcoholic solution was then concentrated at a low temperature, when the sugar was obtained as a white, amorphous, extremely hygroscopic powder. When this was mounted on a microscopical slide in absolute alcohol, distinct triangular plates momentarily appeared, but attempts to prepare permanent crystals were unsuccessful owing to the extremely

hygroscopic nature of the sugar. The anhydrous substance melts sharply at 202–203° to a colourless liquid. The sugar possesses a sweeter taste than maltose (Found: C = 43·01; H = 6·49; $M = 480$. Calc. for $C_{18}H_{32}O_{16}$, C = 42·85; H = 6·40 per cent.; $M = 504$).

The hexatriose gives a phenylosazone which is very soluble in water and crystallises therefrom in rosettes of minute needles. It melts at 122° [Found: N = 8·14. $C_{18}H_{30}O_{14}(N_2HPh)_2$ requires N = 8·21 per cent.].

When the hexatriose is submitted to the action of β -glucosidic enzyme prepared as already described, it is hydrolysed giving a mixture of glucose and maltose. In one quantitative experiment 31·8 per cent. of glucose was obtained, instead of 35·7 per cent. On the other hand, when it is submitted to the action of yeast maltase or malt diastase, glucose and isomaltose are obtained. The isomaltose was identified by means of its osazone, which had the characteristic appearance and melted sharply at 152°.

The hexatriose, as might be expected from its behaviour towards yeast maltase, is slowly fermentable by *Saccharomyces cerevisiae* (top variety), leaving a residue of isomaltose which was identified by its osazone.*

iso-Maltose.—We have now definitely settled the existence of this sugar amongst the products of hydrolysis of starch by malt diastase, concerning which so much controversy has taken place. As long as studies were confined to the action of malt diastase on starch, it was practically impossible to settle the question, since by that enzyme both polymerised amylose and amylopectin are hydrolysed, giving rise to a mixture of maltose and isomaltose, which are difficult to separate by fractionation with alcohol. It is different when resort is had to an enzyme which only saccharifies polymerised amylose, such as dry precipitated barley diastase. When the last-mentioned enzyme is allowed to act on starch, the products are maltose and $\alpha\beta$ -hexa-amylose. Baker obtained under these conditions in one experiment a reducing power as high as 66·6 per cent., expressed as maltose. In our own experiments, we have obtained barley diastase conversions giving reducing powers as high as 70 per cent., expressed as maltose. The conditions were so adjusted in these cases that no glucose was produced (compare Ling and Nanji, *Biochem. J.*, 1923, 17, 593).

Many investigators have claimed to have converted starch com-

* This hexatriose must not be confused with that isolated in the form of its osazone by Ling and Baker (*T.*, 1895, 67, 702) from the products of the action of restricted malt diastase on starch at 70°. This sugar was probably a mixture derived from polymerised amylose and amylopectin.

pletely into maltose by the action of malt diastase. Thus Ling and Davis (*J. Inst. Brewing*, 1902, 8, 475), employing malt diastase, showed that the starch of potato maize and rice, when hydrolysed with a solution of precipitated malt diastase at 55° for prolonged periods, gave conversions the dissolved solids of which had the following constants: Potato, $[\alpha]_{D^{25}}$ 138.5°, R_{25} 96.7. Maize, $[\alpha]_{D^{25}}$ 139.4°, R_{25} 96.7. Rice, $[\alpha]_{D^{25}}$ 139.4°, R_{25} 96.1. Ling and Davis state that in such solutions they were able to detect nothing but maltose. It should here be pointed out that amylopectin, when hydrolysed in presence of malt diastase at 55°, yields a mixture of maltose (1 part) and isomaltose (2 parts). In this case α -glucosidoisomaltose is not produced as an intermediate substance. It will be noticed that whilst the rotatory powers above quoted are substantially those of maltose, the reducing powers are on the average 96.4 instead of 100. According to Lintner, isomaltose has the following constants: $[\alpha]_D$ 140°, R 80, and we have confirmed these values. If we assume, therefore, that starch under the action of malt diastase yields ultimately a solution containing a mixture of approximately 80 per cent. of maltose and 20 per cent. of isomaltose,* the constants of such a mixture should be $[\alpha]_D$ 138.4, R 96, values which agree closely with those of Ling and Davis. In fact, Ling (*Brit. Assoc. Report*, Southport, 1903) states that potato starch paste is never completely converted into maltose by the action of malt diastase and that a substance is always present which is identical with the isomaltose of Lintner. We have repeated some of Ling and Davis's experiments with potato starch paste, and whilst we can confirm the values they obtained, we have proved the presence of isomaltose in the final products by fermenting the maltose with yeast, preparing and examining the osazone from the unfermented matter, and finally submitting the sugar to the action of the β -glucosidic enzyme from bitter almonds.

Since Lintner and other workers separated isomaltose from the products of the action of malt diastase on starch, the preparations were always of very uncertain purity. Still it is remarkable that Lintner's preparations gave the true constants for this sugar. It was, in fact, due to the difficulty of isolating isomaltose except in the form of its osazone that led several chemists to deny its existence, which Lintner, however, strongly maintained to the last. In view of our present knowledge it must, however, be admitted that Lintner's views were correct and his work must be classed as among the most important on the subject. Lintner regarded the isomaltose obtained

* This would not be strictly accurate for all starches, as we shall show in a subsequent communication.

by the action of malt diastase on starch and that produced by Fischer (*Ber.*, 1890, 23, 3687) by the action of hydrochloric acid on glucose as identical, basing this conclusion on the fact that the osazones from the two products melt at about the same temperature. Lintner and Düll (*Ber.*, 1895, 28, 1522) showed that hydrolysis of potato starch with oxalic acid under a pressure of $1\frac{1}{2}$ atmospheres yielded 34 per cent. of isomaltose in the crude product.

We have repeated this experiment and find that the isomaltose obtained is not identical with the sugar which Lintner isolated from the products of the action of malt diastase on starch. It appears to be a mixture, and we hope to deal with it in a future communication.

Preparation of isoMaltose.—We have already referred to various means of obtaining isomaltose. The most convenient way of preparing it in large quantities is to use as starting material either crude amylopectin or $\alpha\beta$ -hexa-amylose, and to allow a solution of precipitated malt diastase to act on either of these at 50° until the rotatory power remains constant. The product consists of isomaltose, glucose, and a little maltose. The solution is next fermented with yeast and after the termination of the fermentation, the yeast is filtered off, the solution decolorised with norit, and evaporated under diminished pressure to a thick syrup, which is taken up by boiling 90 per cent. alcohol, when mineral matters, proteins, etc., remain undissolved. The alcoholic solution is then concentrated at a low temperature, when the sugar is obtained as a white, amorphous, fairly hygroscopic powder. It does not possess any definite melting point, nor can it be induced to crystallise. It has a sweeter taste than maltose, a fact to which Lintner has already directed attention. Several experiments for the preparation of isomaltose in large quantity were carried out in a manner following the directions given by Baker and Day (*Brit. Assoc. Rep.*, 1908, Sect. B, 671) for the preparation of maltose, only that in place of barley diastase barley extract was used. Starch paste is treated with barley extract at 50° for six hours and the conversion kept at room temperature for a further twelve hours. The conversion liquid is then boiled and concentrated to a syrup, which is poured into so much alcohol that the resulting mixture contains 60 per cent. of alcohol. The supernatant liquid is then poured off, the crude $\alpha\beta$ -hexa-amylose, contaminated with maltose, is dissolved in water, and the solution treated with precipitated malt diastase at 50° until the rotatory power is constant. The product is then fermented with yeast as described above.

The specific rotatory power of the pure sugar ($c = 3-4$) is $[\alpha]_D + 140^\circ$ and the reducing power R 80, as stated by Lintner

[Found: C = 41.9; H = 6.6; M , by the cryoscopic method, = 332. $C_{12}H_{20}O_{11}$ requires C = 42.1; H = 6.4 per cent.; M = 342. Found: for the osazone, N = 10.65. $C_{12}H_{20}O_9(N_2HPh)_2$ requires N = 10.76 per cent.].

Discussion of Results.

Throughout this communication we have dealt with the nature of two constituents of starch granules, namely, polymerised amylose and amylopectin, and as a result of a study of their behaviour towards certain enzymes we have been able to arrive at definite conclusions regarding their constitution. Before discussing these, it will be useful to give a brief sketch of the views and conclusions of other workers.

Unlike the older school of chemists, recent workers regard starch as made up of a polymerised basal unit and suggestions have been made by Pictet, Karrer, Pringsheim, and Irvine as to the constitution of this basal unit. Pictet regards it as β -glucosan, Karrer as anhydro-maltose, whilst Pringsheim and Irvine both regard it as triamylose. Irvine and Macdonald, on the evidence obtained by a study of the methylation products of purified rice starch, suggest a constitutional formula for the triamylose, based on the fact that starch, when methylated by the methyl sulphate and caustic soda method, yields a product having a methoxyl content of 37 per cent. as would be required by a derivative in which one hexose residue has acquired three methyl groups, whilst four are shared by two hexose residues. Ultimate analysis of the product gave results in agreement with this view. It gave on hydrolysis about 23 per cent. of 2:3:6-trimethyl glucose, about 46 per cent. of a dimethyl glucose, and about 31 per cent. of depolymerised starch. This leads them to draw the conclusion that there is present in the starch molecule a hexose residue in which the two potential linkages to the other residues are in the positions not occupied by the methyl groups, namely, 1 and 5. It is pointed out that the structure which can be developed to admit of one of the linkages being in position 5 is characteristic of β -disaccharides such as cellobiose and lactose, but not of maltose. Irvine and Macdonald propose three formulæ for the basal unit of starch and of these they give preference to the following:

That these workers regarded starch as a homogeneous substance is easy to understand, since none of them was aware of the fact that amylose and amylopectin give rise to different products on hydrolysis with enzymes. In view of our present knowledge, therefore, in arriving at any conclusions as to the constitution of starch, each of its constituents must be considered separately.

Polymerised Amylose.—We have seen that polymerised amylose may be converted quantitatively and with extreme ease into maltose, which is known to be an α -disaccharide. The simplest basal unit which suggests itself at first sight for polymerised amylose is therefore that proposed by Karrer, namely, anhydro-maltose or diamylose. Karrer's latest formula for this substance is the following :

FIG. 1.

Diamylose.*Tetra-amylose.*

It will be remembered, however, that the primary amylose of the α -series obtained by the action of *B. macerans* on starch is, according to Pringsheim, a hexa-amylose which, when treated with acetic anhydride and zinc chloride, is depolymerised into a tetra-amylose and finally into a diamylose.

In view of the fact that this depolymerisation is brought about by vigorous chemical means, we consider that α -hexa-amylose rather than the tetra- or the di-amylose should be regarded as the basal unit of polymerised amylose, the latter two being derived from the

former by depolymerisation. The following formula will account for all the properties of α -hexa-amylose. From a substance having this structure under certain conditions of hydrolysis a hexatriose may be produced. Further work is being carried out to settle this point. However, such a fission must be regarded as abnormal, the constituting unit of the hexa-amylose being the diamylose. In

FIG. 2.
 α -Hexa-amylose.

(ab), (cd) and (ef) Diamylose; (def), (abef) and (abcd) Tetra-amylose.
The potential positions of residual valencies on fission and depolymerisation of the structure are shown in dotted lines.

proposing this structural formula, we have kept in mind the views of Pringsheim, Karrer, and Irvine. Those of Pringsheim and Karrer will now, we hope, be easily reconciled and accommodated with our own. Irvine, on the other hand, does not accept the structural formula proposed by Karrer for diamylose, which comprises that proposed by us for α -hexa-amylose. Irvine's contention

that such a structure as proposed by Karrer for the diamylose would give rise to 2:3:5-trimethyl glucose is scarcely well founded. It must be remembered that in the case of the amyloses we are dealing with closed-chain structures, and although these are closely related to the open-chain reducing polysaccharides, the same arguments which are applicable in establishing the constitution of the latter need not necessarily hold in the case of the former. In establishing the constitution of such closed-chain compounds, a very important factor presents itself which has been left out of consideration, namely, that of steric hindrance. This, if ignored, may lead to erroneous conclusions. It is in fact conceivable that Irvine's failure to obtain 2:3:5-trimethyl glucose from starch may have been due to this cause. Thus we know from the work of Pringsheim and of Karrer, which need not be referred to in detail, that of the three hydroxyl groups for every glucose residue present in such closed-chain compounds, all the three can be acetylated without involving the rupture of the ring, whereas only two can be methylated readily. The third can be methylated only with difficulty even when the hydroxyl groups are in the position 2:3:6 and not at all when they are in the position 2:3:5. This behaviour towards methods of methylation is quite general in the case of such closed-chain compounds as the amyloses which have the three hydroxyl groups in 2:3:5-positions. It may be concluded, therefore, that two of those hydroxyl groups behave differently from the third when submitted to methylation methods. Since closed-chain compounds containing hydroxyl groups in the 2:3:6-positions can be methylated, it would seem that steric hindrance is offered by the hydroxyl group in position 5.

Amylopectin.—It has already been stated that amylopectin is a phosphoric ester of a polysaccharide which we shall now show to be an $\alpha\beta$ -hexa-amylose in which two carbinol hydroxyl groups adjacent to the β -linkings are esterified (see p. 2686). The first conclusive evidence pointing to the nature of this phosphoric ester was furnished by Northrop and Nelson (*loc. cit.*), who isolated it from the products of partly hydrolysed starch by hydrochloric acid. They then determined the percentage of inorganic phosphoric acid in the liquid and found that only 3—5 per cent. of the total phosphoric acid was set free, the remainder still being in organic combination. When the acid liquid was neutralised with solid baryta and two volumes of 85 per cent. alcohol were added, they obtained a white, hygroscopic, amorphous substance containing 3—5 per cent. of phosphorus, the yield being 0.6 per cent. of the starch employed. The barium compound was decomposed with dilute sulphuric acid, the excess of sulphuric acid removed with lead carbonate, and after hydrogen sulphide had been passed through the liquid to precipitate the lead,

the filtrate was concentrated in a vacuum to a syrup, to which glacial acetic acid was added. The resulting precipitate of the free ester thus obtained contained 4.9 per cent. of phosphorus. When this product was further purified through the lead salt, preparations were obtained containing uniformly 5.3 per cent. of phosphorus.

FIG. 3.

 $\alpha\beta$ -Hexa-amylose.

(abc) Hexatriose; (ab) *iso*Maltose; (aa), (bc) and (cc) Maltose.

The potential positions of residual valencies on fission and depolymerisation of the structure are shown in dotted lines.

The authors believe that the substance contains one phosphoric group to three hexose residues. As the substance did not reduce Fehling's solution, the authors conclude that it was an ester of a closed-chain compound analogous to inositol, which was found to be absent. The nature of the carbohydrate was left undecided. In all probability the compound which these chemists isolated is the

tions. The ultimate products of hydrolysis which he obtained from methylated starch were a dimethyl glucose and 2:3:6-trimethyl glucose in the proportion of 2:1. The major portion of the dimethyl glucose must have been derived from the amylose portion of starch, whilst the trimethyl glucose was derived from the isomaltose unit contained in the amylopectin. Since, however, Irvine employed rice starch, it is very difficult to interpret his results quantitatively, as we find that purified rice starch contains the largest percentage of the other constituents of the nature of hemicellulose (see p. 2671). In some samples, we have found as much as 18 per cent. of these constituents. The details of the method of isolating and estimating them will be dealt with in another paper.

In conclusion, we desire to express our thanks to Professor C. J. Lewis of the Public Health Department in this University for placing at our disposal an electrically driven centrifuge and an ice-chest. Our thanks are also due to W. J. Harper for the assistance he has rendered.

CCCVII.—*The Velocity of Reaction in Mixed Solvents.*
Part VI. The Velocity of Saponification of certain
Methyl Esters by Potassium Hydroxide in Methyl
Alcohol-Water Mixtures.

By WALTER IDRIS JONES, HAMILTON MCCOMBIE, and
HAROLD ARCHIBALD SCARBOROUGH.

IN a series of communications (T., 1921, 119, 970 *et seq.*) a study has been made of the velocity of reaction in mixed solvents and it has been shown that the curve expressing the relation between k and the composition of the solvent is, in most cases, made up of a series of linear sections. The change from one section to the adjacent one occurs at such compositions of the solvent mixture that simple complexes seem to be indicated. It has been suggested that this type of curve is peculiar and is dependent on the possibility of formation of a complex between one of the reactants and the solvent complex. Only a few reactions have been considered and from the limited number of reactants studied it would appear that a strong base (or a strong acid) plays an important rôle.

The solvent mixtures employed have been ethyl alcohol-water and benzene-nitrobenzene mixtures, and in view of the important

part which may have to be ascribed to the base (or acid), this choice is unfortunate owing to the very limited range of bases which could be examined, as their low solubility prevented reasonable accuracy.

Methyl alcohol-water mixtures appear to be free from this objection and possess an additional advantage in that the physical properties of such mixtures have been studied widely and thus the results obtained by a study of the velocity of saponification can be compared readily with the data obtained from the physical measurements.

The work has thus been extended to include the velocity of saponification of the methyl esters of certain aliphatic and aromatic monocarboxylic acids in methyl alcohol-water mixtures.

As a solvent, methyl alcohol has not been used so extensively as ethyl alcohol and as a component of a binary solvent medium there are but few examples of its use.

Trey (*Z. physikal. Chem.*, 1895, **18**, 193; 1903, **46**, 621) records the fact that the velocity of inversion of lactose in methyl alcohol-water mixtures is inversely proportional to the percentage of methyl alcohol. Lobry de Bruyn and his collaborators in a series of papers (*Rec. trav. chim.*, 1899, **18**, 13, 41, 311; 1901, **20**, 292) have shown that certain reactions taking place in methyl alcohol-water mixtures give a maximum value of k , but unfortunately the deductions to be drawn from the study of these reactions were limited by solubility in one case and in another by the comparatively small effect of a change in the composition of the solvent on the value of k .

Tubandt (*Annalen*, 1907, **354**, 259) and Kullgren (*Z. physikal. Chem.*, 1901, **37**, 613) have employed a few mixtures of methyl alcohol and water, but the data are insufficient for the deduction of any definite conclusions. Senter (T., 1915, **107**, 1070) found that the velocity of interaction of certain bromo-acids with an alkali reaches a maximum in a mixture containing about 40 per cent. by volume of methyl alcohol. Finally, Kremann (*Monatsh.*, 1905, **26**, 279) investigated the velocity of saponification of methyl acetate and showed that as the percentage of water increases in the solvent mixture k rises very slowly until about 60 per cent. of water is present and then the value of k increases rapidly. In the range, however, between pure methyl alcohol and pure water there are only some three measurements and the curve plotted from these values can be regarded only as an indication of the real shape of the curve.

The examination of the physical properties of methyl alcohol-water mixtures has led to the prediction that numerous hydrates must exist. These hydrates are tabulated on p. 2690.

TABLE I.

Formula.	Composition by weight (Per cent. of alcohol).	Measurement.
$2\text{CH}_3\cdot\text{OH}, \text{H}_2\text{O}$	78	D.E.C.

$\text{CH}_3\cdot\text{OH}, 3\text{H}_2\text{O}$	37.2	Viscosity (1, 2, 3).
$\text{CH}_3\cdot\text{OH}, 4\text{H}_2\text{O}$	30.8	D.E.C.
$\text{CH}_3\cdot\text{OH}, 5\text{H}_2\text{O}$	26.2	Viscosity (2).
$\text{CH}_3\cdot\text{OH}, 8\text{H}_2\text{O}$	18.2	
$\text{CH}_3\cdot\text{OH}, 20\text{H}_2\text{O}$	8.2	

D.E.C.: Thwing, *Z. physikal. Chem.*, 1894, **14**, 294. Viscosity: (1) Dunstan, *ibid.*, 1904, **49**, 595, (2) Varenne, *Compt. rend.*, 1911, **133**, 990, (3) Traube, *Ber.*, 1886, **19**, 879. Heat of dilution: Forcrand, *Ann. Chim. Phys.*, 1892, [vi], **27**, 525.

In opposition to the view that hydrates actually exist we have the investigations of Pushin and Glagoleva (T., 1922, **121**, 2815), who made a study of the freezing-point curve of methyl alcohol-water mixtures and found that there was no evidence of hydrate formation at the temperatures they were employing; further, they point out that evolution of heat occurs on mixing methyl alcohol and water and thus any hydrate formed should have an increased stability as the temperature is lowered.

In addition to the measurements which have been used to support the view that hydrates actually exist, there are numerous measurements of the physical properties of methyl alcohol-water mixtures in which maxima, minima, and points of inflection occur at such compositions of the mixture that it might be deduced that hydrates do exist; these points are tabulated below:

TABLE II.

Point of inflection. Approx. per cent. of alcohol.	Measurement.

A consideration of the results given in Table VI shows that the value of k calculated from the equation for a bimolecular reaction was constant over the range of the reaction examined and independent of the initial concentration of the reactants.

The reaction was found to proceed to an end for methyl *n*-butyrate and for methyl benzoate in a solvent mixture containing 90 per cent. of methyl alcohol. This result is of interest in view of the work of Cajola (*Gazzetta*, 1900, 30, i, 233), who has shown that, in absolute methyl alcohol and with equivalent concentrations of the reactants, only some 26 per cent. of methyl acetate is saponified by potassium hydroxide and, further, that the value of k is not constant and falls steadily after a short period. This has been established in these laboratories in the case of methyl benzoate, which is saponified to the extent of less than 1 per cent. even in the presence of 3 molecular proportions of potassium hydroxide.

The ratio $k_{\text{ester}}/k_{\text{methyl benzoate}}$ is found to have a nearly constant value, especially if the solvent contains more than 45 per cent. of methyl alcohol; as was the case with ethyl alcohol-water mixtures, a rise or fall in the value of this ratio constant appears to be associated with the relative solubilities of the esters.

TABLE III.
(Methyl benzoate. $k = 1$).

	<i>n</i> -Butyrate.	<i>iso</i> Butyrate.	<i>m</i> -Toluate.	<i>o</i> -Chloro- benzoate.	<i>p</i> -Chloro- benzoate.
90	2.45	1.36	0.71	2.35	3.45
84.9	2.25	1.48	0.71	2.05	—
82.5	2.40	1.60	0.75	2.25	3.55
80	2.25	1.54	0.70	1.97	3.50
77.4	2.25	1.50	0.76	1.99	3.25
75.25	2.25	1.58	0.73	2.02	3.45
70	2.38	1.42	0.75	1.86	3.10
66.1	2.30	1.54	0.74	1.97	3.25
62.5	2.35	1.58	0.74	1.95	3.35
60	2.32	1.53	0.74	1.87	3.05
55	2.05	1.47	0.66	1.66	2.70
50	1.85	1.28	0.63	1.52	2.35
45	2.10	1.38	0.70	1.90	2.95
42.5	1.98	1.28	0.69	1.63	2.55
40	2.02	1.30	0.76	1.58	2.48
35	2.20	1.17	0.71	1.51	2.40
32.75	2.50	1.20	0.76	1.48	2.53
30	2.75	1.20	0.77	1.44	2.25

It will be seen that methyl *o*-chlorobenzoate behaves quite normally throughout and does not, as was found with the corresponding ethyl ester (T., 1922, 121, 243), give a section in which the acceleration due to an increasing percentage of water is zero or negative.

The ratio $k_{ester}/k_{methyl\ benzoate}$ has been tabulated (T., 1922, 121, 246), and it is of interest to compare with this the ratio for the methyl esters and methyl benzoate; it is seen that the ratio is much more constant for the methyl esters than for the ethyl esters.

The ratio values for methyl *n*-butyrate, *m*-toluate, and *p*-chlorobenzoate are almost identical with those for the corresponding ethyl esters, whereas the ratio values for methyl isobutyrate and *o*-chlorobenzoate are much higher, —1.45 and 1.75 for the methyl esters compared with 1.1 and 1.2 for the ethyl esters, the abnormal section in the case of ethyl *o*-chlorobenzoate not being taken into account. This high value in the case of the methyl esters is probably a steric effect and would thus show the influence of an α -methylene group in acids which contain substituents in close proximity to the carboxyl group.

A study of the curves showing the relation between the value of k and the percentage composition of the solvent mixtures shows that we are dealing with a reaction which passes through a succession of five linear sections. The observed values of k and those calculated on the basis of this linear relationship are shown for methyl isobutyrate.

TABLE IV.

Alcohol per cent.	$k_{obs.}$	$k_{calc.}$	Alcohol per cent.	$k_{obs.}$	$k_{calc.}$
90	0.0145	0.0148	60	0.22	0.22
84.9	0.0325	0.032	55	0.315	0.315
82.5	0.038	0.0385	50	0.41	0.41
80	0.0475	0.0475	45	0.47	0.47
77.4	0.063	0.063	42.5	0.57	0.58
74.8	0.078	0.079	40	0.69	0.69
70	0.108	0.110	35	1.04	1.02
66.1	0.137	0.136	32.75	1.35	1.42
60.5	0.172	0.172	30	1.90	1.85

The points at which one section intersects with the adjacent section have been calculated with one exception. In certain cases, it is found that the third and fourth sections have no point in common, and this indicates a discontinuity the position of which can be fixed only by reference to the curves.

The points of intersection vary from ester to ester, but lie within 0.75 per cent. of the mean; a divergence which would be accounted for by quite a small experimental error.

The average values for the three points of intersection calculated are 79, 63.6, and 36.7 per cent. methyl alcohol. The fourth point of intersection can be calculated in two cases and is found to occur at 48.1 per cent. methyl alcohol. In the remaining four cases this point should be given by the intersection of the section extending from 64 to 50 per cent. methyl alcohol and that section extending

from 45 to 37 per cent. methyl alcohol, but the value of k in 45 per cent. methyl alcohol is so low that the value is smaller than the value required if the point at 45 per cent. was on the section 64 to 50 per cent. methyl alcohol. This would seem to indicate

FIG. 1.
Methyl butyrate.

a minimum in the curve in this neighbourhood. The points of intersection for each ester are shown in Table V :

TABLE V.

Ester.	Points of intersection (per cent. methyl alcohol).			
<i>n</i> -Butyrate	78.9	63.7	47.5	36.5
<i>iso</i> Butyrate	79.2	63.6	"	36.2
Benzoate	79.0	63.6	"	37.0
<i>m</i> -Toluate	79.4	63.2	"	36.1
<i>o</i> -Chlorobenzoate	78.8	63.5	48.1	36.9
<i>p</i> -Chlorobenzoate	78.8	64.0	48.1	37.4

It will be seen that these values are in close agreement with those demanded by the hydrates $2\text{CH}_3\cdot\text{OH}, \text{H}_2\text{O}$, $\text{CH}_3\cdot\text{OH}, \text{H}_2\text{O}$, $\text{CH}_3\cdot\text{OH}, 2\text{H}_2\text{O}$, and $\text{CH}_3\cdot\text{OH}, 3\text{H}_2\text{O}$, which require the percentage compositions 78.1, 64, 47.1, and 37.2 per cent. methyl alcohol, respectively.

The evidence thus seems to point strongly to the existence of certain hydrates of methyl alcohol and it is difficult to explain away as a mere coincidence the occurrence of so many points of inflection at such compositions of the solvents as would represent the simplest complexes.

FIG. 2.
Methyl butyrate.

EXPERIMENTAL.

The methyl alcohol was obtained from a commercial spirit by purification according to the method described by Regnaud (*Ann. Chim.*, 1885, [vi], 4, 431); it was found, however, that if 1,300 c.c. of the spirit were heated under reflux with 500 grams of freshly burnt lime and 26 grams of sodium hydroxide for eighteen hours, fractionated, and then subjected to the treatment with iodine, the quantity of iodine required per litre was reduced to about half (50 grams).

The methyl alcohol-water mixtures were prepared and stored in the manner described for the ethyl alcohol-water mixtures.

The methyl esters were prepared by the usual methods and purified

by two distillations. Methyl *p*-chlorobenzoate was recrystallised from dilute methyl alcohol until it melted at 43°.

The standard solutions of alkali, acid, and ester were prepared in the manner previously described.

The experiments were carried out at $30^{\circ} \pm 0.05^{\circ}$; no modifications in the methods previously described were required.

Summary.

(1) The velocity of saponification of six methyl esters in a number of methyl alcohol-water mixtures has been determined and the reaction shown to be strictly bimolecular.

(2) The curve showing the relation between the velocity coefficient, k , and the percentage composition of the solvent mixtures is divisible into five linear sections.

(3) The points of intersection of the linear sections occur at such compositions of the solvent that solvent complexes are indicated.

(4) A comparison is drawn between the data obtained from physical measurements on the solvent mixtures and those obtained from the velocity measurements and it is found that certain peculiarities are common.

(5) The relative velocities of saponification of methyl esters to methyl benzoate and of ethyl esters to ethyl benzoate are compared and these relative velocities are found to be identical provided there is no substituent in the acid radicle in close proximity to the carboxyl residue.

The authors wish to express their thanks to the Government Grant Committee of the Royal Society for funds placed at their disposal which have defrayed the cost of this research. One of us (W. I. J.) begs to express his thanks to the Master and Fellows of Gonville and Caius College for a scholarship which has enabled him to collaborate in this work.

CAMBRIDGE.

[Received, July 17th, 1923.]

CCCVIII.—*The Preparation of the Isomeric Methoxybenzyl Bromides.*

By JOHN BALDWIN SHOESMITH.

THE isomeric methoxybenzyl bromides were first obtained by Späth (*Monatsh.*, 1913, **34**, 1995), who employed in their preparation the reactions summarised in the following scheme:

The present communication gives details of methods which were employed in order to obtain the intermediate compounds in better

yields and with greater certainty than was formerly possible. Improved methods are given for the preparation of the hydroxybenzaldehydes, *o*-hydroxybenzyl alcohol (saligenin), and *p*-methoxybenzaldehyde (anisaldehyde).

The hydroxybenzaldehydes are obtained by hydrolysing the dichlorinated tolyl carbonates with formic acid, with a mixture of formic and oxalic acids, or with sodium acetate in alcoholic solution. The ortho-compound hydrolyses directly to salicylaldehyde, whilst the meta- and para-compounds yield the aldehyde carbonates, $\text{CO}(\text{O}-\text{C}_6\text{H}_4\cdot\text{CHO})_2$. Boiling sodium bisulphite solution completes the hydrolysis. These reagents are much more convenient than the calcium carbonate and water at 5 atmospheres pressure recommended by Raschig (D.R.-P. 233631).

Salicylaldehyde is best converted into *o*-methoxybenzyl alcohol by reduction to saligenin and subsequent methylation. In the case of the meta- and para-compounds the order of the reactions is reversed.

p-Methoxybenzaldehyde (anisaldehyde) is prepared by oxidising anethole with chromic and sulphuric acids. Anethole is oxidised by sodium chlorate directly to anisaldehyde, the intermediate glycol not being produced. This is in agreement with the results of similar oxidations carried out by Hofmann (*Ber.*, 1912, 45, 3329; 1913, 46, 1657).

Direct halogenation of the tolyl methyl ethers results in the formation of a mixture of nuclear and side-chain substituted halogen compounds from which methoxybenzyl halides cannot be isolated.

EXPERIMENTAL.

Chlorination of the Tolyl Carbonates.

The tolyl carbonates were prepared by the general method of Holleman and Hoeflake (*Rec. trav. chim.*, 1916, 36, 261). Carbonyl chloride was passed into a 10 per cent. solution of the sodium tolyl-oxide until precipitation of the carbonate was complete. The ortho- and para-compounds gave the carbonates at once. *m*-Cresol gave the intermediate tolyl chloroformate, $\text{C}_6\text{H}_4\text{Me}\cdot\text{O}\cdot\text{COCl}$, which was converted into the carbonate by heating it with the equivalent amount of *m*-cresol dissolved in rather more than the theoretical quantity of caustic soda. The carbonates were all carefully crystallised from alcohol.

When the ω -chlorotolyl carbonates, $\text{CO}(\text{O}-\text{C}_6\text{H}_4\cdot\text{CH}_2\text{Cl})_2$, were hydrolysed, the resulting hydroxybenzyl alcohols were never isolated owing to their remarkable tendency to resinify in presence of acids. Chlorine was therefore passed into the vigorously stirred, molten

carbonate at 170–180° until a gain in weight of 60 per cent. of the original compound had taken place. Slight hydrolysis of the carbonate occurred in all cases, and an odour of carbonyl chloride was perceptible. To prevent unnecessary tarring at this stage, the carbonates had been freed from chloroformate by recrystallisation from alcohol. The chlorinated compounds show a tendency to crystallise when kept at room temperature for some time, but attempts to separate pure compounds have met with little or no success.

o-Methoxybenzyl Bromide. *Hydrolysis of Dichlorinated o-Tolyl Carbonate*.—This product was found to contain 36.6 per cent. of chlorine hydrolysable with alcoholic potash ($C_{10}H_{10}O_3Cl_4$ requires $Cl = 37.3$ per cent.).

(a) Hydrolysis with formic acid. Twenty-five grams of the viscous chlorinated carbonate were boiled with 200 c.c. of 80 per cent. formic acid for two hours, hydrogen chloride being evolved. The deep red solution was diluted with 500 c.c. of water, and the salicylaldehyde* distilled in steam and purified by extraction with ether and conversion into the bisulphite compound. A yield of 40 per cent. of the theoretical was thus obtained.

(b) Hydrolysis with formic and oxalic acids. Twenty-five grams of the oil were boiled with a mixture of 75 c.c. of 80 per cent. formic acid and 35 grams of anhydrous oxalic acid. The aldehyde was then separated and purified as before. The yield was slightly improved.

(c) Hydrolysis with sodium acetate. Twenty-five grams of the oil were boiled with 75 c.c. of alcohol, 15 grams of anhydrous sodium acetate, and 25 grams of sodium acetate crystals for two hours, sodium chloride being precipitated. The alcohol, now contaminated with ethyl acetate, was as far as possible distilled off, the residue diluted with five parts of water and acidified, and the aldehyde distilled in steam. This method gave by far the best yield (60 per cent.) of purified aldehyde.

o-Hydroxybenzyl Alcohol.—Twelve grams of redistilled salicylaldehyde were emulsified by shaking with 100 c.c. of water, and 300 grams of 1.5 per cent. sodium amalgam added in small quantities. The spent amalgam was continuously removed and excessive alkalinity was avoided by the gradual addition of 25 grams of sodium bicarbonate. When the yellow colour due to the presence

* When this aldehyde and related aldehydes derived from resorcinol are mixed with Schiff's reagent, the normal reaction appears to be the precipitation of yellow hydrated Schiff's bases, and not the formation of the usual soluble red dye (Wieland and Scheuing, *Ber.*, 1921, 54, [B], 2527). This point is undergoing further investigation.

of aldehyde had disappeared and the evolution of hydrogen was marked, the solution was cooled in ice and the saligenin, which crystallised in almost the theoretical yield, was filtered off and purified by shaking it in water solution with animal charcoal for three hours. After filtration, extraction with ether, and recrystallisation from ligroin, the sample melted at 86°. The method of purification was that adopted by Hart and Hirschfelder (*J. Amer. Chem. Soc.*, 1920, 42, 2680). The saligenin was methylated and converted into *o*-methoxybenzyl bromide by the methods of Lapworth and Shoosmith (*T.*, 1922, 121, 1392). The bromide thus prepared crystallised from light petroleum in colourless, six-sided plates, m. p. 46°.

m-Methoxybenzyl Bromide. *Hydrolysis of Chlorinated m-Tolyl Carbonate*.—*m*-Tolyl carbonate after chlorination was found to contain 35.5 per cent. of hydrolysable halogen. The details set out below must be followed carefully to ensure a good yield of *m*-hydroxybenzaldehyde.

(a) Hydrolysis with formic acid. Twenty-five grams of the oil were hydrolysed with 100 c.c. of 80 per cent. formic acid as in the case of the *o*-tolyl compound. The impure *m*-aldehydophenyl carbonate, which was completely precipitated by addition of 150 c.c. of water to the cooled solution, was rapidly hydrolysed by freshly prepared, boiling aqueous sodium bisulphite. The filtered solution was acidified and steam-distilled to remove sulphur dioxide, the aldehyde extracted with ether, and the ethereal solution evaporated after neutralisation with sodium carbonate to destroy any trace of acid. The *m*-hydroxybenzaldehyde (yield 40 per cent.) was recrystallised from boiling water (yield 25 per cent.) and it then melted at 103–104°. A sample prepared from *m*-nitrobenzaldehyde melted at 104°.

(b) Hydrolysis with formic and oxalic acids. The same quantities were used as in the case of the ortho-compound; hydrolysis, yielding the aldehyde carbonate, was complete in one and a half hours. Subsequent hydrolysis with bisulphite solution gave the hydroxy-aldehyde in slightly better yield than that obtained in (a).

(c) Hydrolysis with sodium acetate. The same quantities were used as in the preparation of salicylaldehyde, but the improvement in the yield was not so marked in this case.

There are no further details to add to those already communicated on the conversion of this aldehyde into *m*-methoxybenzyl bromide.

p-Methoxybenzyl Bromide. *Hydrolysis of Chlorinated p-Tolyl Carbonate*.—A summary of the yields given by methods employed is all that is necessary in this case. Formic acid alone and formic

and oxalic acids gave in each case a yield of 40 per cent. of the theoretical. Sodium acetate and alcohol gave a yield of 50 per cent.

p-Methoxybenzaldehyde (Anisaldehyde).—Nitric acid alone (Cahours, *Annalen*, 1845, 56, 307) or diluted with acetic acid (Labbe, *Bull. Soc. chim.*, 1899, [iii], 21, 1076) oxidised anethole too violently to produce anisaldehyde in good yield.

Fifty grams (3 mols.) of anethole, emulsified in 500 c.c. of water and 10 grams of kieselguhr, were oxidised by adding a solution of 50 grams (more than 4 mols.) of chromic acid in 80 c.c. of water so slowly that the temperature did not rise above 28°. A faint odour of acetaldehyde was perceptible. The mixture having been stirred for half an hour, when the temperature was once more normal, a well-cooled solution of 80 grams (6 mols.) of sulphuric acid in 100 c.c. of water was added during one and a half hours. The temperature of the mixture gradually rose to 27° and the colour changed to green. When the temperature had fallen to 16–18°, the kieselguhr was filtered off and washed twice with ether. The main solution was shaken four times with ether, the mixed ethereal extracts were washed free from anisic acid with 5 per cent. caustic soda solution, most of the ether was evaporated, and the residual impure anisaldehyde converted into the bisulphite compound, which was filtered, pressed, and washed free from unoxidised anethole with alcohol. The aldehyde, liberated from a warm, aqueous solution of the bisulphite compound by concentrated sodium carbonate solution, was extracted with ether, dried, and distilled. Half the expected aldehyde was obtained in a pure condition.

The semi-oxidised mixture which was extracted by alcohol from the bisulphite compound gave a further 5 per cent. of aldehyde. Anisic acid (8 per cent.) was liberated by acid from the alkali washings above.

Oxidation of Anethole by Sodium Chlorate.—A solution of 4.5 grams of anethole (3 mols.) in a mixture of 80 c.c. of acetone, 40 c.c. of 5 per cent. sodium chlorate solution (2 mols.), and 4 c.c. of 2 per cent. osmic acid solution was boiled at 65° for ten hours, 2 c.c. of the solution being titrated at regular intervals with silver nitrate solution. At the end of the time stated, the quantity of chloride in the dark solution was constant, that is, the reaction

was complete. The acetone was then evaporated off and the aldehyde isolated from the residue as in the previous case, 2.2 grams of the pure aldehyde being obtained along with a trace of anisic acid.

Experiments carried out since the last communication (Lapworth

and Shoesmith, *loc. cit.*) on the conversion of this aldehyde into *p*-methoxybenzyl bromide * bear out the necessity for a second reduction with alcoholic potash of the anisyl alcohol produced from this aldehyde by Cannizzaro's method. A solid anisyl alcohol was thus obtained. The bromide itself, which resulted on passing dry hydrogen bromide into the benzene solution of anisyl alcohol, was found to be very pure and crystallised in long needles. These needles are extremely sensitive to the action of moist air, and the bromide only existed as such for a few moments after removing into the atmosphere.

Chlorination of the Tolyl Methyl Ethers.—Chlorine was passed in a slow stream into the tolyl methyl ethers for half an hour. The introduction of cold air with the chlorine maintained the temperature at 40°. The quantity of hydrogen chloride not carried away mechanically was found in no case to exceed 0.10 per cent. The total halogen was estimated by the method of Carius, the hydrolysable halogen by boiling for half an hour with 10 per cent. alcoholic potash and estimating volumetrically the potassium chloride so produced.

The results are summarised.

Compound chlorinated.	Free HCl. Per cent.	Total chlorine. Per cent.	Chlorine hydrolysable compared with	
			Total Cl. Per cent.	Total compound. Per cent.
ortho.	Nil	31.4	19.0	5.98
meta.	0.01	22.3	8.8	1.96
para.	0.10	29.2	24.8	7.20

When the ethers were exposed to the glare of a mercury vapour lamp the results were unaltered.

The author wishes to express his gratitude to Prof. A. Lapworth, F.R.S., who supervised his work in the Manchester University, and to the Advisory Council of the Department of Scientific and Industrial Research for a grant which enabled him to undertake the investigation.

* The marked difference in lachrymatory properties between *m*-methoxybenzyl bromide and the very easily hydrolysed, non-lachrymatory *para*-isomeride finds a parallel in the vesicant properties of $\beta\beta'$ -dichlorodiethyl sulphide and its non-vesicant, easily hydrolysed isomeride, $\alpha\alpha'$ -dichlorodiethyl sulphide (Bales and Nickelson, T., 1922, 121, 2137).

CCCIX.—*Condensation of Diphenylformamidine with Phenols. Part I. A New Synthesis of β -Resorcyaldehyde.*

By JOHN BALDWIN SHOESMITH and JOHN HALDANE.

THE condensation which takes place when diphenylformamidine is heated with compounds containing an active methylene group was first pointed out by Dains (*Ber.*, 1902, **35**, 2504). As an example of this may be quoted the condensation of the amidine (I) with acetylacetone, which probably takes place in two stages. The intermediate compound (II) is never isolated, aniline being liberated at once.

Anilinomethylenecetylacetone (III) is isolated in almost quantitative yield.

This type of reaction appears to be a very general one and has been extended by Dains and his co-workers (*J. Amer. Chem. Soc.*, 1909, onwards) to a large number of similar compounds.

The present investigation has shown that condensation also takes place between diphenylformamidine and resorcinol. Aniline is liberated and a solid compound results. The course of the reaction is represented thus:

The crude condensation product, which consists essentially of the Schiff's base (IV) of β -resorcyaldehyde, unchanged resorcinol, and diphenylformamidine, is hydrolysed by boiling caustic soda and β -resorcyaldehyde can thus be obtained in a very simple manner.

It is, however, necessary to say that the structure to be assigned to compound (IV) is not yet decided. Its physical and chemical properties show that it is slightly different from the Schiff's base of the aldehyde which was prepared by Dimroth and Zoepfritz (*Ber.*, 1902, **35**, 995) by another method.

The present communication details the method of preparing β -resorcyaldehyde in appreciable yield; the extension of the method to other phenols and the constitution of the intermediate compound are reserved for further investigation.

EXPERIMENTAL.

Diphenylformamidine.—This was prepared by boiling together aniline and formic acid (Weith, *Ber.*, 1876, 9, 454). Forty grams (1 mol.) of 80 per cent. formic acid were mixed with 160 grams ($2\frac{1}{2}$ mols.) of aniline. The water which was present in the original acid together with that produced in the reaction was distilled away through a fractionating column. The head of the column was fitted with a device for trapping the water so soon as it reached the top. After four hours' gentle boiling, the temperature was raised until 60 c.c. of aniline had distilled over. The residual diphenylformamidine solidified on cooling and after recrystallisation from alcohol melted at 137° (yield 63 grams).

Condensation of Diphenylformamidine with Resorcinol.—A long series of experiments has shown the following to be the best conditions for the preparation of β -resorcyaldehyde by this method.

A finely powdered mixture of 5 grams (1 mol.) of carefully dried resorcinol with 9 grams (1 mol.) of diphenylformamidine was heated in a small, thin-walled flask,* totally immersed in the vapour of boiling water to ensure a temperature of 100° . The mixture first liquefied; solid appeared after five hours' heating. At the end of six hours, the condensation product was dissolved in 50 c.c. of hot 12–15 per cent. caustic soda solution, the liberated aniline distilled with steam, and the cooled filtered solution made slightly acid with dilute hydrochloric acid. The small quantity of resin here precipitated was separated and extracted with 20 c.c. of boiling water. The extract was added to the main solution, from which a saturated solution of aniline hydrochloride (15 c.c.) precipitated β -resorcyaldehyde as the hydrochloride of the hydrated Schiff's base, $C_6H_3(OH)_2 \cdot CH(OH) \cdot NHPh \cdot HCl$. After one hour, the hydrochloride was collected and the base remaining in the filtrate was precipitated by adding a saturated solution of sodium acetate. The free base was filtered off, mixed with the hydrochloride, and the whole hydrolysed with caustic soda solution. The liberated aniline was removed with steam, the bright red solution acidified, and the aldehyde, extracted with ether (yield 45–50 per cent. of the theoretical), was recrystallised from hot water. It was identified by mixed melting-point determinations (135 – 136°), the deep brown colour given by ferric chloride to its aqueous solution, the feathery needles of its phenylhydrazone, the oxime of melting point 192° , and the peculiar yellow precipitate which it gives with Schiff's reagent.

* It is hoped to publish details of this simple thermostat shortly.

The method of purification adopted is very much better than any involving the use of sodium bisulphite solution.

Condensation under other Conditions.—The same quantities of resorcinol and diphenylformamidine were heated at 130° for one and a half hours, and the hydrolysis was carried out as before. Acid, however, precipitated a considerable quantity of red needles, which were characterised as the dialdehyde of resorcinol, $C_6H_2(OH)_2(CHO)_2$, m. p. 126° (Tiemann and Lewy, *Ber.*, 1877, 10, 2211). They represented 25 per cent. of the resorcinol; a smaller quantity (25–30 per cent.) of monaldehyde was isolated from the acid solution, whilst the resin present represented 30–40 per cent. The aldehyde was difficult to purify.

When the condensation was effected at 100° for nine hours, 40 per cent. of the expected monaldehyde, a trace of dialdehyde, and 25–30 per cent. of the resinous compound were produced.

An increase in the quantity of resorcinol used caused a corresponding increase in the amount of aldehyde produced.

The effect of moisture on this condensation is remarkable. The free hydrated Schiff's base which is probably formed in the condensation in presence of moisture was found to decompose at 100° in the impure condition into aniline and a resin. This caused the yield of monaldehyde to be very poor whenever precautions were not taken to dry the resorcinol before use. Under these conditions, it is interesting to point out the as yet inexplicable formation of dialdehyde.

Five grams of resorcinol (which had not been dried in any way), on condensing with 9 grams of diphenylformamidine, gave 25 per cent. of the monaldehyde, 27 per cent. of the dialdehyde, and resin representing 20 per cent. of resorcinol.

Distillation with steam in the absence of caustic alkali is not a practicable method of removing the aniline from the Schiff's base produced in the condensation. This is due to the decomposition of the hydrated Schiff's base by moisture at 100°, as already stated. The resin obtained dissolves afterwards in caustic alkali with a deep red colour, but does not appear to be a definite compound.

Summary.

- (1) Diphenylformamidine and resorcinol condense together on heating with liberation of aniline. The condensation product, hydrolysed by caustic alkali, yields aniline and β -resorecylaldehyde.
- (2) The method by which the best yields of β -resorecylaldehyde may be obtained is described and the deleterious effect of moisture, too long heating, and condensation at too high a temperature pointed out.

The authors wish to state that the suggestion that such a condensation might take place was due to Prof. A. Lapworth, F.R.S. They also wish to thank the Advisory Council of the Department of Scientific and Industrial Research for grants which enabled each of them in turn to undertake these investigations.

CCCX.—*Use of the Salts of the Arylsulphonhalogenoamides in the Estimation and Iodination of Phenols.*

By ELWYN ROBERTS.

THE arylsulphoniodoamides of the alkali metals, $\text{Ar}\cdot\text{SO}_2\cdot\text{NIM}$, recently prepared by the author (this vol., p. 849) are a highly convenient source of hypiodous acid, which is slowly formed by the hydrolysis of their aqueous or alkaline aqueous solution, and can be used for iodination of certain organic compounds :

The iodination of phenols by any of the many methods which have been proposed is solely due, as Cofman (T., 1919, 115, 1040) has demonstrated, to the hypiodous acid or hypiodite contained in the reagent. In place of the salts of iodoamides as a source of hypiodite, mixtures of a chloroamide, such as "chloramine-T" and potassium iodide or a bromoamide, such as potassium *p*-toluenesulphonbromoamide and potassium iodide, may be used, for hypochlorous acid and potassium iodide (Klimenko, *Z. physikal. Chem.*, 1897, 23, 552, 558; Bray, *ibid.*, 1906, 54, 563) have been proved to yield hypiodous acid; the same is probably true of hypobromous acid and potassium iodide.

With phenol, salicylic acid, and resorcinol, these reagents give as a first stage tri-iodo-derivatives, which undergo in time further change. The salts of arylsulphonchloro- and -bromo-amides used alone, on the other hand, show no arrest at a trihalogen derivative, but effect a more profound transformation.

The iodination of phenols (phenol, salicylic acid, resorcinol, α - and β -naphthols) as a means of estimating phenols in solution has, in spite of the work of many chemists, proved disappointing; a quantitative relation has been found only for a few phenols, and then only within very narrow limits of concentration and under carefully defined conditions (Messinger and Vortmann, *Ber.*, 1890, 23, 2753; Kuster, *Ber.*, 1894, 27, 1905; Richard, *J. Pharm. Chim.*,

1902, [vi], 15, 217; Pence, *J. Ind. Eng. Chem.*, 1911, 3, 820; Wilkie, *J. Soc. Chem. Ind.*, 1911, 30, 398; 1912, 31, 208; Vortmann, *Ber.*, 1923, 56, [B], 234). A solution of iodine in aqueous potassium iodide, made sufficiently alkaline, is the reagent generally recommended. One of the reagents above named, preferably "chloramine-T" and potassium iodide, is for this purpose more convenient, especially for the estimation of phenol and salicylic acid, when accurate results are obtained over a wide range of concentrations. It is not, however, more widely applicable than the commonly used reagent. With α - and β -naphthols and resorcinol, the concentrations of the solutions affect the extent of the reduction of the hypiodous acid. The further oxidation of iodinated phenols is similar with both reagents; thus tetraiododiphenylenequinone (Wilkie, *loc. cit.*) is the final product of the reaction with phenol and salicylic acid.

From *o*-nitrophenol a new mono-iodonitrophenol, m. p. 80–81°, probably 4-iodo-6-nitrophenol, has been prepared. From the product of iodination by other methods, 2 : 4-di-iodo-6-nitrophenol has alone been isolated (Korner, *Jahresber.*, 1867, 617; Datta and Prosd, *Amer. Chem. J.*, 1917, 39, 441), as it is doubtful if the mono-iodonitrophenols melting respectively at 90–91° and 66–67° described but not analysed by Busch (*Ber.*, 1874, 7, 462) are pure materials, for they are not identical with either of the products obtained by Brenans (*Compt. rend.*, 1902, 134, 357), in the nitration of *o*-iodophenol, which are taken to be 2-iodo-6-nitrophenol (m. p. 110°) and 2-iodo-4-nitrophenol (m. p. 86–87°).

EXPERIMENTAL.

Estimation of Phenol and Salicylic Acid.—Five c.c. of the aqueous phenol solution, or of salicylic acid (the potassium salt), containing 0.025 gram (1 mol.), are pipetted into 25 c.c. of 2.5 per cent. potassium iodide solution. An accurately weighed quantity (at least 3 mols. equivalent) of the halogenoamide salt of known halogen content is then added, which dissolves with slight liberation of iodine. The salts, $p\text{-CH}_3\text{C}_6\text{H}_4\text{SO}_2\text{NXM}$, where X = Cl, Br, I; M = K or Na, were used. The whole is warmed at 60° and maintained at this temperature for five minutes. At first the colour of the iodine deepens and then fades as iodination ensues. The solution, which is now clear and yellow in colour, is cooled and then acidified with dilute sulphuric acid, when tri-iodophenol is precipitated. This is collected and well washed with aqueous potassium iodide and with water; the iodine in the filtrate, which represents the excess of halogenoamide salt used, is titrated with *N*/10-thio-sulphate.

If the period of heating is prolonged, it is observed that after thirty minutes the apparent amount of phenol increases by about 1 per cent.; this is in part due to volatilisation of iodine and also probably to slight oxidation of the methyl group by hypohalogen acid.

The iodination of phenol and salicylic acid (potassium salt) (1 mol.) by the iodoamine salt, $o\text{-CH}_3\cdot\text{C}_6\text{H}_4\cdot\text{SO}_3\cdot\text{NKI}\cdot\text{H}_2\text{O}$ (4 mols.), in aqueous solution in the cold reaches first the tri-iodophenol, but finally the tetra-iododiphenylenequinone stage (Wilkie, *loc. cit.*; Vortmann, *loc. cit.*). The first stage has been attained in twenty-four hours, but subsequently the precipitation from the hitherto clear solution of the reddish-purple tetra-iododiphenylenequinone marks the advent of the second stage. It is very remarkable that during this second stage in the oxidation the titre of the solution remains constant (compare Wilkie, *loc. cit.*; Vortmann, *loc. cit.*).

α - and β -Naphthols.—An identical method was used in an attempt to estimate α - and β -naphthols, but proved of little value. Only with given concentrations, and a fixed period of heating, could definite ratios (1:1.75) be secured (compare Messinger and Vortmann, *loc. cit.*; Kuster, *loc. cit.*). On addition of the halogenoamide salt to the α -naphthol (potassium salt) solution, a dark violet, amorphous powder was immediately precipitated. A similar precipitate was obtained with a sulphonbromoamide salt alone, but chloramine-T gave a violet coloration only (Found: I = 17.22. $\text{C}_{10}\text{H}_6\text{I}\cdot\text{OH}$ requires I = 47.01 per cent.). β -Naphthol yields during the period of heating a green, amorphous precipitate.

Resorcinol.—The method is also of little value for estimating resorcinol (compare Richard, *loc. cit.*; Pence, *loc. cit.*). Addition of a halogenoamide salt to a neutral aqueous solution of resorcinol in the presence of potassium iodide gives a solution the dark colour of which becomes more intense on warming. On acidification, a dark brown, amorphous precipitate, which appears to be identical with that obtained from tri-iodoresorcinol (see below), is thrown down [Found: I = 42.53. $\text{C}_6\text{H}_3\text{I}(\text{OH})_2$ requires I = 53.32 per cent.].

2:4:6-Tri-iodoresorcinol, $\text{C}_6\text{H}_3\text{I}_3(\text{OH})_2$, was first prepared by Michael (*Ber.*, 1876, 9, 1752) and later by Claisen (*Ber.*, 1878, 11, 1442). We find that the best method of preparation is to mix quickly a solution of 1 gram of resorcinol (1 mol.) with a solution of 24 grams of potassium iodide ($4\frac{1}{2}$ mols.) in 200 c.c. of water, and a solution of 8 grams of chloramine-T (3 mols.) in 1800 c.c. of water. Air is bubbled rapidly through the mixture and very dilute acetic acid (10 c.c. of glacial acetic acid diluted to 200 c.c. with water) run in fairly rapidly, whereupon a slate-coloured material is pre-

precipitated. This compound, which is possibly a tri-iodoresorcinol periodide, is filtered off, washed, pressed, dried, and then quickly dissolved in glacial acetic acid containing potassium iodide crystals, and after the free iodine has been decolorised with alkaline sulphite the solution is diluted rapidly with water. The white precipitate is filtered off, washed with water, dried, and dissolved in warm carbon disulphide; this solution is filtered from a minute quantity of a dark chocolate-brown, amorphous material, and then allowed to crystallise. Tri-iodoresorcinol separates in white, needle-shaped crystals, m. p. 154° ; the yield is 47 per cent. of the theoretical.

Tri-iodoresorcinol (potassium salt) was oxidised by hypiodous acid, namely, by warming at 60° for five minutes with two mols. of a halogenoamide salt in presence of potassium iodide, to a dark brown solution. On cooling and acidifying, a dark brown, amorphous precipitate was thrown down which was very difficult to filter. The brown product was redissolved in alkali, the solution diluted largely with water in order to keep in solution any sulphonamide formed on acidifying from the excess of halogenoamide salt, and then reprecipitated by acidifying with dilute sulphuric acid. It was filtered off, washed with water, and dried (Found: I = 42.10 per cent.). It will be noted that 5 mols. of halogenoamide salt (equivalent to 10 atoms of iodine) are required to convert resorcinol into the brown product.

4-Iodo-6-nitrophenol, $\text{NO}_2 \cdot \text{C}_6\text{H}_3\text{I} \cdot \text{OH}$.—A mixture of 10 grams of *o*-nitrophenol dissolved in 800 c.c. of *N*/10-potassium hydroxide solution (1 equiv.), a solution of 75 grams of potassium iodide in 4,000 c.c. of water, and 40 grams of chloramine-T was heated at 60° for thirty minutes. The solution was afterwards cooled and acidified, being stirred meanwhile, with a solution of 100 c.c. of glacial acetic acid in 1,000 c.c. of water. The precipitate obtained consisted of a mixture of iodo-derivatives together with *p*-toluenesulphonamide; it was filtered off, well washed with water, pressed, and steam-distilled for about eight hours; a little iodine which adhered to the solid and came over on distillation, was removed by alkaline sulphite from the mixture of iodo-derivatives, which were thus separated from the non-volatile sulphonamide. 2:4-Di-iodo-6-nitrophenol was but slightly volatile with steam and in the main was left in the residue in the distilling flask, from which it could be isolated. The crude mixture of volatile iodo-derivatives (15 grams) was dissolved in 1,500 c.c. of warm *N*/10-potassium hydroxide (1 equiv.). Separation was effected by fractional precipitation of the cooled solution, which was well stirred meanwhile, by very gradual addition of *N*/10-hydrochloric acid. A first fraction, which melted at $72-77^{\circ}$, was obtained after addition of 1,125 c.c., and a second

fraction, melting at 46–95°, on acidification. The latter, which might have contained 2-iodo-6-nitrophenol as well as 2:4-di-iodo-6-nitrophenol, could not be easily separated into fractions. The first fraction, after being filtered, washed with water, and pressed, was dissolved in 750 c.c. of *N*/10-potassium hydroxide, in which it was more easily soluble than the initial product. To the cool, well-stirred solution, *N*/10-hydrochloric acid, in all 625 c.c., was again added drop by drop. It is to be noted that in both precipitations about one-half the hydrochloric acid was added before separation began. The final product weighed 5 grams after washing and drying, and melted at 79–81°. From alcohol it crystallised in long, yellow needles, *m. p.* 80–81° (Found: *I* = 48.64. $C_6H_4O_3NI$ requires *I* = 47.89 per cent.). On acidification in the second fractionation, a second precipitate, melting at 58–67°, was obtained. All attempts at isolation of 4-iodo-6-nitrophenol by fractional crystallisation from various media of the mixture or of salts prepared therefrom, were unsuccessful.

The potassium, sodium, and ammonium salts of 4-iodo-6-nitrophenol were prepared by dissolving the iodonitrophenol in alcoholic solutions of the alkalis, or in a warm aqueous 10 per cent. alkali and allowing to crystallise. The potassium salt forms red prisms, the sodium salt long, red needles, the ammonium salt short, red needles. The salts decompose explosively on heating with deposition of carbon; the ammonium salt decomposes in the air, the crystals falling to a powder and ammonia being evolved.

The *benzoyl* derivative, $NO_2 \cdot C_6H_3I \cdot OBz$, is best prepared by dissolving 0.2 gram of the substance in a little ether, adding the equivalent of pyridine (0.2 c.c. approx.), followed by addition of an ethereal solution of benzoyl chloride (1 equiv.). The ether is evaporated on the water-bath, the residual oil extracted with dilute hydrochloric acid, and the white, solid residue filtered off, washed with water, and dried. It crystallises from alcohol in long, flat plates, *m. p.* 102–103°.

The *acetyl* derivative, prepared in the usual way, is an oil.

2:4-Di-iodo-6-nitrophenol, $C_6H_3I_2 \cdot NO_2$, can be readily prepared: (a) by adding a solution containing 12 grams of potassium iodide and 6 grams of chloramine-T (3 equivs.) to a solution of 1 gram of *o*-nitrophenol in 80 c.c. of *N*/10-potassium hydroxide (1 equiv.) and boiling the mixture for two hours. The cooled solution is acidified with acetic acid and the precipitate recrystallised twice from alcohol; (b) by adding a solution of 5 grams of potassium iodide in 5 c.c. of water to a solution of 1 gram of *o*-nitrophenol (1 mol.) and 3.5 grams of *p*-toluenesulphondichloroamide (2 mols.) in 40 c.c. of glacial acetic acid, and heating the mixture on the water-

bath for ten to fifteen minutes. On dilution, a mixture of iodo-derivatives is obtained from which the di-iodo-derivative (m. p. 98°) is obtained by two recrystallisations from alcohol. By either process 1 gram of *o*-nitrophenol gave 1 gram of di-iodo-derivative, but the yield can be increased by using excess of chloramine-T or *p*-toluenesulphon dichloroamide and the corresponding quantity of potassium iodide.

Potassium Toluene-p-sulphonbromoamide,

—Chattaway (T., 1905, 87, 145 *et seq.*) states that the best method of preparing this bromoamide salt is by dissolving *p*-toluenesulphondibromoamide in warm 10 per cent. caustic potash and allowing to crystallise. A convenient method of preparation of this salt, which was used in the above experiments, is to cover 10 grams of *p*-toluenesulphonamide with 40 c.c. of water, and then add 4 c.c. of bromine (20 per cent. excess); the amide dissolves on mixing. Fifteen c.c. of strong caustic potash solution (50 per cent. by weight) are gradually stirred into the mixture, when the whole dissolves with slight rise of temperature, forming a clear solution. On cooling, potassium toluene-*p*-sulphonbromoamide crystallises out in a pure state (yield 85 per cent.) (Found: Br = 24.32. Calc., Br = 24.65 per cent.).

The author desires to thank Professor Orton, F.R.S., for the interest he has taken in this work.

UNIVERSITY COLLEGE OF NORTH WALES, BANGOR.

NOTES.

Constitution of Benzene. By RONALD FRASER.

FURTHER consideration of the structure of benzene which the author has recently proposed (T., 1922, 121, 188) has made it clear that it cannot be accepted as it stands: and for two reasons. (1) The evidence in favour of a static formula (*loc. cit.*, p. 188) is based on false argument; the ultra-violet absorption spectrum of benzene points indubitably to the presence of oscillatory electrons in the molecule. Vibration of the crowded central electrons (*vide photograph of model, loc. cit.*) seems incompatible with stability. (2) The

author considers that evidence of some value was advanced (p. 191) for the tetrahedral form of the carbon octet, which is now generally adopted. Nevertheless, the complicated system of sharing among the central electrons which results from the adoption of this form makes the stability of the arrangement very doubtful.

Thus the closely packed orientation of the six central electrons cannot be maintained; they must be regarded as situated at distances from the centre of the molecule comparable with its average radius; definite electron sharing between carbon atoms in the para-relation is no longer possible. This granted, the guiding principle used in evolving the author's original structure, namely, symmetry consistent with electron-sharing on the Lewis-Langmuir theory, leads immediately to substantially the same arrangement, for the resting state of the molecule, as those of Kaufmann ("Die Valenzlehre," p. 539), Sir J. J. Thomson (*Phil. Mag.*, 1921, [vi], 41, 521), Kermack and Robinson (*T.*, 1922, 121, 427), and Crocker (*J. Amer. Chem. Soc.*, 1922, 44, 1618). Whether such an arrangement is two- or three-dimensional can be satisfactorily decided only by conclusive experiment.

It may be mentioned that the structure originally proposed has been adversely criticised (compare *Ann. Rep.*, 1922, 19, 87; *Science Progress*, 1923, 17, 548), on the ground that the ortho-positions were separated; this objection does not, of course, apply to the final arrangement.—CHEMISTRY DEPARTMENT, UNIVERSITY OF ABERDEEN. [Received, May 29th, 1923.]

Solubility of Sodium Chlorate. By HUGH CHESTER BELL.

In connexion with some experiments on the supersaturation of solutions of analytically pure sodium chlorate it became necessary to know with some precision the solubility of this salt in water. The data quoted in Landolt and Börnstein's tables, from the results of Kremers and Graebe, yield a curve showing an inflection between 20° and 40°. It was therefore of interest to explore this temperature region more carefully.

The results obtained indicate that Kremers's figures are too high, due probably to the fact that his solutions were not effectively stirred during cooling. Equilibrium in a solution below 40° is only slowly attained.

From the figures given below, the solubility curve appears to be very nearly a straight line from 10° to 100°, which would on extrapolation give a melting point of the pure solid 245°. According to Retgers, the melting point is 248°.

Poppe (*Jahrb. Min.*, 1914, Beil. Bd., 38, 363) finds the solubility at 30° to be 51.12 per cent. of chlorate.

In these determinations a solution of sodium chlorate, saturated at the boiling point, was stirred vigorously in an electrically controlled thermostat at the required temperature for about three hours. The temperature was read on a certified thermometer and was constant to at least 0.02°. A weighed sample was then evaporated in a conical flask by immersing this in a bath at 100° and gently distilling benzene on to the surface of the liquid. In about fifteen minutes the salt was obtained in a thin crust over the bottom of the flask. A shallow layer of benzene was then poured into the flask, which was subsequently heated in an air-oven at 120° until its weight was constant. The necessary buoyancy corrections were made to the observed weighings.

GUY'S HOSPITAL MEDICAL SCHOOL, LONDON, S.E. 1. [Received, August 7th, 1923.]

Esterification of Oxalic Acid. By PAVITRA KUMAR DUTT.

CONSISTENTLY good yields of oxalic esters, except methyl oxalate, can be obtained by passing the vapour of the requisite alcohol through ordinary hydrated oxalic acid until all the water has been driven over with the distilled alcohol. The residue is then purified by distillation in the ordinary way.

Ethyl Oxalate.—Through a boiling mixture of commercial oxalic acid (250 grams) and absolute ethyl alcohol (500 c.c.), contained in a flask fitted with an inlet tube, dipping in the liquid, and a four-bulb column, the vapour of 2000 c.c. of absolute alcohol is passed during about eight to nine hours. Fractional distillation of the product yields 225–230 grams (78–80 per cent. of the theoretical amount) of ethyl oxalate, b. p. 180–182°/740 mm.

Methyl Oxalate.—The yield of this ester obtained from 250 grams of hydrated oxalic acid and 2000 c.c. of absolute methyl alcohol is usually 105–108 grams (45–46 per cent.), m. p. 49–51°. It can be obtained quite pure, m. p. 54°, by crystallising once from spirit. The yield is not improved by using a larger quantity of alcohol, and is appreciably diminished by using less.

n-Butyl Oxalate.—The flask contains 100 grams of commercial oxalic acid and 100 c.c. of *n*-butyl alcohol, and the vapour of 500 c.c. of the same alcohol is passed through the boiling mixture.

The water in the distillate forms a distinct layer at the bottom, and the reaction is complete when no more comes over (about two hours). The yield of the ester, b. p. 239—240°/740 mm., is 144 grams (90 per cent.).

isoAmyl Oxalate.—Only a moderate yield of this ester is obtained (53 per cent.) by carrying out the operation as previously described, a good deal of decomposition taking place at the temperature of boiling amyl alcohol. The reaction proceeds very smoothly under reduced pressure (100—150 mm.) and at the temperature of the water-bath, 100 grams of oxalic acid and about 300 c.c. of commercial amyl alcohol yielding 155 grams of the ester (85 per cent.), b. p. 260—262°/740 mm.

Most of the experiments described above have been carried out by Mr. Harold Howson, to whom the author's thanks are due.—
THE UNIVERSITY, LEEDS. [Received, May 17th, 1923.]

Electrolytic Generator for Pure Hydrogen. By VISCOUNT ELVEDEN
and ERIC SINKINSON.

A CONVENIENT and trustworthy generator for the supply of pure hydrogen in connexion with the measurement of hydrogen-ion concentrations is as follows. Ten electrolytic cells are connected electrically in series. Each cell is composed of an outer "boiling-tube" 12 inches in length and $1\frac{3}{4}$ inches in diameter, and an inner tube 12 inches by $\frac{3}{4}$ inch which is open below and is fitted axially into the outer tube by a waxed cork which also carries the anode and a tube for the escape of oxygen. Through a stopper at the top of the inner tube pass the cathode and a tube 2 inches long for the delivery of hydrogen. The electrodes are of pure nickel wire of No. 10 gauge, and are bent so that one wire forms the cathode of one cell and the anode of its neighbour. The electrolyte is a saturated solution of barium hydroxide. The cells, preferably mounted on a stand in two banks of five, deliver hydrogen to a common main. The pressure of hydrogen in each cell should be no greater than is necessary to allow of half an inch of electrode being covered by the baryta in the inner tube. In order to regulate this, the common main is connected to a wash-bottle fitted with an adjustable inlet tube. The pressure is controlled by the depth of immersion of the inlet tube in dilute sulphuric acid in the wash-bottle. If the pressure is too great, the electrolyte will be forced below the end of the electrode and arcing will result.

A refinement introduced to destroy traces of methane that might possibly be present consists in passing the gas through a

tungsten filament lamp heated by a current which causes it to glow without melting the filament when the lamp has been completely filled with hydrogen. This fitting can be made from an ordinary lamp of suitable voltage; or a special lamp fitted with inlet and outlet tubes may be obtained cheaply.

The generator is connected in series with a resistance of 70 ohms to the mains at 220 volts; it then consumes 1.5 amperes and delivers 6 litres of hydrogen per hour.—[Received, June 7th, 1923.]

A New Method for the Resolution of Asymmetric Compounds—A Reply. By JULIUS BEREND COHEN.

IN the absence of my friend and co-worker, Mr. A. Shimomura, I take the responsibility of replying to a criticism of the above paper (T., 1921, 119, 1816) by McKenzie and Smith which appeared in the last issue of this Journal (p. 1967). McKenzie and Smith have confirmed our observation that the menthyl ester of inactive mandelic acid yields a small amount of levorotatory phenylchloroacetic acid by the action of thionyl chloride or phosphoric chloride; in other words, by replacement of one group in an inactive substance by another under asymmetric conditions, an active product can be obtained. The observation, so far as I know, is new, and that is all Mr. Shimomura and I set out to show. The criticism of McKenzie and Smith turns entirely on the interpretation of this observation. We offered no explanation; they call it "displacement racemisation," and no doubt their explanation is sound *as far as it goes*; but it involves the phenomenon of racemisation, of which we know little, and the Walden inversion, of which we know less. They then proceed to point out the very obvious fact that if "displacement racemisation" is excluded, that is to say, *the very phenomenon upon which our experimental evidence is based*, no active product would result. But this is surely begging the whole question, and does not affect in the smallest degree our claim to the discovery of a new method for resolving asymmetric compounds, a fact which they themselves confirm.—THE ORGANIC CHEMICAL LABORATORIES, THE UNIVERSITY, LEEDS. [Received, September 6th, 1923.]

CCCXI.—*The Adiabatic Cooling of Water and the Temperature of its Maximum Density as a Function of Pressure.*

By NICOLAI ANTONOVITCH PUSHIN and ELIJAH VASILJEVICH GREBENSHCHIKOV.

THE changes of temperature of water on adiabatic compression or expansion have been already investigated (see E. Cohen and W. Schut, "Piezochemie kondensierter Systeme," 1919, pp. 143—152). Putting aside all criticism of the older works, some of which are only of historical interest, we may say that the results differ widely and that they are all obtained for pressures below 500 kgm./cm.². Recently, however, Bridgman (*Proc. Amer. Acad.*, 1912, **48**, 355) has calculated theoretically the value of the coefficient of adiabatic cooling for pressures up to 12,000 kgm./cm.².

As the method adopted by us in the investigation of the equilibria under high pressures (Pushin and Grebenshchikov, *J. Russ. Phys. Chem. Soc.*, 1912, **44**, 112) enabled us to determine experimentally the change of temperature of a substance due to an adiabatic change of its volume, we resolved to determine the coefficient of the adiabatic cooling of water at various temperatures for pressures up to 4000 kgm./cm.².

EXPERIMENTAL.

The cylinder was of Tammann's type (Tammann, "Kristallisieren und Schmelzen," 1903, p. 201), and was placed in a thermostat filled with paraffin oil or some other suitable liquid. The substance to be investigated was put in a glass tube, *g* (Fig. 1), placed in the cylinder, *k*, and separated by mercury, *l*, from the liquid, *d* (usually castor-oil), which transmitted the pressure. The temperature in the thermostat was controlled within $\pm 0.01^\circ$ by means of an electric heater. The temperature of the substance was measured by means of an iron-nickeline thermo-element, *e*, which was sealed in the upper end of the glass tube, *g*. The wire of the thermo-element within the glass tube was very thin, in order to increase as much as possible its sensitiveness to changes of temperature. The junction was in the centre of the tube. Since the deflection of the galvanometer occupied only a few seconds, and the liquids and glass tube were very poor conductors of heat, the temperature of the surroundings could not influence the records of the galvanometer to any marked extent. The outer ends of the thermo-element passed through a stopper, *a*, to a thermostat filled with melting ice, and were connected to the terminals of

a sensitive reflecting galvanometer. The deflections of the galvanometer were automatically recorded on a photographic paper by the recording pyrometer of Kurnakov, and were also followed by direct observation. A compensation apparatus was inserted in the circuit of the galvanometer, so that measurements could be made with the same precision at various temperatures.

The pressure was measured by means of a Bourdon gauge from Schäffer and Budenberg, Magdeburg-Buckau, who also supplied the cylinder and the pump. With this gauge we were able to

FIG. 1.

measure pressures up to 6000 kgm./cm.^2 with a precision of 5–3 kgm./cm.^2 .

Before the changes of temperature during the adiabatic process were recorded, two or three constant temperatures were registered on the photographic paper. Thus before the adiabatic changes at 25° were determined, the constant temperatures 24.00° and 26.00° were recorded on the paper. In that interval a millimetre of the galvanometer scale corresponded to 0.0136°. Determinations were then made at the desired temperature, both with adiabatic compression and adiabatic expansion. On the whole the deter-

minations by means of adiabatic expansion yielded more trustworthy results than those by means of compression, especially at high pressures, since the expansions occupied only one or two seconds, whilst the compressions required more time. The effects of adiabatic expansion were measured as follows.

FIG. 2.

Coefficient of adiabatic cooling of water as a function of pressure.

After the temperature in the cylinder, as shown by the records of the galvanometer, had become constant, the reading of the pressure gauge was recorded by one observer. After releasing the compressing plug to a suitable extent, he opened quickly the valve which separated the plug from the cylinder and immediately

closed it again. The pressure in the cylinder diminished and the observer noted the new record of the gauge. Meanwhile, the other observer read the galvanometer which recorded the changes of temperature of the liquid; as a control these were also recorded photographically.

Experimental Results.—Tables I—V and Fig. 2 show the results of the determination of the coefficient of the adiabatic cooling, and heating, of water, $(dt/dp)_a$, at 0°, 25°, 37°, 54°, and 80°. In the tables, p is the mean value for the pressures at the beginning and at the end of the adiabatic process, Δp the difference between these two values,* and Δt the change of temperature of water, which corresponds to a change of pressure of 1 kgm./cm.² at a pressure p . It should be noticed that the values for $(dt/dp)_a$ shown in the tables do not refer to the temperatures $T = 0^\circ, 25^\circ, 37^\circ, 54^\circ$, and 80° , but to the temperature $t - \Delta t/2$ for the coefficient of cooling, and to the temperature $t + \Delta t/2$ for the coefficient of heating, which differ, although only slightly, from t .

The curve $(dt/dp)_a$ was investigated at 0° up to 3155 kgm./cm.² by adiabatic expansion and up to 1125 kgm./cm.² by adiabatic compression. The results of the two series of determinations

* The initial and final pressures, p_1 and p_2 , recorded by the gauge before and after the adiabatic process are given by the equations $p_1 = p + \Delta p/2$; $p_2 = p - \Delta p/2$.

agree satisfactorily. With increasing pressure, (dt/dp) , at 0° increases continually from -0.00096 at 141 to $+0.00187$ at 3000 kgm./cm.^2 , whilst the curve bends obviously towards the axis of pressure. According to the calculations of Bridgman, the curve reaches a maximum at a pressure of 4000 kgm./cm.^2 .

Changes of the Temperature of Maximum Density of Water with Changes of Pressure.

Amagat (*Ann. Chim. Phys.*, 1893, [vi], **29**, 559) first noticed that the maximum density of water moved towards lower temperatures with increase of pressure. According to his determinations, the temperature of maximum density would fall to 0° at a pressure between 143 and 197 kgm./cm.^2 . Almost the same value was given by Lussana (*Nuovo Cim.*, 1895, [iv], **2**, 233), who found that the maximum density moves towards 0° at an approximate pressure of 180 kgm./cm.^2 .

Bridgman in his investigations of the thermodynamic constants of water established the fact that at a temperature below 0° (about -4°), water occupied a minimum volume at a pressure of 1500 kgm./cm.^2 . According to his determinations, a temperature of 0° corresponds to a maximum density of water at pressures between 500 and 1000 kgm./cm.^2 (*Z. anorg. Chem.*, 1912, **77**, 387). From our determinations of the function (dt/dp) , it is, however, possible to determine precisely the pressure at which the maximum density of water is at 0° .

The increase of temperature, Δt , in an adiabatic process can be calculated thermodynamically from the equation

$$\Delta t = \frac{T}{C_p} \left(\frac{dv}{dt} \right)_p \Delta p,$$

where T is the temperature at which the thermodynamic process goes on, C_p is the specific heat of the substance at constant pressure, and $(dv/dt)_p$ the coefficient of expansion of the substance at pressure p . From the equation it can be seen that substances which expand when heated ($dv > 0$) became warmer when compressed ($\Delta t > 0$), and colder when the external pressure diminishes, and conversely. When $(dv/dt)_p = 0$, no thermal effect takes place during adiabatic compression or expansion. In this case $\Delta t = 0$ and $(dt/dp)_p = 0$ also. This rule was excellently confirmed in the case of water, as can be seen from Tables I and II and from the photographs shown in Fig. 3. The tables show that the temperature 0° corresponds to a maximum density of water at 600 kgm./cm.^2 . Therefore every compression of water at 0° up to a pressure of 600 kgm./cm.^2 must be accompanied by a cooling of water, as is well shown, for example, by the curves 1, 2, and 3,

which refer to compressions from 102 to 180, from 175 to 250, and from 247 to 325 kgm./cm.^2 , respectively. In the case of compression at pressures greater than 600 kgm./cm.^2 , heating of water takes place, as shown in the curves 4, 5, and 6, which correspond to a compression of water from 763 to 1003, from 960 to 1140, and from 1125 to 1335 kgm./cm.^2 , respectively.

The adiabatic expansion of water, on the other hand, at pressures below 600 kgm./cm.^2 is accompanied by heating, as experiments 7 and 8 show (expansion from 675 to 100 and from 600 to 200 kgm./cm.^2). Under pressures above 600 kgm./cm.^2 , cooling occurs,

FIG. 3.

as is the case with every normal liquid [curves 9, 10, 11 (1728—1340, 1362—1000, 1040—630 kgm./cm.^2)]. The curve $(dt/dp)_a$ passes through zero at a pressure of 600 kgm./cm.^2 .

Bridgman's theoretical calculations, which are only expressed graphically, show that the function $(dt/dp)_a$ passes through 0° at a pressure of about 100 kgm./cm.^2 . The other values of the curve at 0° also differ from the values for $(dt/dp)_a$, which we have found, by an almost constant quantity $+0.0006$, as can be seen from the comparison given below.

p .	$(dt/dp)_a \times 10^4 \text{ at } 0^\circ$		
	Pushin and Grebenschikov.	Bridgman.	Δ .
500	-2.0	7	9
1000	+6.4	13	6.6
1500	11.7	18	6.3
2000	15.3	21	6
2500	17.5	23	5.5
3000	19.1	25	6

Bridgman's observations, however, do not agree with the supposition that a maximum density of water at 0° corresponds to a pressure of 100 kgm./cm.^2 . According to his own observations, a maximum density at 0° corresponds to a pressure within the limits 500—1000 kgm./cm.^2 .

The lowering of the maximum density of water with increased pressure affords an explanation of certain geophysical phenomena. Thus the temperature of the deep sea is below $+4^\circ$, a fact which cannot be explained if we do not take into consideration the pressure of the upper layers of water. It is interesting that the Challenger expedition * determined the temperature at the bottom of the ocean to be $+0.3^\circ$ at a depth of 2800 fathoms (5100 m.). If we take into account that the density of water under a pressure of 500 kgm./cm.^2 and a salinity of 3.5 per cent. increases by about 5 per cent., there will be at the depth of 5100 m. a pressure of 535 kgm./cm.^2 . We can therefrom calculate that 0° corresponds to a pressure of 580 kgm./cm.^2 , a value which agrees fairly well with that obtained by us (600 kg./cm.^2).

TABLE III.

Change of temperature of water with adiabatic change of its volume at 25° .

413	0.845	1954	204	195	0.468	4078	240

From Table III and Fig. 2 it can be seen that the coefficient of adiabatic cooling increases constantly with increasing pressure at 25° just as at 0° , instead of diminishing as in the case of other liquids. At a pressure of about 3400 kgm./cm.^2 the curve changes its direction and goes almost horizontally. The relative heating of water (for a change of pressure of 1 kgm./cm.^2) in the interval from 3400 to 4100 kgm./cm.^2 is nearly independent of the pressure. It must be remarked, however, that near a pressure of 3500 kgm./

* Report on the Voyage of the Challenger, 1873—1876, vol. I, p. 91.

cm.² there is the transition point from ice III to ice V (Bridgman, *Proc. Amer. Acad.*, 1911, 47, 524; *Z. anorg. Chem.*, 1912, 77, 377). It is possible that to the various modifications of water in the crystalline state, various degrees of association of liquid water correspond. With the help of such a supposition the change in the direction of the curve $(dt/dp)_s$ can be explained.

TABLE IV.

Change of temperature of water by adiabatic expansion.

At 37°.

At 54°.

385	1.408°	642	306	525	1.690°	2312	322
385	1.392	1008	361	560	1.867	2825	331
425	1.457	1388	343	270	0.856	3715	318
505	1.712	1822	339				

At 80°.

335	1.577°	418	471	453	1.846°	1719	408
430	1.972	765	459	455	1.809	2588	397
560	1.539	1230	436	462	1.761	3031	381

The values for $(dt/dp)_s$ obtained at 80° agree fairly well with the values calculated theoretically by Bridgman, as can be seen from the comparison given below.

p .	$(dt/dp)_s \times 10^4$ at 80°.		
	Pushin and Grebenshchikov.	Bridgman.	Δ .
1000	44.5	46	-1.5
1500	42.3	43	-0.7
2000	40.6	40	+0.6
2500	39.2	38	+1.2
3000	38.2	37	+1.2

From Table V and also from Fig. 2 it is quite obvious that the value $(dt/dp)_s$ at 0° and at 25° constantly increases with increased pressure and approaches a final value. At 37°, the value is almost independent of pressure within the limits from 1 to 3500 kgm./cm.². At 54° and at 80°, the value diminishes with increasing pressure as it does for all other substances which we

TABLE V.

CCCXII.—Two Heterogeneous Gas Reactions.

By CYRIL NORMAN HINSHELWOOD and CHARLES ROSS
PRICHARD.

THE number of gas reactions which proceed without disturbance by the walls of the containing vessel is so limited that a homogeneous change must be regarded as an exceptional case. At high temperatures the homogeneous reaction may predominate over the wall reaction owing to its greater temperature coefficient, and homogeneous reactions obviously come into play in the propagation of explosion waves through gases, but, under conditions when the change is slow enough to measure, it must be recognised that chemical reactions between gases, and especially gaseous decompositions in which only one molecule is involved, take place more readily on most surfaces than in the gas phase. Since this must now be recognised as a general rule, the influence of the solid surface should not be dismissed as a "disturbing factor," but some general explanation of it should be sought. The interest of the exceptional homogeneous reactions is, however, only increased.

It was proposed, therefore, to investigate various gas reactions

* The results will be published separately.

which might *a priori* have been expected to be unimolecular, with the object of ascertaining whether they would be markedly catalysed by the walls of the glass containing vessel and thus conform to the general rule, or whether they would be homogeneous reactions, in which case their dynamics would be of special interest. The reactions studied were the thermal decomposition of hydrogen peroxide, and of sulphuryl chloride in the gaseous state, and the thermal decomposition of chlorine monoxide. Diazoacetic ester was also examined, but found to be unsuitable for quantitative measurements, as tarry deposits were formed.

The decomposition of chlorine monoxide proved to be homogeneous, and the results are described in the following paper (p. 2730), whilst the hydrogen peroxide reaction and the sulphuryl chloride reaction were found to be typical heterogeneous reactions the details of which are described below.

The Thermal Decomposition of Hydrogen Peroxide.

Hydrogen peroxide readily decomposes into water and oxygen and the reaction is irreversible, but its course in the gaseous state does not seem to have been followed. The range of investigation is limited by the fact that at above 80° the reaction is extremely rapid, whilst at low temperatures the saturation pressure of hydrogen peroxide is small. The method was to place in a glass bulb of about 200 c.c. capacity a capillary containing a known weight of a 30 per cent. solution of hydrogen peroxide (Merck's perhydrol); the bulb was then evacuated and sealed off. The quantity of perhydrol was chosen so as to exert a pressure less than the saturation pressure of hydrogen peroxide at the temperature of the experiment. The bulb was then heated in a vapour-bath. The hydrogen peroxide boils off almost instantaneously, so that practically no decomposition can occur while it is in the vapour state. After a given time, the bulb was taken out, the tip broken under distilled water, and the undecomposed hydrogen peroxide estimated by titration with *N*/50-potassium permanganate.

Preliminary experiments showed that carbon tetrachloride, b. p. 76°, was a suitable liquid for the vapour-bath.

The approximate unimolecularity of the reaction is shown by the following results made by successive fillings of the same bulb. When the decomposition was allowed to proceed in a bulb containing glass wool previously treated with nitric acid to remove free alkali, the experiments failed to detect any trace of undecomposed hydrogen peroxide even after exceedingly short heating. Thus it may be concluded that the reaction is so strongly catalysed by glass that it must be a typical wall reaction.

Temperature 76.0°.			
Weight of hydrogen peroxide.	Time of heating.	Per cent. decomposed (x).	$\frac{1}{t} \log \frac{100}{100-x}$
0.0216	2 mins. 30 secs.	41.5	0.22
0.0128	4 " 0 "	71.5	0.31
0.0130	4 " 15 "	82.0	0.41
0.0230	6 " 20 "	87.0	0.32
0.0180	10 " 30 "	98.0	0.38

The Thermal Decomposition of Sulphuryl Chloride.

The equilibrium $\text{SO}_2\text{Cl}_2 \rightleftharpoons \text{SO}_2 + \text{Cl}_2$ has been investigated by Trantz (*Z. Elektrochem.*, 1908, 14, 534), who used a catalyst in

FIG. 1.

Thermal decomposition of sulphuryl chloride at 283°.

- I. Bulb A. IV. Bulb B + glass rods.
 II. Bulb B (pressure 180 mm.). V. Bulb A + glass rods.
 III. Bulb B (pressure 790 mm.).

order that equilibrium might be attained. It is evident from his results that the equilibrium lies on the side of almost complete decomposition above about 200°. It was therefore considered worth while to investigate whether the homogeneous reaction might set in at some temperature above 200°, where the rate of reaction might still be measurable.

The pressure doubles during decomposition, so that the reaction was measured manometrically, the capillary leading from the reaction bulb to the mercury manometer being electrically heated to prevent condensation of the sulphuryl chloride, and filled with a

buffer of air to prevent the chlorine formed from attacking the mercury. This device proved quite satisfactory.

The course of the reaction is shown by the curves in the figure.

Curves II and III refer to experiments in which the initial pressure of sulphuryl chloride was 180 mm. and 790 mm., respectively, and which were carried out in the same bulb, and show that the rate of reaction is independent of pressure. This is also shown by the following experimental data in which unimolecular velocity coefficients are calculated.

Temperature 283.5°.

t (minutes).	p (mm. of mercury).	$\frac{1}{t} \log_e \frac{p_\infty}{p_\infty - p}$	t (minutes).	p (mm. of mercury).	$\frac{1}{t} \log_e \frac{p_\infty}{p_\infty - p}$
2.0	35	0.108	10.0	122	0.113
4.0	66	0.114	15	150	0.118
6.0	89	0.114	∞	180	—

The effect of the walls of the reaction vessel may be seen by comparing curves II and III with curve I, which refers to a different bulb. Addition of fine glass rods to the bulb increased the reaction velocity in approximate proportion to the increased surface. This is illustrated by comparison of curve I with curve V and of curves II and III with curve IV.

The addition of glass wool had the effect of diminishing the time required for the completion of half the reaction at 211° from 172 minutes to 6.6 minutes.

The influence of temperature is shown below. The experiments were carried out successively in the same vessel.

Temperature.	" Half-life " in minutes.	Ratio for 10°.	Heat of activation.
211.0°	172	2.06 1.85	35,000 cals.
237	26.5		34,000 "
283	1.6		

In a vessel containing glass wool two successive experiments gave the results: at 211.5°, half-life 6.6 minutes; at 184°, half-life 35.5 minutes. From this the temperature coefficient for 10° over the range considered is 1.85.

Discussion of Heterogeneous Reactions.

When a molecule is adsorbed by a surface the forces between it and the molecules constituting the surface modify the internal forces in a way which is at present quite incalculable and must be entirely specific. Generally speaking, it might be expected that the stability would be increased as often as it is decreased. Yet the accumulation of observations showing that almost any gas reaction takes place more readily on a given surface such as glass

than in the homogeneous phase raises the question whether the operation of some general cause is not superimposed on the various specific influences. In the case of combinations in which two or more molecules are involved the encounter of two types is obviously facilitated by the more or less prolonged sojourn of one of them on the surface, but this factor is inoperative in the case of the simple unimolecular decompositions. It seems relevant, therefore, to ask whether one universal factor may not be simply the second law of motion. Consider a molecule composed of two parts, A and B, the disruption of which constitutes the decomposition of the molecule. Let B receive an impact from another molecule which imparts to it momentum directed away from A. The small inertia of A, however, enables it to follow B, without the development of much strain between the two. If, however, A were firmly enough held to a surface, its inertia might be so great that the accelerating force, instead of drawing A after B, would cause the disruption of the "bond" between them. The reluctance of homogeneous gas reactions to proceed might thus be due to the small inertia of the different parts of the molecules rendering disruption by collision very improbable. This is only suggested as one of several possibilities. That it is a mechanical picture, whilst we now believe "activation" to consist in the passage of an electron to an orbit of higher quantum number, is not a relevant criticism, since the results of work on the collision of electrons with gas molecules show that a definite correlation exists between quasi-mechanical and quantum processes.

Summary.

The velocity of thermal decomposition of hydrogen peroxide and of sulphuryl chloride in the vapour state has been investigated. Both are found to be typical heterogeneous reactions taking place on the walls of the glass containing vessel, and following the unimolecular law. The heat of activation for the sulphuryl chloride reaction is calculated from the results.

It is pointed out that the almost universal occurrence of "wall" reactions makes some general explanation desirable. A possible factor is discussed in the explanation of the greater ease with which "wall" reactions as compared with homogeneous reactions occur in gases.

CCCXIII.—*A Homogeneous Gas Reaction. The Thermal Decomposition of Chlorine Monoxide. Part I.*

By CYRIL NORMAN HINSHELWOOD and CHARLES ROSS
PRICHARD.

THE theory of the velocity of unimolecular chemical reactions in gases can scarcely be regarded as placed upon a sound basis until unequivocal examples of such changes have been found. Usually reactions which might at first sight have been expected to be unimolecular gas reactions proceed almost exclusively on the walls of the vessel up to temperatures where the rate of change becomes too great to be measurable with any precision, and complicating factors enter into the few remaining cases with the possible exception of the decomposition of phosphine at high temperatures, studied by Trautz and Bhandarkar (*Z. anorg. Chem.*, 1919, **106**, 95). Thus the thermal decomposition of ozone is homogeneous but bimolecular (Chapman and Jones, T., 1910, **97**, 2463), that of nitrogen pentoxide appears to be autocatalytic and not to proceed in the absence of nitrogen peroxide (Daniels, Wulf, and Karrer, *J. Amer. Chem. Soc.*, 1922, **44**, 2402), and the decomposition of phosgene at high temperatures is proportional to the square root of the chlorine concentration, and therefore presumably dependent on collision between phosgene molecules and chlorine atoms (Christiansen, *Z. physikal. Chem.*, 1922, **103**, 99).

We have made a preliminary investigation of the thermal decomposition of chlorine monoxide, and find that the change is a homogeneous one, but that the decomposition occurs in consecutive stages, and the rate of reaction is dependent on pressure in such a way as to show that it is a collision effect and not a spontaneous unimolecular process.

Apparatus.—The apparatus employed was very simple and is shown in Fig. 1. A few trials soon showed the impossibility of sealing without explosion even the finest capillary tip of a vessel containing chlorine monoxide. Consequently taps had to be employed. The chlorine monoxide was prepared and liquefied in bulb *A* by cooling to -25° ; from here it was allowed to boil off into the evacuated reaction bulb, *B*, by the ground joint, *C*, and the tap, *D*. Once in the reaction bulb, the slowness of diffusion through the capillaries prevented it from attacking the tap grease, and the mercury in the manometer was protected by a buffer of air between *a* and *b*. The question of the chlorine monoxide and chlorine attacking the tap grease was tested by leaving the apparatus filled in the cold, when no appreciable change occurred, and also by

observing the constancy of the "end-point" of the reaction. The taps were not heated by the vapour-bath in which the reaction bulb was immersed, and were of capillary bore. The bulb was wrapped in tin-foil to exclude light.

Preparation of Chlorine Monoxide.—The chlorine monoxide was prepared by passing chlorine over mercuric oxide previously heated at about 200° . It was liquefied and subsequently boiled off into the reaction bulb. The liquid dissolved considerable quantities of chlorine. It was found that the increase of pressure attending decomposition amounted only to about 75 per cent. of that to be

FIG. 1.

expected from the equation $2\text{Cl}_2\text{O} = 2\text{Cl}_2 + \text{O}_2$. At first this was attributed to decomposition of the oxide during the filling of the apparatus, but analysis of the gas which boiled off from the liquid showed that it contained about 25 per cent. of chlorine. It was soon found, however, that the rate of reaction was independent of the chlorine concentration, so that the gas containing chlorine was used. The independence of the rate of reaction of chlorine concentration was tested from about 30 mm. to 700 mm. Whether the relationships found would be modified in the complete absence of any chlorine initially will be dealt with in Part II of this paper.

Course of the Reaction.—The rate of increase of pressure is shown by the curves in Figs. 2 and 3, and is seen to be markedly accelerated. The following is a typical record of an experiment made at 110.5° .

Time (mins.).	Pressure increase (mm. of mercury).	Pressure increase as % of total increase.	Time (mins.).	Pressure increase (mm. of mercury).	Pressure increase as % of total increase.
0	0	0	45	168	60.4
5	0	0	50	188	67.7
15	3	1.1	65	232	83.5
20	18	6.5	80	249	89.5
25	47	16.9	102	263	94.6
30	78	28.1	170	276	99.2
38	121	43.5	280	278	100.0
40	140	50.4	350	278	100.0

The constancy of the final readings is a good guarantee that the taps were tight and that the chlorine did not diffuse round to the mercury.

FIG. 2.

The initial stages of the reaction are somewhat variable, but different experiments gave results which were reproducible after the first 10 or 15 per cent. This is illustrated by Fig. 2, in which the time origin is taken at a point corresponding to 30 per cent. of the final pressure increase; the results of five independent experiments are here plotted and after a variable "induction" period the points are seen to lie on a single curve in a very satisfactory manner. The experiments were made at 110.7° . In some cases a slight contraction was observed during the first few minutes amounting to about 5 mm.

The possible causes of the acceleration are (a) autocatalysis, (b) consecutive reactions, (c) the presence of an inhibitor which is gradually destroyed.

Homogeneous Nature of the Reaction.—It may be concluded that the reaction must take place in the gaseous phase, since the addition of clean dry glass wool, which increases the surface of glass many times, has no influence on the velocity of the reaction, beyond modifying slightly the initial variable portion of the curve. Thus in Fig. 2, two of the five curves were obtained with bulbs filled with glass wool, and the others with simple bulbs of soda glass (110.7°). In Fig. 4, the curve obtained with glass wool in the bulb is exactly parallel to the others after the first 10 per cent. (131.3°). The slight initial influence cannot be definitely attributed to the glass

FIG. 3.

- I. Cl_2O — 220 mm., O_2 — 675 mm. IV. Cl_2O — 250 mm., Cl_2 — 690 mm.
 II. Cl_2O — 252 mm., no added Cl_2 or O_2 . V. Cl_2O — 232 mm., O_2 — 720 mm.
 III. Cl_2O — 242 mm., „ „ „ „ „ „

wool, since curves with similarly shortened initial periods were sometimes obtained when no glass wool was added. Possibly the effect is due to minute traces of organic matter unavoidably introduced with it.

Influence of Added Oxygen and Added Chlorine.—At first the acceleration was attributed to autocatalysis by the chlorine or oxygen produced in the reaction. Experiment, however, soon showed that addition of a five-fold excess of dry air, oxygen, or chlorine produced no appreciable effect; oxygen in excess had, if any, a very slightly retarding influence. Moreover, the acceleration still persists in presence of excess of chlorine or oxygen; this disposes of the possibility that small quantities of these gases

might have a catalytic action and larger amounts no further influence, as seems to happen in the catalysis of the nitrogen pentoxide decomposition by nitrogen peroxide according to the results of Daniels and Johnston, and of Daniels, Wulf, and Karrer. Fig. 3 shows the inappreciable influence of chlorine and oxygen. The experiments were made at 131.3° . As soon as this point was cleared up, the use of chlorine monoxide containing 25 per cent. of chlorine was felt to be justified. The same fact is illustrated in Fig. 5.

FIG. 4.

Influence of Pressure.—The speed of the reaction is dependent on pressure, the time required for the completion of a given fraction of the total change at 131.3° being inversely proportional to the initial pressure of the chlorine monoxide. As we are dealing with consecutive reactions, the influence of pressure might vary at different stages if the consecutive reactions were not of the same order. In Fig. 4, the results are plotted in such a way as to test this point directly. The initial pressure of chlorine monoxide in the experiments varied from 242 mm. to 738 mm. The curve for 242 mm. is plotted with the observed times, that for 738 mm. with the

observed times multiplied by 738/242, and similarly for the others. The coincidence of the various curves shows that at 131.3° the rate of reaction may be regarded as directly proportional to the initial pressure of chlorine monoxide, and that the influence is practically the same over the whole course of the reaction at this temperature. Hence it would seem that the whole series of changes at this temperature is approximately of the second order. The decomposition is thus a collision effect and not a spontaneous unimolecular process.

FIG. 5.

The following table illustrates the uniformity of the influence of pressure throughout the reaction at 131.3°.

Initial pressure of Cl ₂ O (mm.).	Time for decom- position to proceed from 20% to 40%.		Time for decom- position to proceed from 70% to 90%.		Ratio.
	Ratio.		Ratio.		
576	2.38	2.5	2.3	6.0	2.5
242		5.8		15	
738	2.91	2.3	2.9	5.0	3.2
252		6.4		16.4	

Since the influence of pressure may thus be taken to operate uniformly throughout the course of the reaction, the time taken for the change to proceed from 40 per cent. to 80 per cent. will serve as a convenient measure of the rate of reaction. In Fig. 5, the reciprocal of this time is plotted against pressure, and it is

evident that the rate is directly proportional to the pressure of chlorine monoxide. This figure also shows that the presence of chlorine and oxygen has little influence.

A few experiments carried out at 110.7° showed that diminution of pressure lowered the rate of reaction at this temperature also, but it is not certain that here the influence of pressure remains uniform throughout the course of the reaction. This point will receive further consideration.

From the known influence of pressure a slight correction was applied to the times in Fig. 3 on account of the small differences in the chlorine monoxide pressure in the various experiments.

Influence of Temperature.—Since we are dealing with consecutive reactions, at least two velocity coefficients are involved. In general, the influence of temperature on these will not be the same. Nevertheless, the fact that the form of the curves at 131.3° , 110.7° , and 100.0° is approximately the same shows that the temperature coefficients of the separate velocity coefficients do not differ very greatly. We will therefore compare the times taken for the change to proceed from 40 per cent. to 80 per cent. at the temperatures 131.3° and 110.7° . The times are corrected to a standard initial pressure of 400 mm. of chlorine monoxide.

Temperature.	Time for reaction to proceed from 40% to 80% (minutes).	Initial pressure of Cl_2O .	Time corrected to pressure of 400 mm.
131.3°	6.0	576	8.65
"	7.4	502	9.25
"	15.0	242	9.05
"	5.0	738	9.15
"	6.2	572	8.85
		Average	9.0
110.9	37.0	394	36.3
110.6	32.5	490	39.9
"	25.5	556	35.3
110.7	35.0	422	37.0
"	23.0	570	32.8
		Average	36.3

The actual concentration corresponding at 110.7° to 400 mm. corresponds at 131.3° to $400 \times 404.3/383.7 = 421$ mm.

The time at 131.3° should therefore be reduced to $400 \times 9.0/421 = 8.55$ minutes in order to be strictly comparable with the 36.3 minutes at 110.7° .

Ratio of speeds for the range 110.7° to $131.3^\circ = 36.3/8.55 = 4.25$.

Ratio for $10^\circ = 2.03$.

The reaction is not a simple change; hence the energy of activation cannot be calculated, because the observed effect of temperature depends on at least two such quantities. A sort of average value may, however, be obtained by applying the Arrhenius equation

to the above results. It amounts to 22,000 calories for the activation of two gram-molecules.

Evidence for the Existence of Consecutive Reactions.—The acceleration might be attributed to autocatalysis, consecutive reactions, or the initial influence of inhibitors. The possibility of autocatalysis by chlorine or oxygen has been eliminated. If the acceleration were only apparent and the reaction were really a simple bimolecular reaction, initially retarded by inhibitors, then it should show the simple bimolecular form in its later stages. In this case, the expression $\text{Velocity}/[\text{Cl}_2\text{O}]^2$ should reach a constant value after the initial stages. Incidentally, in the unlikely case of autocatalysis by some by-product other than chlorine and oxygen, this expression should increase linearly with the amount decomposed. Actually, however, the expression shows a continuous increase which is much more than linear. This is quite characteristic of consecutive reactions, but very difficult to explain on any other hypothesis.

Velocity expressed as % per 5 minutes.	$[\text{Cl}_2\text{O}]$. Relative values.	$[\text{Cl}_2\text{O}]^2$. Relative values.	Velocity $[\text{Cl}_2\text{O}]^2$. Relative values.
4.1	98.0	9600	4.25
9.1	91.4	8300	10.9
15.2	79.2	6200	24.5
17.7	62.8	4000	44.2
17.4	45.2	2030	85.2
11.1	31.0	910	122
8.7	21.0	410	213
4.6	14.4	210	220
4.6	9.8	96	470
3.0	6.0	36	600

It should be mentioned that the volume changes accompanying the various consecutive reactions may not be the same. Hence increase of pressure, although effectively measuring the course of the reaction, does not allow one to calculate the actual chlorine monoxide concentration at any moment. In testing the above alternatives to the assumption of consecutive reactions, however, we were justified in calculating $[\text{Cl}_2\text{O}]$ in this way.

Inspection of the equations of bimolecular consecutive reactions reveals the fact that it is not practically possible to extract the separate velocity coefficients from the curves giving pressure changes. They must be determined separately by other devices. The method by which it is hoped to do this is by simultaneous observations on the pressure changes and the relative amounts of iodine and alkali liberated from potassium iodide. The nature of the intermediate product may also be found in this way. Probably chlorine peroxide or an unknown oxide of chlorine may be transitorily formed.

Propagation of Explosion Waves in Chlorine Monoxide.—It is well known that explosion waves are easily set up in the gas. Although it was not possible to find accurately the various heats of activation from the temperature coefficient, the order of magnitude is 22,000 calories. The heat liberated by the reaction $2\text{Cl}_2\text{O} = 2\text{Cl}_2 + \text{O}_2$ is about 32,000 calories. The reaction products therefore have an excess energy of about 54,000 calories. If this appears as kinetic energy, each of the three molecules formed has an excess corresponding to about 18,000 calories. This, if transferred to an average chlorine monoxide molecule by collision, would be almost enough to enable it to enter into reaction with the next average chlorine monoxide molecule it encountered. Hence it is clear how with a little extra stimulation the slow reaction may be superseded by an explosion wave propagated through the gas.

Summary.

The thermal decomposition of gaseous chlorine monoxide is found to be a homogeneous reaction uninfluenced by the glass walls of the containing vessel. The velocity of reaction increases as the change proceeds. This is not due to autocatalysis, since oxygen and chlorine have no influence on the rate of decomposition, but is attributable to the occurrence of the change in consecutive stages. The rate of reaction at 131.3° is inversely proportional to the initial pressure of the chlorine monoxide, and the influence of pressure appears to operate uniformly throughout the course of the change at this temperature. Hence the decomposition depends on a collision effect and is not a spontaneous unimolecular process.

The influence of temperature on the reaction is such that the time required for the change to proceed from 40 per cent. to 80 per cent. is increased 2.03 times for every 10° decrease in temperature between 131.3° and 110.7° . From the influence of temperature and from the heat of reaction it is shown that explosion waves should be readily propagated in the gas.

CCCXIV.—*The Dissociation of certain Oxalato-salts.*

By GEORGE JOSEPH BURROWS and GEORGE WALKER.

DURING the investigation of certain derivatives of ferrioxalic acid (Burrows and Turner, *Proc. Roy. Soc. N.S.W.*, 1921, 55, 263) it was found necessary to prepare comparatively large quantities of

sodium ferrioxalate, and although several pure specimens were analysed, the salt was always found to contain 5 mols. of water of crystallisation. Mitscherlich, Rammelsberg, and Schabus (*Jahresbericht*, 1854, 393), who appear to have been the first to prepare oxalato-salts of this type, described the potassium and ammonium salts of chromoxalic and ferrioxalic acids as crystallising with 3 mols. of water, and the sodium salts with 4.5 mols. This result has been confirmed by various workers in this field, including Wyruboff (*Bull. Soc. Min.*, 1900, 5, 65), who studied the crystallography of these salts in detail. Sodium ferrioxalate, sodium chromoxalate, and sodium aluminioxalate were found to be isomorphous, and Wyruboff assigned to them the formula $\text{Na}_3\text{M}_2(\text{C}_2\text{O}_4)_6 \cdot 9\text{H}_2\text{O}$. Rosenheim (*Z. anorg. Chem.*, 1896, 11, 175), however, had previously concluded that the chromoxalate crystallised with 9 and the aluminioxalate with 9.5 mols. of water.

In view of the fact that sodium ferrioxalate had been found to crystallise with 5 mols. of water, it was decided to prepare and analyse pure specimens of the isomorphous sodium chromoxalate and sodium aluminioxalate. The dissociation of these, as well as of salts of ferrioxalic acid, was also studied.

Sodium chromoxalate and sodium aluminioxalate were prepared by digesting excess of the freshly precipitated hydroxides in sodium binoxalate and concentrating the filtered solution under diminished pressure until the salt crystallised on cooling. The salt was then recrystallised from aqueous alcohol. Prepared in this way, it was found to be impure, containing varying amounts of sodium oxalate, from which the salt could not be entirely freed by further crystallisation. These salts are readily purified through the barium salts, which are fairly soluble in hot water, although only sparingly soluble in cold. The barium salts, prepared by precipitation with barium chloride, were recrystallised several times from hot water. Samples dried in air contained in both cases 12 mols. of water of crystallisation, a result in harmony with that already published in the case of barium ferrioxalate (*loc. cit.*). The barium salt was then decomposed with the calculated weight of sodium sulphate, and the sodium salt obtained by evaporation of the filtrate from the barium sulphate was recrystallised from aqueous alcohol. These salts crystallised with 5 mols. of water. We therefore conclude that the sodium salts of ferrioxalic, chromoxalic, and aluminioxalic acids are correctly represented by the formula $\text{Na}_3\text{M}(\text{C}_2\text{O}_4)_3 \cdot 5\text{H}_2\text{O}$, and not by $\text{Na}_6\text{M}_2(\text{C}_2\text{O}_4)_6 \cdot 9\text{H}_2\text{O}$.

The conductivity of salts of this type has been previously studied. Rosenheim (*Z. anorg. Chem.*, 1896, 11, 240) compared the conductivities of the potassium salts of these acids at 18°. The

conductivity and cryoscopic measurements recorded below were carried out for the purpose of ascertaining the apparent number of ions into which each molecule dissociates. It has been found that for solutions of concentration not less than one-tenth molecular, sodium chromoxalate, sodium aluminioxalate, sodium ferrioxalate, and potassium ferrioxalate all give four ions per molecule, a value which indicates that in concentrated solutions these salts dissociate thus: $R_3[M(C_2O_4)_3] = 3R^+ + [M(C_2O_4)_3]^{3-}$. At higher dilutions, the values are apparently greater than four, which may be interpreted as indicating a further dissociation of the complex ion, or else hydrolysis of the salt into $3ROH$ and $H_3[M(C_2O_4)_3]$. In the latter case, results obtained for the ammonium salts of these acids should be higher than those for the other salts, and this has been found to be so. The fact that the numbers found for ammonium chromoxalate and ammonium ferrioxalate are greater than five indicates that oxalato-salts of this type are hydrolysed to a certain extent in aqueous solution.

EXPERIMENTAL.

Barium chromoxalate, obtained by adding barium chloride to a solution of sodium chromoxalate, crystallised in very fine, violet needles (Found: Ba = 32.7; Cr = 8.28; C_2O_4 = 41.8).

requires Ba = 32.7; Cr = 8.25; C_2O_4 = 41.9 per cent.).

Note.—In the analysis of this and other chromoxalates, a known amount of the salt was oxidised in the boiling solution with a standard solution of potassium permanganate. A known amount of ferrous ammonium sulphate was then added, and the excess determined in the usual way. An independent estimation of the chromium content was also made and from these two results the amount of C_2O_4 was calculated.

Barium ammonium chromoxalate was obtained by adding the calculated amount of ammonium sulphate to a hot aqueous solution of barium chromoxalate, concentrating the filtrate from the barium sulphate, and recrystallising the product from hot water. The salt separates in fine needles intermediate in colour and solubility between barium chromoxalate and ammonium chromoxalate (Found: Ba = 26.3; Cr = 9.8; C_2O_4 = 50.3. $C_6H_4O_{12}NBaCr.3H_2O$ requires Ba = 26.2; Cr = 9.9; C_2O_4 = 50.2 per cent.).

Sodium chromoxalate was prepared from the barium salt as described above [Found: Na = 14.4; Cr = 11.0; C_2O_4 = 55.4. $Na_3Cr(C_2O_4)_3.5H_2O$ requires Na = 14.5; Cr = 11.0; C_2O_4 = 55.6 per cent. $Na_6Cr_2(C_2O_4)_6.9H_2O$ requires Na = 14.8; Cr = 11.3; C_2O_4 = 56.7 per cent.].

Sodium aluminioxalate, prepared by decomposing the barium salt with sodium sulphate, crystallised in thin, colourless needles [Found: Na = 15.0; Al = 6.1; C_2O_4 = 58.4; H_2O = 19.6. $Na_3Al(C_2O_4)_3 \cdot 5H_2O$ requires Na = 15.3; Al = 6.0; C_2O_4 = 58.7; H_2O = 20.0 per cent. $Na_3Al_2(C_2O_4)_6 \cdot 9H_2O$ requires Na = 15.7; Al = 6.1; C_2O_4 = 59.9; H_2O = 18.3 per cent.].

In the following tables, v is the volume in litres containing one gram-molecule of the salt, μ is the molecular conductivity, α the degree of dissociation, Δ the observed depression of the freezing point of water, $M\Delta$ the molecular lowering, and i the van't Hoff coefficient; k , the number of ions into which each molecule dissociates, is calculated from the equation $i = 1 + (k - 1)\alpha$.

THE UNIVERSITY OF SYDNEY.

[Received, September 24th, 1923.]

CCCXV.—*The Formation of Stable β-Lactones.*

By LESLIE BAINS and JOCELYN FIELD THORPE.

UNTIL quite recent years, the group of β-lactones was a very small class of substances of which few examples were known. This was at first thought to be due to the preferential decomposition of the β-bromo-acids into unsaturated hydrocarbons (Erlenmeyer), and later to the irreversible nature of their formation from β-hydroxy-acids (Johannson). The first representative of the group was obtained by Einhorn in 1883 (*Ber.*, **16**, 2208) by the action of sodium carbonate on β-bromonitrophenylpropionic acid, and the isomeric lactone of *p*-nitrophenyl-lactic acid was prepared by Basler (*Ber.*, 1883, **16**, 3001). It was then considered that the existence of these two lactones was due to the stabilising effect of the nitro-group, but it is now known that their isolation was rendered possible owing to their insolubility, which protected them from decomposition after formation.

The simplest β-lactones were successfully prepared and investigated by Johannson (*Dissert.*, Lund, 1916), who showed that the β-bromo-derivatives of propionic, butyric, and isobutyric acids, when treated with their equivalent of sodium carbonate, were decomposed simultaneously in the two possible ways, forming both the unsaturated hydrocarbons and the β-lactone.

As long ago as 1879, Fittig and Pagenstecher (*Annalen*, **195**, 108) observed the production of *ψ*-butylene from β-bromo-*α*-methylbutyric acid by the action of boiling aqueous sodium carbonate; and Fittig and Howe (*Annalen*, 1880, **200**, 21) identified among the products of the action of this alkali on β-bromo-*α*-ethylbutyric acid both amylene and β-hydroxy-*α*-ethylbutyric acid, so that it is probable that they had had the intermediate β-lactone in their hands. But it was not until quite recently that Johannson and Hagman

(*Ber.*, 1922, 55, [B], 647) proved that β -lactones were also produced from these two acids by actually isolating them.

The unsubstituted β -hydroxyglutaric acid, when distilled under reduced pressure, undergoes the usual decomposition into vinyl-acetic acid, although Fichter and Krafft (*Ber.*, 1899, 32, 2799) assumed the intermediate production of an unstable β -lactone. Similarly, the simpler β -hydroxy-dibasic acids, when boiled for twenty-four hours with 10–20 per cent. sodium hydroxide, are converted into $\alpha\beta$ -unsaturated acids (for example, β -hydroxyglutaric acid gives glutaconic acid, malic acid yields fumaric acid, and phenylparaconic acid a mixture of phenylitaconic and phenylisoparaconic acids (Fichter, *Ber.*, 1900, 33, 1452). The parent substance of the β -lactones derived from dibasic acids, malic acid lactone, has quite recently been prepared from iodosuccinic acid by the action of moist silver oxide (Holmberg, *Svensk. Kem. Tidskr.*, 1918, 30, 190; compare A., 1919, i, 309). It is readily hydrolysed irreversibly in acidic or alkaline solution to the corresponding acid. A homologue of this β -lactone had been obtained previously by Baeyer and Villiger, who prepared the lactone of dimethylmalic acid (*Ber.*, 1897, 30, 1954) and found that it could be distilled under reduced pressure without loss of carbon dioxide; the product of distillation was subsequently identified by Fichter and Hirsch as dimethylmalic anhydride (*Ber.*, 1900, 33, 3270). Komppa suggested that the trimethyl derivative behaved in a like manner (*Ber.*, 1902, 35, 534). The isomeric lactone from β -hydroxyisopropylmalonic acid is very unstable and on heating breaks down, giving carbon dioxide and other products (Meldrum, T., 1908, 93, 598).

During an investigation of the products derived from a tri-brominated dialkylglutaric acid a higher homologue of malic acid lactone was obtained in quite a new way. It is a remarkably stable compound, whereas all the β -lactones previously described are unstable substances in the sense that they undergo decomposition by alkali and do not yield, as do the γ -lactones, salts of hydroxy-acids from which the lactones can be regenerated. The production of this stable four-atom ring compound provides further evidence of the effect of the *gem*-dipropyl grouping on the carbon tetrahedral angle.

Three atoms of bromine were readily introduced into $\beta\beta$ -di-*n*-propylglutaric acid by the action of thionyl chloride and excess of bromine, and the product (I) was isolated as its dibromolactonic ester (II).

Further, when the crude bromination mixture was treated with a warm solution of sodium hydroxide it was slowly dissolved, and a crystalline compound having the empirical formula $C_{10}H_{16}O_4$ (III) was produced. This substance on titration behaved as a monobasic acid in the cold, but became dibasic on heating with alkali, and could only have been derived from the intermediate tribromo-acid in the following way:

It formed a very soluble silver salt, and when distilled under reduced pressure yielded a hygroscopic, viscous oil—probably the impure anhydride (compare Fichter and Hirsch, *loc. cit.*). The lactone ring was opened with slight decomposition by boiling with 10 per cent. sodium hydroxide for one and a half hours, but on acidification at 0° the original lactone was recovered and not the hydroxy-acid.

It is evident, therefore, that the deflection of the carbon tetrahedral angle caused by the volumes of the two propyl groups attached to two of the valencies causes the carboxyl group and the β -hydroxyl group to be relatively the same distance apart as the carboxyl group and the γ -hydroxyl group in an ordinary unsubstituted chain. The effect is thus to confer the same order of stability on the β -lactone as is shown by γ -lactones. Other instances of this kind are now under investigation.

EXPERIMENTAL.

Tribromination of $\beta\beta$ -Di-n-propylglutaric Acid.—Ten grams of the acid (prepared as previously described, Bains and Thorpe, this vol., p. 1209) were warmed with freshly distilled thionyl chloride (7 c.c.) on the steam-bath until effervescence ceased, and then in a partial vacuum at 60° to remove sulphur dioxide and excess of thionyl chloride. The dark liquid remaining was warmed at 70° , 3.6 mola. (11 c.c.) of dry bromine were added in the course of four hours, and the reaction mixture was kept on the steam-bath for twenty-four hours. The excess of bromine was removed by a current of air, and the product divided into two portions.

Lactone of Ethyl $\alpha\alpha'$ -Dibromo- α' -hydroxy- $\beta\beta$ -di-n-propylglutarate (II).—One portion of the bromination product was poured into absolute alcohol and, after keeping for a day, worked up in the usual

way. The brown, oily neutral ester obtained slowly solidified when kept for a week and, after the adherent oil had drained off, was crystallised from dilute (60 per cent.) alcohol. It formed colourless needles melting at 84° (Found: C = 38.9; H = 5.2; Br = 40.2. $C_{13}H_{20}O_4Br_2$ requires C = 39.0; H = 5.0; Br = 40.0 per cent.).

Lactone of $\beta\beta$ -Di-n-propylmalic Acid (III).—The other portion of the bromination mixture was poured into water, dissolved in hot dilute aqueous sodium hydroxide, reprecipitated by dilute sulphuric acid, and taken up in ether. The ethereal extract, dried over anhydrous sodium sulphate, left a faintly yellow oil on evaporation of the solvent. This became semi-solid on keeping for a few weeks, and after draining on a porous tile was crystallised from benzene containing a little ether. It separated slowly in colourless, shining prisms, soluble in water, ether, or hot benzene, but insoluble in cold benzene; m. p. 127° . The substance behaved as a monobasic acid towards barium hydroxide, although the end-point was not very definite [Found: C = 59.7, 59.8; H = 8.0, 8.0; M (monobasic), by titration = 197. $C_{10}H_{16}O_4$ requires C = 60.0; H = 8.0 per cent.; M = 200].

The authors' thanks are due to the Royal Society for a grant which defrayed the cost of this investigation, and to the Department of Scientific and Industrial Research for a grant to one of them (L.B.) which enabled this work to be carried out.

CCCXVI.—*The Additive Formation of Four-membered Rings. Part II. The Conditions which confer Stability on the Dimethinediazidines.*

By CHRISTOPHER KELK INGOLD and HENRY ALFRED PIGGOTT.

IN Part I (T., 1922, **121**, 2795) it was suggested, in analogy with the well-known tendency displayed by nitroso-compounds towards the establishment of equilibria with their dimeric forms, that azomethines also possess a general tendency to pass reversibly into compounds containing the dimethinediazidine ring:

Naturally the position of such an equilibrium (that is, the amount of dimerisation) under given conditions of temperature and dilution will vary from case to case. In the series of azomethines previously

investigated, the equilibria near the ordinary temperature were in all instances such as to favour the azomethines themselves, the dimethinediazidines being present in small amounts only; indeed, it was in consequence of this that indirect methods had to be adopted in order to obtain evidence of the existence of equilibria. Therefore it seemed to be of interest to search for an example in which the opposite should be the case; that is, one in which the dimethinediazidine should possess greater stability than the azomethine and should preponderate when in equilibrium. Further, there appeared to be no reason why an instance should not be realised in which a fairly even balance would subsist between the azomethine and the dimethinediazidine at some easily available temperature, so that by warming or cooling it would be possible to obtain either individual free from the other.

An examination of the facts relating to the formation and stability of four-membered rings in general shows that their stability is greatly affected by substitution, and especially by the combined bulk of the substituent groups. As another occasion will be taken in order critically to examine this point, it will suffice to state here the general conclusion, which is that maximal stability is reached at a certain optimum degree of substitution; further substitution beyond this optimum, or substitution by larger groups, leads to division * into unsaturated compounds (as witness the greater tendency of the tetraphenyl derivative of *cyclobutanedione*, as compared with the corresponding tetramethyl derivative, to undergo division into the keten), whilst a deficit in substituents, or in their bulk, leads to scission * and, frequently, the subsequent formation of larger rings.

The dimethinediazidine derivatives previously studied each contained four substituents, which were all phenyl, benzyl, or substituted phenyl or benzyl groups (type I), and hence the instability and strong tendency to division is accounted for. In order to increase the stability of the four-membered ring, it is necessary to diminish the number or bulk of the substituents to the optimum, but not beyond it. A preliminary examination of a number of instances was therefore commenced, and a substance, namely, the di-*p*-tolyl derivative (II), was soon found which has the degree of stability required; that is to say, at the ordinary temperature its properties are essentially those of the diazidine (II),

* For the definition of these terms, see Part I, p. 2793, footnote.

hilst at a somewhat higher temperature they are those of the azomethine (III) and there can be no reasonable doubt that at intermediate temperatures the two substances (II and III) are in mobile equilibrium.

Before considering the evidence afforded by physical and chemical properties, it is of interest to note, in connexion with the greater ability of the diazidine at the ordinary temperature, that this substance is formed directly by rational ring closure, rather than indirectly through dimerisation of the azomethine. The first product of the action of formaldehyde on *p*-toluidine is presumably the additive product (IV), and the main possibilities which have to be kept in mind arise from the fact that this can lose water in three ways: (a) it might utilise the hydroxyl group and its own imino-hydrogen atom, and yield the azomethine (III); (b) it might utilise the imino-hydrogen atom of a second molecule, giving the compound (VI); (c) it might utilise the amino-hydrogen atom of a molecule of *p*-toluidine, giving the diamine (V). The scheme set out below shows how each of these possibilities could lead ultimately to the dimethinediazidine (II); but the alternatives (b) and (c) represent the process as a rational ring closure, whereas in (a) the monomeric azomethine intervenes. Now the experiments described in this paper clearly show that the diamine (V) (a remarkably stable substance, which can be boiled for long periods in anhydrous solvents without decomposition) is actually an intermediate product in the formation of the diazidine. By operating at low temperatures, it can be isolated in a yield sufficient to account for almost the whole of the diazidine which could have been produced from the experiment; and on condensation with formaldehyde, either in water under the usual conditions, or in non-hydroxylic solvents, it yields the diazidine. Hence mechanism (c) must represent the main course of the reaction; but since, even in the most carefully regulated experiments, a small amount of diazidine was always produced, in the formation of which the diamine (V) could not be proved to have intervened (although it may have done so), both mechanisms (a) and (b) may possibly constitute subsidiary avenues along which the reaction can proceed to a small extent.

Although it can scarcely be doubted that, even at low tem-

peratures, the diazidine (II) is in mobile equilibrium with a small proportion of azomethine (III), its molecular weight at the freezing point of benzene is that which corresponds with the diazidine formula. It behaves in every way as a ditertiary base, giving neither acyl derivatives nor nitrosoamines, whilst it is completely broken down by strong mineral acids. A remarkable additive reaction occurs with phenylcarbimide, giving a product to which, from its formation, hydrolytic scission, and general properties, must be assigned the six-membered ring structure (VII). This substance is saturated, weakly basic, and generally very stable, although on boiling with mineral acids it undergoes hydrolysis, the recognisable products of which are phenyl-*p*-tolylcarbamide (IX), formaldehyde, and (probably) *p*-toluidine. These reactions may be represented by the following scheme, in which the hypothetical hydrolysis product (VIII) gives rise to the formaldehyde and *p*-toluidine contained in the final product of change:

From the above description it will be evident that the ditolyl-dimethinediazidine (II) has a much greater stability near the ordinary temperature than the tetra-substituted derivatives previously investigated. Nevertheless, it is not an exception to the general rule that all these substances tend to undergo reversible division into azomethines, and to establish mobile equilibria with their products of division. In the present instance, division into methylene-*p*-toluidine (III) is practically complete at 250°; but at much lower temperatures additive reactions can be carried out in which the azomethine must intervene. Thus ditolyl-dimethinediazidine, when heated in boiling light petroleum for a few hours with *p*-toluidine, is nearly quantitatively converted into the diamine (V), a type of additive reaction characteristic of the monomeric azomethine.

Hence the general relationship of the dimethinediazidine group to the azomethine group, previously inferred from an investigation of a very unstable class of dimethinediazidines, appears to be confirmed by the more detailed examination which is possible only

in the case of the more stable members of the series. The sensitiveness of the substances of this series to changes of structure has already been noted, and it is well illustrated by an experiment in which it was hoped to produce a trisubstituted derivative by the condensation of the diamine (V) with benzaldehyde :

At the ordinary temperature, the reaction took place rather slowly, and perhaps on account of this, and the ease with which the diazidine appeared to undergo division in accordance with the characteristic properties of its class, nothing but these division products (or their polymerisation products) could be isolated.

Finally, mention should be made of a property which seems to be of common occurrence amongst lightly substituted derivatives containing the less stable types of four-membered ring, namely, the conversion of these substances into compounds containing six-membered rings by an additive process. The formation of a six-membered ring from the diazidine (II) and phenylcarbimide has already been noted, and it is probable that the same diazidine can also react with its own azomethine in an analogous way to give the compound (X) :

It has not been possible to establish this point with certainty, because the amount of the compound formed at equilibrium is small, and its molecular weight could not be determined, as it quickly reverted to the diazidine on dissolving in organic solvents. But there are many analogies which suggest the view now advanced, and perhaps the most striking is that of the corresponding aniline compound, the structure of which is known, and is the most stable polymerised form of the azomethine $\text{CH}_2 \cdot \text{NPh}$.

EXPERIMENTAL.

(A) Mechanism of Formation of Di-*p*-tolylidimethinediazidine (II).

(i) *Condensation of Formaldehyde with p-Toluidine.*—In general, three substances are formed by the action of formaldehyde on *p*-toluidine, namely, methyleneditolylamine (V), the diazidine (II), and the substance (formula X?), m. p. 225°, into which the diazidine is partly convertible (compare Eibner, *Annalen*, 1898, 302, 350). At higher temperatures, no diamine is obtained, and the yield of diazidine, allowance being made for the "polymerised" form,

m. p. 225°, amounts to 80 per cent. of the theoretical. At lower temperatures, a more or less considerable proportion of the expected yield of diazidine appears in the form of diamine, although it was not found possible entirely to inhibit the subsequent conversion of this into diazidine. This point was proved by a series of experiments of which the following are typical:

(a) *Temperature 45–70°*. Twelve c.c. of 40 per cent. aqueous formaldehyde, and a solution of 12 grams of *p*-toluidine in 30 c.c. of alcohol, were heated to 45° and mixed. The temperature rose rapidly to 60°, and an oil separated, which, on stirring, quickly solidified, the temperature rising to 70°. Crystallisation from alcohol, benzene, or light petroleum (b. p. 60–80°) yielded 10.5 grams of the diazidine accompanied by a trace of the substance, m. p. 225°, but no diamine.

(b) *Temperature 15°*. The mixture was made at 15°, and kept at this temperature for one hour. The crystalline product was collected and fractionally crystallised from alcohol and light petroleum. Yields: 1.5 grams of the diamine and 8.5 grams of the diazidine, allowing for the "polymeride."

(c) *Temperature 0°*. This experiment was carried out similarly to (b). Yields: 7.5 grams of diamine and 2.5 grams of the diazidine, allowing for the small amount of "polymeride."

Methylenedi-p-tolylamine (V) crystallises from alcohol or ligroin in colourless, pearly leaflets, m. p. 85° (Found: C = 79.9; H = 8.2. Calc., C = 79.6; H = 8.0 per cent.). It is much more soluble in alcohol, benzene, or ligroin than the diazidine. It can be recovered unchanged after being heated in boiling dry organic solvents for prolonged periods.

Di-p-tolyldimethinediazidine (II) crystallises from alcohol, benzene, or ligroin in long needles, which felt together into masses resembling glass wool. It is obtained free from the "polymeride" described below only with difficulty, owing to the fact that in hot organic solvents it undergoes partial conversion into that substance, an equilibrium being established. Purification is best effected by crystallising the thoroughly dried substance rapidly from hot ligroin, in which the "polymeride" is insoluble. The pure substance melts at 127° (Found: C = 80.3; H = 7.9. $C_{16}H_{18}N_2$ requires C = 80.7; H = 7.6 per cent.).

The "polymeride" (X?) forms a microcrystalline powder, insoluble in water and most organic solvents in the cold, but moderately soluble in hot benzene or alcohol, and readily soluble in hot chloroform or toluene. Once in solution, it rapidly undergoes decomposition, yielding the diazidine, but the reaction does not proceed quantitatively owing to the establishment of an equilib-

brium with the reverse process. The equilibrium mixture contains a small proportion only of the "polymeride." The "polymeride" melts at 225° with slight decomposition, but owing to its slight solubility in solvents and instability in solution it was not found possible to ascertain its molecular weight (Found: $N = 11.9$. $C_{24}H_{27}N_3$ requires $N = 11.8$ per cent.).

(ii) *Condensation of Formaldehyde with Methylenedi-p-tolylamine.*—

(a) An alcoholic solution containing 6 grams of the diamine was mixed with 5 c.c. of 40 per cent. aqueous formaldehyde and the mixture maintained at 15° for one hour. The crystalline product was collected, dried, and crystallised from ligroin, when 5.5 grams of pure diazidine and a trace of the "polymeride" were obtained.

(b) A similar experiment was carried out in the absence of water, the solvent being carefully dried chloroform. On evaporation of the chloroform a solid mass was obtained (6.3 grams) from which 5.5 grams of diazidine were isolated in a condition of purity, besides a trace of the "polymeride."

(iii) *Condensation of Benzaldehyde with Methylenedi-p-tolylamine.*—

In this experiment, which was carried out like the preceding one in anhydrous chloroform solution, the expected diazidine was not isolated as such, but only in the form of its products of division, benzylidene-*p*-toluidine and the two polymerised forms, m. p. 127° and 225° , of methylene-*p*-toluidine.

(B) *Properties of the Diazidine and Corresponding Azomethine.*

At low temperatures, the diazidine has the molecular weight corresponding with its formula, the tendency being towards slightly high values owing to the reversible formation of small quantities of the polymeride (m. p. 225°) (for example, Found: in freezing benzene, $M = 254$. Calc., $M = 238$). Its general chemical properties are those of a ditertiary base; that is to say, it gives neither acyl derivatives nor nitrosoamines. Its additive reactions with phenylcarbimide and with its own azomethine have been described in the introduction, and details of the former reaction are given below.

At higher temperatures, the diazidine appears to undergo division into two molecules of the azomethine, and at 250° this reaction is practically complete, as is shown by the fact that the molecular weight at this temperature is sensibly that required for methylene-*p*-toluidine (Found: by vapour density determinations at 250° by Victor Meyer's method, $M = 119, 122, 121$. Calc., $M = 119$). An additive reaction of the azomethine is described below.

Addition of the Diazidine to Phenylcarbimide: Formation of 2-Keto-1-phenyl-3:5-di-p-tolylohexahydro-1:3:5-triazine (VII).—A mixture

of 2 grams of the diazidine, 4 c.c. of benzene, and 2 c.c. of phenylcarbimide was heated at 100° for twenty-four hours in a closed tube, and then cooled in ice. The crystalline product, after recrystallization from a mixture of benzene and ligroin, melted at 148° (Found: C = 77.5; H = 6.5; N = 12.3. $C_{23}H_{23}ON_3$ requires C = 77.3; H = 6.4; N = 11.8 per cent.).

On hydrolysis by hot, dilute, mineral acids, this substance yields phenyl-*p*-tolylcarbamide, formaldehyde, and *p*-toluidine (?), together with gummy products.

Addition of the Azomethine to p-Toluidine: Formation of Methylenedi-p-tolylamine (V).—The diazidine (0.66 gram, carefully purified and dried over phosphoric oxide) and *p*-toluidine (0.6 gram, freshly distilled and then dried for a short time over phosphoric oxide) were dissolved in 15 c.c. of dry ligroin (b. p. 60–80°), and the solution was boiled for two hours under a reflux condenser fitted with a drying tube; on evaporating to 5 c.c. and cooling, it yielded 0.6 gram of pure methylenedi-*p*-tolylamine. A further small amount, accompanied by a trace of unchanged diazidine, was obtained from the mother-liquors.

CCCXVII.—*The Photochemical Reactivity of Ozone in Presence of Other Gases. Part I.*

By ROBERT OWEN GRIFFITH and WILLIAM JAMES SHUTT.

In a recent paper (T., 1921, 119, 1948), the authors have shown that ozone, subjected to the action of light of the visible portion of the spectrum, decomposes. The results obtained, however, were, owing to the inconstancy of the source of light employed—the carbon arc—mainly of a qualitative nature, and the effect on the velocity of the photochemical reaction of variation of the concentration of ozone could not be determined. The present investigation deals with this effect, and as it was expected that addition of other gases might throw some light on the mechanism of the process, experiments in which hydrogen, nitrogen, helium, argon, carbon monoxide, or carbon dioxide was added have been carried out. This paper presents the results obtained in the presence of hydrogen, whilst those with the other gases will be found in the succeeding paper.

EXPERIMENTAL.

In the experiments to be described, mixtures of ozone and oxygen, or of ozone, oxygen, and hydrogen, were prepared and a portion of

the mixture was separated and its ozone content determined by analysis. The remainder was subjected to illumination of constant intensity for a given time, during which the variation in pressure of the gas mixture was determined. At the end of this period, the percentage of ozone in the residual gas was again measured by direct analysis. In the experiments with mixtures containing hydrogen, the initial concentration of the latter was also determined in the majority of cases.

The apparatus employed is shown diagrammatically in Fig. 1. It contains the ozone generator, *A*, generator, *D*, for oxygen or hydrogen, the reservoir, *B*, in which the gases were collected over

FIG. 1.

concentrated sulphuric acid, and the tubes, *F*, *G*, and *J*, and manometer, *H*, connected by capillary tubing as shown. All the parts of the apparatus with which ozone came in contact were made entirely of glass and all taps were lubricated with metaphosphoric acid.

Ozone was prepared electrolytically by Fischer and Massenez's method (*Z. anorg. Chem.*, 1907, 52, 202, 229), and the generator shown at *A* is identical with the one described previously (Griffith and Shutt, *loc. cit.*). It yields an ozonised oxygen mixture of 11–12 per cent. ozone (by volume) when the anode temperature is maintained below 6–8°. From *A* the gas was drawn into the reservoir, *B*, where it was stored over concentrated sulphuric acid;

alternatively it could be aspirated through a potassium iodide solution at C_1 for the determination of its ozone content. In order to facilitate complete absorption of the ozone at C_1 , the gas was broken up into very small bubbles by being passed through a long capillary tube of very small bore, placed almost horizontally, and dipping in 0.1*N*-potassium iodide solution. After acidifying the latter with dilute sulphuric acid, the liberated iodine was titrated with standard thiosulphate solution. C_2 is another analyser of the same form.

Oxygen and hydrogen were prepared by electrolysis (between sheet nickel electrodes) of a 15 per cent. solution of sodium hydroxide in the glass U-tube, *D*. The gases were dried by passing over calcium chloride. Either gas could be admitted to the reservoir, *B*, and allowed to mix therein with ozonised oxygen over concentrated sulphuric acid. From *B* the gas mixture was transferred to tubes *F* and *G*, which were first thoroughly exhausted through taps t_1 and t_2 by means of water and mercury pumps. The mercury of the latter was protected from attack by ozone by interposition of solid potassium hydroxide, which, if the rate of pumping were not too rapid, catalytically decomposed practically all the ozone. Tubes *F* and *G* thus each contained initially a gas mixture of the same composition at atmospheric pressure. By forcing dry air through taps t_1 and t_2 , the contents of tube *F* (volume between t_2 and $t_3 = 108.9$ c.c.) were immediately swept into a potassium iodide solution contained in C_2 and the percentage of ozone in the gas mixture was determined. Tube *G* (volume between taps t_3 and $t_5 = 137.0$ c.c.) is a tube of white glass 46 cm. long and about 2 cm. in diameter, closed, at one end, by a window, blown so as to be as flat and uniform as possible. Very near to this end is sealed on a capillary side tube connecting to the three-way tap, t_6 . Tube *G* was illuminated and the course of the ozone decomposition followed by reading the pressure changes indicated on the manometer, *H*, which contained concentrated sulphuric acid (d 1.84). As shown in Fig. 1, this is connected on the one side, through tap t_4 , to the experimental tube, *G*, on the other to the compensating tube, *J*, which contained pure dry air and is of the same capacity as *G*. Both *G* and *J* are surrounded by water-jackets, the one round the experimental tube being closed by an optically flat glass window, *K*. To ensure exact equality of temperature of tubes *G* and *J* during an experiment, water from a large, well-stirred thermostat, not shown in Fig. 1, was syphoned through both jackets at a rate of 1.5 litres per minute, fresh water being continuously supplied to the thermostat. A difference of temperature of only 0.005° between the tubes causes a manometric change of 0.1 mm. of sulphuric acid, but the above

arrangement effectively prevented any temperature fluctuations exceeding this amount.

The source of light employed was a 1000 watt, 115 volt, gas-filled lamp of projection pattern. A voltmeter was placed across the lamp terminals and the intensity of the light kept steady by hand regulation of a large wire resistance, for coarse adjustment, and a carbon plate rheostat, for fine adjustment. By this means the voltage drop across the lamp terminals could readily be kept at 115 volts within 0.2 of a volt. The light was concentrated by a condenser lens of 11 cm. diameter and passed through a slab of crown glass of 1.6 cm. thickness and through a water layer of 8 cm. thickness (between *K* and *G*) before reaching the experimental tube. The limits of wave-length of the light employed were about 360μ and 770μ .* Since, in this work, it was necessary to use light of the same intensity in each experiment, the optical system and tube *G* were rigidly supported on a common base so that no relative displacement could occur.

In the case of mixtures of hydrogen and ozonised oxygen, the concentration of the former in the original gas mixture was usually determined by displacing 10—15 c.c. from the reservoir, *B*, through $\frac{1}{2}$ into a solution of potassium iodide and thence to a eudiometer. The ozone in the original gas was thus converted into an equal volume of oxygen and the concentration of hydrogen determined by explosion in the usual way.

With regard to the use of this apparatus, brief mention of the following points should be made.

(1) It will be noticed that the concentration of ozone in the mixture before illumination was not obtained by analysis of a sample from *B*, but was determined from the contents of tube *F*, which was filled simultaneously with *G*. The reason for this procedure is that ozone, allowed to stand in reservoir *B*, gradually decomposed, owing to the fact that it was impossible to keep the inner glass surface free from dust particles, etc., which act catalytically in promoting ozone decomposition. Since the time required for efficient absorption of the necessary amount of gas exceeds thirty minutes, if a sample had been taken from *B* before or after filling *G*, the ozone concentration found would not necessarily be that of the gas taken for illumination. Tubes *F* and *G*, however, were specially treated in order to ensure that their surfaces were clean and that no appreciable decomposition of ozone took place

* The lower limit was established by a photograph, kindly taken by Dr. H. A. Taylor, on a Hilger quartz spectrometer, and the upper limit from a consideration of the absorption coefficient of water (Griffith and Shutt, *loc. cit.*, p. 1954).

on standing in absence of direct illumination (see Griffith and Shutt, *loc. cit.*, p. 1950). This point was tested, from time to time, for tube *G* throughout this work and, in all the experiments to be given in this paper and in the great majority of those in the succeeding one, the "dark" decomposition of ozone was entirely negligible compared with that on illumination.

(2) Preliminary experiments with ozone-oxygen-hydrogen mixtures indicated that, on illumination, water vapour was produced. In order that the manometric measurements should be of significance with these mixtures, one of two possible procedures had to be adopted; either all the water vapour formed had to remain as such, or it had to be entirely absorbed by some desiccating agent so that its partial pressure was reduced to zero. In early experiments the first method was tried but, owing to partial absorption of the water vapour by the metaphosphoric acid used to lubricate the taps, satisfactory results could not be obtained. The second procedure was therefore adopted and 1 or 2 c.c. of pure concentrated sulphuric acid were introduced into tube *G* and spread along its entire length.

(3) The observed manometric differences need correction owing to the small changes in volume of the gases in tubes *G* and *J* caused by movement of the manometric liquid. The corrected pressure can be shown to be $L + pL\gamma/V$, where *L* is observed pressure difference in millimetres of sulphuric acid, *p* the total pressure in the tubes (1 atm.) expressed in millimetres of sulphuric acid, γ the volume per millimetre of manometer capillary tube, and *V* the common volume of tubes *G* and *J*. The correction amounts to about 14 per cent. of the observed difference, the value of γ being 0.003665 c.c. per millimetre.

Method of Experiment.—After evacuating tubes *G* and *F* (tap *t*₄ closed) to within 0.5 mm. of mercury, they were filled with the required gas mixture from *B* at a pressure slightly greater than atmospheric. Water from the thermostat was circulated through the jackets surrounding these tubes and, after temperature equilibrium had been established, the pressure in *F*, *G*, and *J* was made equal to that of the atmosphere through *t*₆ and *t*₃, *t*₂ and *E*. Taps *t*₃ and *t*₆ were then closed, *t*₄ was opened, and the contents of tube *F* swept into potassium iodide solution in *C*₂. Readings of the manometer, *H*, were then begun and continued until no movement occurred during an interval of fifteen minutes. Pressure constancy being established, the lamp was switched on and pressure readings were taken at 1, 6, 11, 16, 21, 26, and 31 minutes from the start. The light was then extinguished and further readings were taken 5, 10, and 15 minutes after. Finally, the residual gas in the experi-

mental tube, *G*, was swept into a solution of potassium iodide in C_2 and a determination of the ozone concentration made.

The general character of the results obtained will probably be most clearly indicated by giving one experiment (the twelfth in Table III) in detail.

Ozone-Oxygen-Hydrogen Mixture.

The mixture contained 15 c.c. of hydrogen and 270 c.c. of ozonised oxygen (about 11.5 per cent. by volume of ozone).

<i>Tube F.</i> Pressure	754 mm. of mercury.
Volume	108.9 c.c.
Temperature	$12.3^\circ + 273^\circ = 285.3^\circ \text{ K.}$
Titre of ozone	17.61 c.c. of 0.05011 <i>N</i> -thiosulphate.
Volume per cent. of ozone = 9.55.	

Estimation of hydrogen content.	Before explosion.	After explosion.
Volume	10.03 c.c.	7.78 c.c.
Temperature	13.4°	13.4°
Corrected pressure	730.1 mm.	727.0 mm. of mercury
Volume at <i>N.T.P.</i>	9.18 c.c.	7.09 c.c.

$$\text{Hence, volume per cent. of hydrogen} = \frac{2 \times 2.089}{3 \times 9.18} = 15.17.$$

The composition of the gas, therefore, by volume,* is ozone = 9.55; hydrogen = 15.17; oxygen = 75.28 per cent.

Tube G. Filled at pressure 754.1 mm. of mercury; volume 135.0 c.c.; temperature $10.6^\circ + 273^\circ = 283.6^\circ \text{ K.}$

Experimental Results.

I. *Ozone-Oxygen Mixture.*—The results obtained with these mixtures are presented in Table I and Fig. 2.

In Table I, the first column gives the initial volume percentage of ozone, the second, the corrected pressure increase in millimetres of sulphuric acid, caused by illuminating with a constant light

4 Z*

intensity for thirty-one minutes, and the third, the fraction of ozone decomposed, calculated from the manometer increase.

In Fig. 2, the values of the second column of Table I (curve *AA*) and of the third column (curve *BB*) are plotted as ordinates and those of the first column as abscissæ.

TABLE I.

Per cent. (vol.) of ozone.	Corr. pressure increase (mm. of H_2SO_4).	Fraction of ozone decomposed.	Per cent. (vol.) of ozone.	Corr. pressure increase (mm. of H_2SO_4).	Fraction of ozone decomposed.

FIG. 2.

In all mixtures containing only ozone and oxygen, assuming the reaction to be $2O_3 \rightarrow 3O_2$, it was found that the decomposition calculated from the observed pressure increase agreed, within the experimental error, with that obtained by direct determination of the ozone content, by the potassium iodide method, before and after illumination. This is illustrated by the figures of Table II.

TABLE II.

Per cent. (vol.) of ozone.	Titre obs.	Titre calc.	Per cent. (vol.) of ozone.	Titre obs.	Titre calc.

6.94	15.71	15.78	8.69	19.31	19.23
7.00	16.14	16.08			

Column 2 of this table gives the number of c.c. of *N*/20-thio-sulphate solution equivalent to the ozone in the residual gas after illumination, and column 3, the titre calculated from the initial ozone content and the observed manometric increase.

The curve *BB* in Fig. 2 is nearly a straight line, indicating that, with the conditions employed, the reaction velocity varies as the square of the ozone concentration; there is, however, a slight falling off at the highest ozone concentrations. This may be due either to experimental error, as the reproducibility of the results is not so good in this region, or, more probably, to the well-known decrease of apparent order of photochemical processes as the extent of absorption increases.

II. *Ozone-Oxygen-Hydrogen Mixtures*.—All the mixtures were made up in such a way that the ratio of ozone to oxygen was approximately constant. This was effected by mixing hydrogen and ozonised oxygen (containing about 11 per cent. of ozone) in various proportions. The results obtained are presented in Table III and Figs. 3 and 4.

TABLE III.

11.57	— †	—	+ 27.0	0.084	—	—

* These values are not experimentally determined, but are calculated on the basis of the mean value of the ratio "ozone to oxygen" (0.121).

† The percentage of hydrogen in this mixture could not be conveniently determined. It is probably about 2.

In the table, the values in the fourth column are the pressure increases (expressed, as usual, in millimetres of sulphuric acid) caused by illumination for thirty-one minutes, while the fifth column gives the fractions of ozone decomposed, obtained directly by analysis.

FIG. 3.

In Fig. 3, the manometric effects are plotted against initial ozone concentration, curve I referring to mixtures containing hydrogen, and curve II being a reproduction of curve AA of Fig. 2 (ozone-oxygen mixtures), obtained with light of the same intensity when exposed for the same time interval.

The hydrogen curve contains a maximum and a minimum. With

concentrations of ozone below about 3.8 per cent., the pressure of the system decreases during illumination, the greatest decrease being at about 1.5 per cent., whilst at about 9.5 per cent. of ozone, the pressure increase is a maximum. The shape of the curve is evidently conditioned by the simultaneous occurrence of two (or more) reactions, one of which is accompanied by a volume decrease, the other by a volume increase. The former exerts the larger effect with small ozone concentrations, and the latter at high concentrations. It may be shown that, whatever the intermediate processes, if we start with a mixture of ozone, oxygen, and hydrogen, and end with a mixture of ozone, oxygen, hydrogen, and water, the *net* result can be expressed in terms of three reactions, which may be regarded as independent, namely,

Since the tube *G* contained sulphuric acid, reaction (2) as well as (3) is attended by a pressure decrease, whilst reaction (1) involves a pressure increase. It is considered improbable that reaction (3) occurs to any appreciable extent, although it cannot be definitely excluded by the experimental data presented above. However, Weigert and Böhm, in an experimental investigation of the effect of ultra-violet light on mixtures of hydrogen, oxygen, and ozone (*Z. physikal. Chem.*, 1915, **90**, 194), have concluded that this reaction does not take place. Also, as will be shown later, the chief conclusion to be drawn from the present investigation is independent of whether reaction (3) occurs or not. We shall therefore assume that only reactions (1) and (2) are to be taken into consideration, and calculate how the fractions of ozone decomposed, analytically determined in each experiment and given in column 5 of Table III, may be shared between these two reactions. This is effected as follows:

Let the fraction of ozone decomposed (values in column 5) = α , the fraction decomposed by reaction (1) = α_1 , and the fraction decomposed by reaction (2) = α_2 . Then $\alpha_1 + \alpha_2 = \alpha$.

Let the total pressure of gas mixture = B mm. of mercury and the corrected pressure increase = p mm. of sulphuric acid (column 4). Then if V = volume of gas mixture and c = initial volume per cent. of ozone, the number of c.c. of ozone decomposed by reaction (1) = $\alpha_1 c V / 100$ and the number of c.c. by reaction (2) = $\alpha_2 c V / 100$. $\alpha_1 c V / 100$ c.c. of ozone, decomposing by (1), cause a volume *increase* of $\alpha_1 c V / 200$ c.c. $\alpha_2 c V / 100$ c.c. of ozone, decomposing by (2), cause a volume *decrease* of $\alpha_2 c V / 100$ c.c.

Therefore, total volume increase = $\alpha_1 cV/200 - \alpha_2 cV/100$ c.c.
 Hence, pressure increase = $B(\alpha_1 c/200 - \alpha_2 c/100)$ mm. of mercury

$$= \frac{B \times c \times 13.59}{1.84 \times 100} \left(\frac{\alpha_1}{2} - \alpha_2 \right) \text{ mm. of H}_2\text{SO}_4$$

That is,
$$p = \frac{B \times c \times 13.59}{184} \left(\frac{\alpha_1}{2} - \alpha_2 \right).$$

From this equation and the equation $\alpha_1 + \alpha_2 = \alpha$,

we obtain
$$\alpha_1 = \frac{(27.18 \times \alpha \times B \times c) + (368 \times p)}{40.77 \times B \times c}$$

and
$$\alpha_2 = \frac{(13.59 \times \alpha \times B \times c) - (368 \times p)}{40.77 \times B \times c}.$$

The values thus obtained for α_1 and α_2 are given in columns 6 and 7 of Table III and are shown plotted, with those of α , against initial ozone concentration, in Fig. 4. The lowest curve in this figure refers to ozone-oxygen mixtures and is a reproduction of curve BB of Fig. 2.

Discussion.

The photochemical decomposition of ozone may be explained in terms of two theories, depending on the nature of the primary process (that caused by absorption of light), which is assumed.

Warburg (*Sitzungsber. Preuss. Akad.*, 1913, 644) has assumed the primary process to be that represented by the equation

which makes possible the following secondary processes,

The net effect of these four reactions is represented by (1).

On the other hand, we may assume the primary process to be an activation of the absorbing molecule, that is, its conversion into one of higher energy content, which is capable of entering into reactions impossible to the non-activated molecule.

Thus we have,

If we take the first mechanism as correct, in the presence of hydrogen, we obtain the possibility of

The sum of (4) and (10) gives (2).

Assuming the second mechanism, process (2) is obtained by summing (8) and (11).

To obtain reaction (3), $\text{O}_3 + 3\text{H}_2 \rightarrow 3\text{H}_2\text{O}$, which we have above eliminated as unlikely, we must assume, on the first mechanism, that the reaction $\text{O}_2 + 2\text{H}_2 \rightarrow 2\text{H}_2\text{O}$ can occur. There appears to be no available evidence that the oxygen formed in reaction (4) is activated sufficiently to enable this process to occur.

FIG. 4.

Curve I.—Total fraction decomposed — α .
 Curve II.—Fraction decomposed by reaction (1) — α_1 .
 Curve III.—Fraction decomposed by reaction (2) — α_2 .
 Curve IV.—Fraction decomposed in mixtures containing ozone and oxygen only.

On the second view, reaction (3) would apparently be of quadri-molecular order, thus,

and, in consequence, if possible at all, much slower than any of the other reactions.

The most important conclusion which emerges from these experiments is the strong catalytic effect of hydrogen on reaction (1). This is clearly shown by the curves in Figs. 3 and 4. In Fig. 3 are plotted manometric increases in the presence and the absence of hydrogen, and it will be seen that, at a concentration of about 9 per

cent. of ozone, the increase in the former case is three times that in the latter. Since the only one of reactions (1), (2), and (3) attended by a pressure increase is (1), it follows that, in presence of hydrogen, this reaction is accelerated to a considerable extent and also that this conclusion is independent of whether (3) is occurring or not. Assuming that this does not occur, Fig. 4 gives the fractions of ozone decomposed by (1) and (2), plotted against ozone concentration. It will be seen that the reaction $2\text{O}_3 \rightarrow 3\text{O}_2$ in a mixture containing 6 per cent. of ozone, 40 per cent. of hydrogen, and 54 per cent. of oxygen is about five times as rapid as in a mixture of ozonised oxygen of the same ozone content, and also that the effect of smaller additions of hydrogen is quite marked. The extent of the reaction

is small with high ozone concentration (that is, small hydrogen concentration), becoming increasingly important as the hydrogen content is increased. At an ozone concentration of about 2.4 per cent., the two reactions take place to an equal extent and, for concentrations below this, the amount of ozone decomposing by (2) exceeds that by (1). Throughout the whole range, however, the velocity of reaction (1) is markedly greater in the presence of hydrogen than in its absence. It is difficult to suggest an adequate explanation of this effect. Among the explanations which may be advanced are the following.

(1) If the mechanism of the reaction $2\text{O}_3 \rightarrow 3\text{O}_2$ is that given by reactions (4) to (7), on displacing oxygen from a mixture by another gas reaction (6) will be hindered and thus ozone decomposition promoted. This explanation does not suffice, however, as is proved by the results given in the succeeding paper for mixtures of ozone with other gases such as nitrogen. The effect found is a comparatively small increase in the velocity of the process $2\text{O}_3 \rightarrow 3\text{O}_2$, much less than the corresponding effect in the presence of hydrogen.

(2) Weigert and Böhm (*loc. cit.*) have measured the photochemical decomposition of ozone in presence of hydrogen, ultra-violet light being employed, and have obtained similar results to those given here. To account for the effect under consideration, Weigert (*Z. physikal. Chem.*, 1915, 90, 223) advanced the theory that the decomposition of ozone in the presence of hydrogen is not a photochemical process but a thermal one. The heat liberated by the reaction $\text{O}_3 + \text{H}_2 \rightarrow \text{H}_2\text{O} + \text{O}_2$ is supposed to warm the gas in the neighbourhood of the absorbing layer to a temperature high enough to enable the bimolecular, thermal reaction $2\text{O}_3 \rightarrow 3\text{O}_2$ to proceed at an appreciable rate. Whether this explanation is applicable or not to the reaction effected by ultra-violet light, it cannot apply

to the present investigation, where visible light was used. This follows from a consideration of the average increases in temperature above that of the surroundings of gas mixtures during illumination. These temperature increases are calculable from the pressure decreases observed on cutting off the light. Thus, in the experiment quoted on page 2757, there is a pressure decrease of $40.7 - 37.8 = 2.9$ mm. of sulphuric acid, or 3.3 mm. corrected, when the light is cut off. This corresponds to an average temperature increase of 0.17° above the surroundings during the experiment. Now if hydrogen is causing the reaction $2\text{O}_3 \rightarrow 3\text{O}_2$ to take place in the manner suggested by Weigert, there should be much greater increases of temperature in gas mixtures containing hydrogen than in those containing only ozone and oxygen. That this is not the case is shown in Table IV.

TABLE IV.

Ozone-Oxygen Mixtures.

Ozone per cent.	6.00	6.57	8.74	9.14	10.27	12.17
Average temp. increase	0.16°	0.18°	0.22°	0.21°	0.23°	0.25°

Ozone-Oxygen-Hydrogen Mixtures.

Ozone per cent.	6.6	7.74	8.92	9.55	10.59	10.82
Average temp. increase	0.15°	0.16°	0.17°	0.17°	0.22°	0.21°

It is seen that, comparing mixtures of equal ozone content, the heating is rather less with hydrogen present than in its absence.

(3) It may be suggested that the water vapour which is formed catalyses the decomposition of ozone. This point was investigated by Warburg (*loc. cit.*) for the decomposition by ultra-violet light. He found that the rate of photochemical deoxygenation in mixtures of ozone and oxygen saturated with water vapour was about twice as great as in dry mixtures of the same ozone concentration. Assuming the same is true for the decomposition by visible light, the magnitude of this effect does not suffice to account for the observed results, especially as in these experiments the partial pressure of water vapour could never attain high values.

Yet the most plausible explanation of the effect appears to us to be a modification of this view, namely, the assumption that the water molecules formed when hydrogen is present, which for some period after their formation possess excess energy, can activate ozone molecules by collision. Water may be formed as a result either of reaction (10) $\text{H}_2 + \text{O} \rightarrow \text{H}_2\text{O}$, or of reaction (9) O_3 (activated) + $\text{H}_2 \rightarrow \text{H}_2\text{O} + \text{O}_2$, depending on the mechanism adopted. The former involves an energy evolution of about 130,000 cal. per gram-molecule of water formed, the latter of 92,000 cal. plus the energy of activation of ozone. In either case, the water molecules

at the instant of their formation are endowed with a large amount of energy in excess of the normal, and it is reasonable to assume that, if they can retain this energy long enough, they may transfer all or a fraction of it to ozone molecules on collision. The assumption of activation by collision has been made by Warburg (*loc. cit.*), Nernst and Noddack (*Sitzungsber. Preuss. Akad.*, 1923, 110), and others. Thus Warburg found in mixtures of ozone with oxygen or with nitrogen that the number of ozone molecules decomposed per quantum of ultra-violet light absorbed increases with increasing concentration of ozone. This result he attributed to the oxygen molecules resulting from the reaction $O + O \rightarrow O_2$ being able to decompose ozone molecules by collision, the magnitude of the effect being greater at high ozone concentrations. Strong evidence for the possibility of activation by collision is afforded by the existence of sensitised photochemical processes such as those studied by Bonhöffer (*Z. Physik*, 1923, **13**, 94) and Grüss (*Z. Elektrochem.*, 1923, **29**, 144). The quantitative application of this hypothesis to the results here presented is not possible at present; qualitatively, however, it appears capable of accounting for the relatively large effect found in these experiments. Among the factors which determine the fraction of ozone decomposed by the reaction $2O_3 \rightarrow 3O_2$ are (a) the value of the ratio ozone molecules decomposed/ozone molecules activated, and (b) the number of ozone molecules activated by collision per water molecule formed. Both these increase with increasing ozone concentration, and it might thus be possible in mixtures strong in ozone for a small formation of water to decompose a relatively large quantity of ozone.

Summary.

(1) The action of visible light (wave-lengths between 360μ and 760μ) of constant intensity on mixtures of ozone and oxygen and on mixtures of ozone, oxygen, and hydrogen has been investigated.

(2) In the former case, the velocity of the reaction which occurs, namely, $2O_3 \rightarrow 3O_2$, is proportional to the square of the concentration of ozone.

(3) With mixtures of ozonised oxygen and hydrogen, two reactions take place on illumination, namely, $2O_3 \rightarrow 3O_2$ and $H_2 + O_3 \rightarrow H_2O + O_2$, and their velocities have been determined in mixtures of composition x per cent. of ozone, $8.4x$ per cent. of oxygen, $100 - 9.4x$ per cent. of hydrogen, where x was varied between 0 and 12.

(4) The reaction $2O_3 \rightarrow 3O_2$ is strongly catalysed in the presence of hydrogen. A discussion and a possible mechanism of this effect are given.

We desire to express out thanks to Professor W. C. McC. Lewis for providing facilities for this work, and to Miss J. MacWillie for assistance in carrying out the experiments.

THE MUSPRATT LABORATORY OF PHYSICAL AND ELECTRO-CHEMISTRY,
THE UNIVERSITY OF LIVERPOOL. [Received, October 11th, 1923.]

CCCXVIII.—*The Photochemical Reactivity of Ozone in Presence of Other Gases. Part II.*

By ROBERT OWEN GRIFFITH and JANE MACWILLIE.

IN the preceding paper, the effect of visible light on mixtures of ozonised oxygen and hydrogen was described, and the velocity of the process $2\text{O}_3 \rightarrow 3\text{O}_2$ compared with that found in the absence of hydrogen, light of the same intensity being employed. As, however, in the former case a simultaneous reaction occurs with formation of water, it was of interest to determine the velocity of photochemical deozonisation in the presence of other gases which might be expected to be chemically indifferent under the conditions of experiment. For this reason, the reaction has been studied in mixtures of ozonised oxygen with argon, with helium, with nitrogen, and with carbon dioxide. Further, carbon monoxide has been employed as a diluent, in order to compare its behaviour in the presence of ozone, photochemically activated, with that of hydrogen under analogous conditions. None of these gases reacts with ozone in the absence of direct illumination, and none of them possesses any appreciable absorption in the visible portion of the spectrum.

EXPERIMENTAL.

The apparatus and method of experiment were as described in the preceding paper, the single difference being that, there now being no need for the presence of sulphuric acid in the experimental tube, *G* (Fig. 1, p. 2753), this was removed.

Carbon monoxide was prepared from sodium formate and sulphuric acid, and carbon dioxide from sodium bicarbonate and dilute sulphuric acid. Tests showed that both gases contained less than 1 per cent. of impurity. Nitrogen was prepared in two ways, (1) by warming a solution containing sodium nitrite, ammonium chloride, and potassium dichromate, the gas evolved being passed through concentrated sulphuric acid, over red hot copper, and finally through potassium hydroxide solution, (2) by drawing air through ammonia solution and over red hot copper, excess of ammonia being removed

by passage through sulphuric acid. The two preparations gave identical results.

Helium and argon were drawn from cylinders and not further purified. The former contained as impurity 7 per cent. of nitrogen, the latter 1 per cent. of oxygen and 10 per cent. of nitrogen. These amounts, although large, are not sufficient to modify the results obtained in this work, since, as will be shown, the effects of helium, argon, and nitrogen differ only to a small extent which makes the difference between the effects of pure argon (or helium) and of argon (or helium) containing 5 to 10 per cent. of nitrogen well within the experimental error. In each case, the gas employed as diluent was dried by passage through sulphuric acid before mixing with ozonised oxygen.

The mixtures employed were such that they contained an approximately constant ratio ozone/oxygen, their composition being expressible as x per cent. of ozone, $10x$ per cent. of oxygen, and $100 - 11x$ per cent. of diluent, where x was varied from 0 to 9. In order to render possible a comparison of the whole of the results, it is necessary that the light intensity should be the same in all the experiments. This was the procedure attempted, but a change in the relative positions of the lamp and the experimental tube had to be made half-way through the course of this work, with the result that the first set of experiments was effected with a light intensity slightly greater than that in the second. In the former series are all the experiments in which carbon monoxide and carbon dioxide were employed as diluents, in the latter all in which argon appeared, whilst both light intensities have been used in the case of mixtures containing helium and those containing nitrogen. It is possible, however, to correct the data obtained with the lower light intensity to those which would have been obtained had it been possible to use the higher intensity throughout, and this has been done. That the method of correction applied leads to no serious error is shown by the fact that the values obtained with mixtures containing either helium or nitrogen at the lower light intensity fall, on correction, on the curves plotted from determinations in which the greater intensity was used.

The results obtained are presented in Tables I—V. The first column in each table gives the initial concentration of ozone in the gas mixture and the second, the increase of pressure,* in mm. of sulphuric acid, caused by illumination of the gas mixture for thirty-one minutes. The third column contains values of the fraction of the initial ozone decomposed, calculated from the increase of pressure assuming the only reaction taking place to be $2O_3 \rightarrow 3O_2$. The

* Corrected in the manner given in the preceding paper, p. 2756.

values in the fourth and fifth columns enable this assumption to be tested. The former gives the number of c.c. of $N/20$ -thiosulphate solution equivalent to the residual ozone in the tube at the completion of the experiment, and the latter the number calculated from the known initial ozone content and the increase of pressure, the same assumption being employed. The bracketed values in the second and third columns were obtained with light of the lower intensity and the corrected values obtained from them are indicated by an asterisk. In order to save space, the results found for mixtures containing oxygen and ozone only are not given in tabular form, as they are similar in all respects to those already published in the preceding paper; the data obtained with these mixtures necessary for the present investigation are however, plotted in Fig. 1.

In Fig. 1, the data of the first and second columns of the tables are plotted, the initial ozone concentration being abscissa and the increase of pressure caused by illumination for thirty-one minutes ordinate. The lowest curve on the figure is a graph showing the

results (not given in the tables) for mixtures of ozone and oxygen with light of the same intensity.

In the figure, the points on the curves for mixtures containing nitrogen, argon, or helium which were obtained by correcting the results obtained using the lower light intensity are indicated by black squares, circles, and triangles respectively.

FIG. 1.

Discussion of Results.

(1) Columns 4 and 5 of Tables I to V enable a comparison to be made of the total ozone which is destroyed in the course of each experiment and that which disappears by the reaction $2\text{O}_3 \rightarrow 3\text{O}_2$. The former column gives the number of c.c. of a standard thio-sulphate solution equivalent to the ozone in the residual gas after illumination and the latter the titre calculated from the known initial ozone content and the observed increase of pressure, assuming the only reaction which occurs to be $2\text{O}_3 \rightarrow 3\text{O}_2$. The tables show that for mixtures containing helium, argon, nitrogen, or carbon

dioxide, the values in the two columns may be taken as equal within the experimental error, but that for mixtures containing carbon monoxide the calculated titre is always slightly greater than that experimentally determined. This shows that, in the former cases, we have no evidence that any other reaction but $2\text{O}_3 \rightarrow 3\text{O}_2$ is taking place, but that in the presence of carbon monoxide another reaction, which is attended either by a decrease of volume or by no volume change, takes place. The most probable process is the formation of carbon dioxide by the reaction $\text{CO} + \text{O}_3 \rightarrow \text{CO}_2 + \text{O}_2$.* Assuming this to be the case, it is possible to deal with the results for mixtures containing carbon monoxide in an analogous way to that employed in the preceding paper for mixtures containing hydrogen, and calculate for each gas mixture the fraction of ozone decomposed by the reaction $2\text{O}_3 \rightarrow 3\text{O}_2$, and that by the reaction $\text{CO} + \text{O}_3 \rightarrow \text{CO}_2 + \text{O}_2$. However, the small differences between the calculated and the observed values of columns 5 and 4 of Table II, and the fact that a very small error in the titration causes a large error in the value calculated from it for the total amount of ozone decomposed, render the values derived for the fraction of ozone decomposed by the reaction $\text{CO} + \text{O}_3 \rightarrow \text{CO}_2 + \text{O}_2$ particularly susceptible to small experimental errors. A complete table of these values is therefore not presented; the general result of the calculation, however, is that, in mixtures containing from 1.6 to 8 per cent. of ozone, the fraction of ozone forming carbon dioxide appears to vary in an irregular manner between 0.06 and 0.01, the mean value being 0.02–0.03. It was shown in the preceding paper that hydrogen reacts with ozone on illumination, and that the fraction of ozone forming water increases from 0.02 in mixtures containing initially 7 per cent. of ozone to 0.15 in a 1.5 per cent. mixture. It is therefore established that in mixtures weak in ozone, hydrogen reacts to a greater extent with ozone photochemically activated than does carbon monoxide under identical conditions.†

(2) The curves in Fig. 1 show that each of the gases helium, argon, nitrogen, carbon monoxide, and carbon dioxide increases the velocity of the photochemical reaction $2\text{O}_3 \rightarrow 3\text{O}_2$. We have compared in these experiments the reaction velocity in a gas of composition

* It was shown by Clausmann (*Compt. rend.*, 1910, **150**, 1332) that carbon monoxide and ozonised oxygen slowly react to form carbon dioxide when exposed to daylight; Remsen and Southworth (*Ber.*, 1875, **8**, 1414) had previously concluded that no reaction occurred between the two even when the mixture was exposed to bright sunlight.

† The light intensity in the experiments with hydrogen was somewhat less than that employed in the experiments described in this paper; correcting for this would make the value 0.15 for hydrogen mixtures weak in ozone still greater.

x per cent. of ozone, $100 - x$ per cent. of oxygen with that in a mixture containing x per cent. of ozone, $10x$ per cent. of oxygen, and $100 - 11x$ per cent. of diluent, that is, effectively some of the oxygen has been replaced by another gas. The increase in velocity of the process $2\text{O}_3 \rightarrow 3\text{O}_2$ found as a result of this substitution may be explained in terms of two theories depending on the primary process assumed.

(a) If, with Warburg (*Sitzungsber. Preuss. Akad.*, 1913, 644), the primary process is taken to be $\text{O}_3 + h\nu \rightarrow \text{O}_2 + \text{O}$, the effect under consideration is a necessary consequence of diminution of the concentration of oxygen. Of the three secondary processes, $\text{O} + \text{O} \rightarrow \text{O}_2$, $\text{O} + \text{O}_2 \rightarrow \text{O}_3$, and $\text{O} + \text{O}_3 \rightarrow 2\text{O}_2$, which are possible, the second will be retarded by a diminution in the oxygen concentration. Since this reaction entails reformation of ozone, it follows that its retardation will increase the total ozone decomposed.

(b) If, on the other hand, the primary process is assumed to be $\text{O}_3 + h\nu \rightarrow \text{O}_3(\text{activated})$ and the secondary $\text{O}_3(\text{activated}) + \text{O}_3 \rightarrow 3\text{O}_2$, it is not so clear why oxygen should have a retarding influence on the rate of decomposition. The simplest assumption appears to be that the activated ozone molecules lose their excess energy more readily on collision with an oxygen molecule than with those of any other gas.

(3) The gases investigated catalyse the photochemical reaction $2\text{O}_3 \rightarrow 3\text{O}_2$ in the order hydrogen, helium, argon, nitrogen, carbon monoxide, and carbon dioxide. The effect of hydrogen is far greater than that of the others; a possible explanation of its mode of action has been given in the preceding paper. Of the other gases, helium, argon, and nitrogen produce a definitely stronger catalytic effect than carbon monoxide and carbon dioxide. If the action of the diluents was merely a displacement effect as described in paragraph 2 (a), the results in the presence of all the gases should be identical (with the possible exception of carbon monoxide, in which case another reaction occurs to a small extent). Since this is far from being the case and each gas produces a specific effect, recourse may be made to the assumption employed in paragraph 2 (b). We are thus led to the hypothesis—necessarily tentative, in view of our lack of knowledge of the mechanism of photochemical processes and the energy interchanges which take place—that the relative catalytic activity of these gases is connected with the readiness with which they cause de-activation of ozone molecules on collision. In paragraph 2 (b) it was assumed that an activated ozone molecule loses its excess energy more readily on colliding with an oxygen molecule than with a molecule of any of the gases helium, argon, nitrogen, carbon monoxide, and carbon dioxide. This would now be extended into the hypothesis that the probability of an activated

ozone molecule retaining its excess energy after collision with a molecule of another gas is greatest for helium, argon, and nitrogen in the order given, less for carbon monoxide and carbon dioxide, and least of all for oxygen. Regarding the position occupied by the inert gases and nitrogen in this scale, nothing at present can be said; as regards that of the other gases it appears suggestive that loss of energy occurs the more readily the greater the percentage of oxygen in the molecule concerned.

Attention may perhaps be directed to one further point. In addition to activated ozone molecules, it is not improbable that during illumination the systems here studied also contain activated oxygen molecules formed as a result of the photochemical decomposition and that these may transfer their excess energy to ozone molecules on collision. Such assumptions have been made by Warburg (*loc. cit.*) to account for the increase of the photochemical efficiency of the deoxygenation process (caused by ultra-violet light) with increasing concentration of ozone. In addition, then, to a consideration of the energy interchanges occurring on collisions between activated ozone molecules and others, a complete discussion of this photochemical reaction might require that the collisions in which activated oxygen molecules take part should similarly be considered.

Summary.

(1) The action of visible light (wave-lengths between 360μ and 760μ) on mixtures of ozonised oxygen with helium, with argon, with nitrogen, with carbon monoxide, and with carbon dioxide has been determined. The mixtures employed were of composition x per cent. of ozone, $10x$ per cent. of oxygen, $100 - 11x$ per cent. of diluent, where x was varied between 0 and 9.

(2) With mixtures of ozonised oxygen and carbon monoxide, two reactions take place, (a) $2O_3 \rightarrow 3O_2$, (b) $O_3 + CO \rightarrow CO_2 + O_2$. In the presence of the other gases, the only reaction taking place is (a).

(3) The velocity of the photochemical reaction (a) in the mixtures investigated is in the order of the gases given in (1), if mixtures containing equal concentrations of ozone are compared. The velocities are all greater than that in ozonised oxygen of the same ozone concentration.

(4) A short discussion of these results is given.

CCCXIX.—*Condensation of Aryldiazonium Salts with Monoalkylated Malonic Acids.*

By THOMAS KENNEDY WALKER.

AMONG the numerous recorded investigations of the action of diazonium salts, and also of nitrous acid or alkyl nitrites, on compounds containing in their molecules reactive methylene or methine groups, there can be discerned many cases of analogies which would seem to indicate that these reactions are all achieved by intermolecular changes of similar mechanism. Typical instances in which these similarities are displayed are to be found in the respective actions of diazobenzene and nitrous acid on ethyl alkylmalonate, monoalkylacetoacetic acid, and ethyl alkylacetoacetate, as the following scheme will show :

The action of diazonium salts on malonic acid and on its esters, resulting in the production of formazyl compounds, was investigated by Pechmann (*Ber.*, 1892, **25**, 3175), whilst from cyanoacetic acid and diazobenzene Rothenburg (*ibid.*, 1894, **27**, 689) prepared cyanoformazyl. Subsequently, Favrel (*Compt. rend.*, 1901, **132**, 983, 1336) succeeded in condensing various diazonium salts with monoalkyl derivatives of ethyl cyanoacetate and of ethyl malonate. Hitherto, however, it would not appear that any attempts have been made to bring about condensations of this type with the monoalkylated malonic and cyanoacetic acids.

Again, although the production of *isonitroso*-compounds by the action of nitrous acid or alkyl nitrites on the monoalkylated acids and esters of the acetoacetic and malonic series is well known (V. Meyer and co-workers, *Ber.*, 1878, **11**, 320, 694; 1882, **15**, 1057; Bergreen, *ibid.*, 1887, **20**, 533; Lapworth and Sharratt, *T.*, 1915, **107**, 1254), the literature contains no reference to the

preparation of similar derivatives from mono-substituted cyano-acetic acids and esters.

In order to fill these blanks in our knowledge of this subject and to obtain a wider basis for a comparison of the respective behaviours of aryldiazonium salts and nitrous acid towards substances of the types under discussion, a series of experiments has been undertaken, and the present communication deals with the action of diazonium salts on monoalkylmalonic acids.

It was found that diazonium acetates react with these acids, usually somewhat readily, carbon dioxide being liberated during the course of the condensations. Thus, when monomethylmalonic acid was treated with benzenediazonium chloride in presence of sodium acetate, a non-acidic substance was produced which proved to be methylformazyl, m. p. 120—121°, prepared by Bamberger and Müller (*Ber.*, 1894, 27, 147) by treating the phenylhydrazone of pyruvic acid with diazobenzene. By similar means, a number of new alkylformazyls have been prepared, amongst which may be mentioned *ethylformazyl*, m. p. 122°, 4 : 4'-*dimethylallylformazyl*, m. p. 117°, and *benzylformazyl*, m. p. 93·5°. The product is the same whether equimolecular quantities of the components or 2 mols. of diazonium salt to 1 mol. of the alkylmalonic acid are employed. No acidic intermediate product can be isolated, but in view of Bamberger and Müller's synthesis of methylformazyl (*loc. cit.*) it may be assumed that in the present cases the reactions proceed in two stages :

an intermediate phenylhydrazone being formed and suffering immediate attack by a second molecule of the diazonium salt.

EXPERIMENTAL.

Twenty-seven grams (2 mols.) of *p*-toluenediazonium sulphate, prepared by passing the vapour of methyl nitrite into a suspension of 28·1 grams of finely divided *p*-toluidine hydrogen sulphate in glacial acetic acid at 10—12°, and precipitating the diazonium salt with dry ether, were dissolved in 40 c.c. of ice-water and mixed with 9·0 grams (1 mol.) of allylmalonic acid in 70 c.c. of ice-water. To this mixture, maintained at 8—10°, a concentrated aqueous

solution of 35 grams (4 mols.) of crystalline sodium acetate was gradually added with shaking, whereupon the liquid assumed a rose-coloured tint and an evolution of carbon dioxide commenced, accompanied by the separation of solid matter which formed a red froth. At the end of one hour the reaction was complete, and the product was filtered, washed with ice-water, and dried in a desiccator. It was purified by repeated crystallisation from hot benzene, a considerable amount of a red dye which accompanied it being extracted with light petroleum. Yield, 50 per cent. of the theoretical, calculated on the weight of allylmalonic acid used. After a final recrystallisation from acetone the compound was obtained in slender, elongated, canary-yellow prisms and melted sharply at 117° (Found: C = 74.3; H = 6.5; N = 19.1. $C_{18}H_{19}N_4$ requires C = 74.22; H = 6.53; N = 19.24 per cent.).

4:4'-Dimethylallylformazyl is readily soluble in the cold in ether, alcohol, acetone, ethyl acetate, or carbon tetrachloride, fairly easily soluble in benzene, and almost insoluble in carbon disulphide or light petroleum.

Attempts were made to obtain crystalline condensation products by the interaction of other diazonium salts and allylmalonic acid, but only by the use of α -naphthylamine could crystalline material be obtained. In this case, the crude reaction product was a dark greyish-brown, amorphous substance, from which light petroleum extracted considerable amounts of a purple dye. The substance which remained was slightly soluble in alcohol, fairly soluble in benzene, and freely soluble in acetone, but would not separate in a crystalline condition from solution in these solvents. By repeated precipitation from solution in benzene by addition of light petroleum, a small amount of material was finally obtained which was seen under the microscope to consist of masses of short, slender, reddish-brown needles. These melted at 114° with decomposition, but the specimen could not be obtained in a sufficiently pure condition to give satisfactory analytical figures. Experiments in which the diazonium chlorides from aniline and *o*- and *m*-toluidine were brought into contact with allylmalonic acid resulted only in the formation of red, tarry matter containing phenolic material, whilst diazotised *p*-nitroaniline and allylmalonic acid gave in good yield a product, of which about 50 per cent. proved to be soluble in caustic soda solution. All attempts to purify the constituents of this mixture were unsuccessful, since resinification occurred under all conditions of treatment. It was considered probable that the alkali-soluble material was either the *p*-nitrophenylhydrazone of allylglyoxylic acid,

or *p*-nitrobenzenecazoallylformaldoxime,

both of which at present are unknown, and its formation led to a study of the simultaneous action of diazobenzene and nitrous acid on the monoalkylmalonic acids, which will form the subject of a future communication.

Ethylformazyl, $\text{NHPh}\cdot\text{N}\cdot\text{C}(\text{Et})\cdot\text{N}_2\text{Ph}$.—Aniline (3.1 grams) was diazotised (10 c.c. of concentrated hydrochloric acid and 15 c.c. of 50 per cent. acetic acid, and 2.4 grams of sodium nitrite in 30 c.c. of ice-water), the resulting solution was mixed with a solution of 2.2 grams of ethylmalonic acid in 10 c.c. of ice-water, and the whole kept for half an hour, when 10.1 grams of crystalline sodium acetate were added with shaking. After the mixture had stood for thirty-six hours in the ice-chest, the separated material was washed and dried in a vacuum. The bright crimson, amorphous powder thus obtained in almost quantitative yield was found to be practically pure and was prepared for analysis by successive crystallisations from warm ethyl alcohol and ethyl acetate. From the latter solvent it separated in clusters of small, carmine needles which melted at 122° with blackening and decomposition (Found: $\text{N} = 22.5$. $\text{C}_{15}\text{H}_{16}\text{N}_4$ requires $\text{N} = 22.22$ per cent.).

Ethylformazyl is sparingly soluble in cold ethyl alcohol, more readily in benzene, methyl alcohol, or ethyl acetate, in the cold, and still more soluble in the warm liquids. Like several compounds of the formazyl class, it yields salts with, and reduces, silver nitrate. When an alcoholic solution of ethylformazyl is mixed with silver nitrate solution a brown precipitate is formed; whilst with ammoniacal silver nitrate the metal is thrown down immediately in a finely divided condition.

Benzylformazyl, $\text{NHPh}\cdot\text{N}\cdot\text{C}(\text{CH}_2\text{Ph})\cdot\text{N}_2\text{Ph}$.—Benzylmalonic acid (3.2 grams), dissolved in 10 c.c. of alcohol, was added to 65 c.c. of a well-cooled aqueous solution of benzenediazonium chloride prepared from 3.1 grams (2 mols.) of aniline, followed after a few minutes by a concentrated aqueous solution of 10.1 grams of crystalline sodium acetate, sufficient to remove the mineral acid. The reaction mixture was maintained at 0° for thirty-six hours and the first portion of the product to separate, which was resinous and had a phenolic odour, was removed, triturated with 10 per cent. aqueous caustic soda, then with water, and finally mixed and purified with the second portion of the product, which separated in a purer state from the filtered reaction mixture. Extraction of the dried material with light petroleum removed a red substance and left a light red, amorphous powder, for which, for purposes of purification, the best solvent was found to be ethyl alcohol. By

crystallisation from this solvent at temperatures below 40° , minute, elongated plates of a deep orange colour were obtained which darkened at 90° and suddenly swelled up and melted at 93.5° . In several experiments, it was not found possible to obtain a yield higher than 50 per cent. of that required by theory (Found: $N = 18.0$. $C_{20}H_{18}N_4$ requires $N = 17.83$ per cent.).

This inquiry was undertaken at the suggestion of Professor A. Lapworth, F.R.S., whose kind interest and helpful advice it is a pleasure to acknowledge. The author's thanks are also due to the Advisory Council of the Department of Scientific and Industrial Research, for a grant which defrayed the expenses of the investigation.

CCCXX.—*Preparation and Chlorination of $\alpha\beta$ -Alkylacylcarbamides.*

By ELWYN ROBERTS.

IN an investigation of the mechanism of chlorination of certain compounds in acetic acid media I had occasion to chlorinate acetamide. The results obtained were interesting, inasmuch as I was able finally to isolate α -acetyl- β -methylcarbamide in a satisfactory yield. The direct conversion of acetamide into the symmetrically substituted α -acetyl- β -methylcarbamide has not hitherto been effected by use of chlorine. This led me to apply the method to the general preparation of $\alpha\beta$ -alkylacylcarbamides.

Unsymmetrical carbamides were obtained by Hofmann (*Ber.*, 1881, **14**, 2725; 1882, **15**, 407) by the action of bromine in alkaline solution on the aliphatic amides; he used bromine in preference to chlorine because of its easier manipulation and measurement. Odenwald (*Annalen*, 1918, **416**, 228; 1919, **418**, 316) has shown that by Hofmann's method the yields of carbamides are variable, and has given methods, still using bromine, in which definite yields are obtained.

The action of chlorine on the amide is in the first instance as follows:

sometimes, as with butyramide and isobutyramide, the chloroamide is quantitatively produced, but with acetamide at least, the reaction is as follows:

the yield of chloroamide is therefore only 50 per cent. In all probability, the solubility and the hydrolysis of the chloroamide, as well as the combination of the amide with hydrogen chloride, play a part in determining the yield of chloroamide in each case.

The action of caustic soda on the chlorinated aqueous solutions of the amides causes transformation of the chloroamides formed into unsymmetrical carbamides. In the case of propionamide, butyramide, and isobutyramide, transformation of the chloroamides into alkylacylcarbamides occurs at the ordinary temperature, the yields being satisfactory when 2 mols. of alkali are used. With acetamide, on the other hand, only 1 mol. of alkali must be used, the yield of α -acetyl- β -methylcarbamide being 50 per cent.; this is the maximum yield obtained by this method; a slight excess of alkali diminishes the yield considerably.

The formation of alkylacylcarbamide in our experiments is adequately explained by the views of Stieglitz and Earle (*Amer. Chem. J.*, 1903, 30, 412), namely, that it is due to the ready condensation of a carbimide, the primary product of the rearrangement of a molecule of an acid halogenamide, with a second molecule of the latter, and to a subsequent hydrolysis of the condensation product.

The action of caustic soda on the pure chloroamides varies with the concentration of the alkali and also apparently with the chloroamide. A molecular proportion of caustic soda in water mainly hydrolyses the chloroamide; heat is developed, and only a small quantity of alkylacylcarbamide is formed. An $\alpha\beta$ -alkylacylcarbamide was not always the only product; butyrylchloroamide yielded propylbutyrylcarbamide slightly contaminated with dipropylcarbamide (compare Hofmann, *loc. cit.*), whilst isobutyrylchloroamide yielded mainly the symmetrical diisopropylcarbamide slightly contaminated with isopropylisobutyrylcarbamide (compare Hofmann, *loc. cit.*; Odenwald, *loc. cit.*).

From molecular proportions of butyramide and butyrylchloroamide and caustic soda a good yield of the alkylacylcarbamide was obtained. The same is true of isobutyramide, but from the corresponding mixture containing acetamide or propionamide no carbamide was isolated.

The carbamides derived in this way were chlorinated and a number of new chloro-derivatives obtained, the yields being almost theoretical.

EXPERIMENTAL.

Preparation of $\alpha\beta$ -Alkylacylcarbamides.—Chlorine, passed into a saturated aqueous solution of the amide (1 mol.) at a moderate rate, is absorbed with slight evolution of heat; when the

passage of chlorine is slow, little or no absorption is observed and no heat change. Precipitation of the corresponding monochloroamide occurs in the case of acetamide, butyramide, or *isobutyramide*, but not in the case of propionamide. Forty per cent. caustic soda (2 mols.) is added drop by drop with cooling to the chlorinated solution, when transformation of the chloroamides into almost pure alkylacilcarbamides takes place at the ordinary temperature, and is complete after twenty-four hours. A very irritating vapour is given off during the later stages of the reaction. Addition of the alkali causes initially precipitation of the impure chloroamide in the case of propionamide. In the case of acetamide 1 mol. of alkali is added and the solution, after standing for eighteen to twenty-four hours, after which period it becomes decidedly viscous, is warmed on the water-bath for a short time, when, on cooling, the alkylacilcarbamide separates out.

The alkylacilcarbamide was converted into its mono- or dichloro-derivative, unless otherwise stated, by passing chlorine into a suspension of 1 gram of carbamide in 10 c.c. of 10 per cent. caustic soda. The oily product was extracted with chloroform, the chloroform extract dried over anhydrous sodium sulphate, and the chloroform evaporated in a current of warm dry air. The residual chloro-derivative obtained was usually a pale yellow, viscid oil having a sharp odour.

For comparison, the yields obtained by Odenwald (*loc. cit.*) are given in brackets.

α -Acetyl- β -methylcarbamide. Yield 50 per cent. (75 per cent.). Monochloro-derivative: Found: Cl = 23.25. $\text{NMeCl}\cdot\text{CO}\cdot\text{NH}\cdot\text{COMe}$ or $\text{NHMe}\cdot\text{CO}\cdot\text{NCl}\cdot\text{COMe}$ requires Cl = 23.55 per cent.

α -Propionyl- β -ethylcarbamide. Yield 66 per cent. (71 per cent.). Monochloro-derivative: Found: Cl = 33.56. $\text{NEtCl}\cdot\text{CO}\cdot\text{NH}\cdot\text{COEt}$ or $\text{NHet}\cdot\text{CO}\cdot\text{NCl}\cdot\text{COEt}$ requires Cl = 33.29 per cent.

Butyrylchloroamide was obtained as a yellow oil on chlorinating butyramide in aqueous solution; yield 90 per cent. (Found: Cl = 30.29. $\text{C}_3\text{H}_7\cdot\text{CO}\cdot\text{NHCl}$ requires Cl = 29.18 per cent.).

α -Butyryl- β -propylcarbamide. Yield 71 per cent. After one crystallisation from hot water, it melted at $100.4\text{--}101.4^\circ$. Hofmann (*loc. cit.*) gives as m. p., 99° .

isoButyrylchloroamide was obtained as a yellow oil on chlorinating isobutyramide in aqueous solution; yield 90 per cent. (Found: Cl = 31.14. $\text{CHMe}_2\cdot\text{CO}\cdot\text{NHCl}$ requires Cl = 29.18 per cent.).

α -isoButyryl- β -isopropylcarbamide. Yield 55 per cent. (22.5 per cent.). Monochloro-derivative. The oily chloro-derivative obtained by chlorinating the carbamide in alkali or dilute acetic acid solidified on standing in a cool place. The solid was purified by

dissolution in the minimum quantity of glacial acetic acid and reprecipitation with water; m. p. 97.5° (Found: Cl = 17.28. $\text{NCIPr}^{\delta}\cdot\text{CO}\cdot\text{NH}\cdot\text{COPr}^{\delta}$ or $\text{NHPr}^{\delta}\cdot\text{CO}\cdot\text{NCl}\cdot\text{COPr}^{\delta}$ requires Cl = 17.16 per cent.).

$\alpha\beta$ -Diisopropylcarbamide. Hofmann (*loc. cit.*) prepared this compound by heating isobutyrylbromoamide with dry sodium carbonate and extracting the product with ether. Odenwald (*loc. cit.*) obtained it as a by-product in the preparation of isobutyrylisopropylcarbamide. I obtained it by the action of 10 per cent. caustic soda (1 mol.) on 1 mol. of isobutyrylchloroamide. A vigorous reaction set in with great development of heat on mixing alkali and chloroamide, and on cooling slightly impure diisopropylcarbamide separated out in a yield of 55 per cent. One crystallisation from dilute alcohol gave pure diisopropylcarbamide in a yield of 30 per cent.

Dichloro-derivative: Found: Cl = 32.91. $\text{NCIPr}^{\delta}\cdot\text{CO}\cdot\text{NClPr}^{\delta}$ requires Cl = 33.28 per cent.

Monochloro-derivative. On chlorinating a suspension of this carbamide in dilute acetic acid, an oily product was obtained which crystallised in long, rectangular rods on standing for several days. The crystals were purified by dissolution in the minimum quantity of glacial acetic acid and reprecipitation with water; m. p. 74° (Found: Cl = 19.69. $\text{NCIPr}^{\delta}\cdot\text{CO}\cdot\text{NHPr}^{\delta}$ requires Cl = 19.86 per cent.).

I wish to express my thanks to Professor Orton, F.R.S., for his guidance and criticism; also to the Department of Scientific and Industrial Research for a grant which has enabled me to carry out the work.

CCCXXI.—*Synthesis of Derivatives of Phenothioxin.*

By SRI KRISHNA.

SYNTHESES of phenothioxin derivatives have been recorded by Mauthner (*Ber.*, 1905, 38, 1411) and by Hilditch and Smiles (*T.*, 1911, 99, 408). In the present communication the synthesis of phenothioxin derivatives from 6-chloro-3-nitrobenzenesulphonic acid is described. This acid condenses with phenols or substituted phenols in boiling alkaline solution, and the diphenyl ethers thus obtained

lose water in presence of concentrated sulphuric acid or, better, acetic anhydride and yield phenothioxins :

Condensation to form the diphenyl ether (I) does not take place quite so readily as in the case of diphenyl sulphide (this vol., p. 156). It is facilitated by prolonged heating at 105–110° in presence of a catalyst such as aluminium powder.

Owing to the extensive sulphonation it causes, sulphuric acid is a less suitable dehydrating agent than acetic anhydride; for example, in the case of 4-nitro-2-sulphinophenyl β -naphthyl ether it produces scarcely any naphthaphenothioxin.

An unsuccessful attempt was made to obtain a phenothioxin by the reactions represented by the scheme

2-Nitrophenothioxin and its monoxide (II) form deep blue or violet solutions in concentrated sulphuric acid, and in this respect resemble the analogous thianthren and thiodiphenylamine compounds (compare Hilditch and Smiles, *loc. cit.*).

EXPERIMENTAL.

4-Nitro-2-sulphinodiphenyl Ether (I).—6-Chloro-3-nitrobenzenesulphinic acid (11 grams), dissolved in 40 c.c. of water containing 2 grams of sodium hydroxide, was slowly added to a boiling solution of sodium phenoxide (0.05 mol. in 30 c.c. of water). The mixture was boiled at 106–107° for three hours, this temperature being attained after addition of 10 grams of anhydrous sodium carbonate. The filtered solution was acidified at 0° with 80 per cent. sulphuric acid, and the yellow precipitate, having been washed with a little

cold water, was crystallised from alcohol. 4-Nitro-2-sulphino-diphenyl ether crystallises from water in colourless needles, m. p. 131° (Found : N = 4.78; S = 11.36. $C_{12}H_9O_5NS$ requires N = 5.01; S = 11.47 per cent.).

In the case of some of the diphenyl ethers described below, it was found preferable to shake the acidified solution with ether and wash the extract with aqueous sodium carbonate; on acidifying the concentrated aqueous extract, the sulphinodiphenyl ether was obtained free from phenol.

3-Nitrophenothioxin (III).—The preceding sulphinic acid (3 grams), suspended in 12 c.c. of cold acetic anhydride, was carefully treated with 1 c.c. of concentrated sulphuric acid, rise of temperature being prevented by cooling the mixture in ice-water. The colour of the solution turned purple and after a few minutes a thick, yellow precipitate began to separate. After remaining for half an hour at room temperature, the mixture was poured into water, and the solid was washed with aqueous sodium hydroxide and with hot water, and dried in a steam-oven. The product, which was a mixture of the phenothioxin and its monoxide (II), was dissolved in 10 c.c. of glacial acetic acid and treated with 2 c.c. of hydrobromic acid. After remaining for two hours on a steam-oven, the solution was diluted with water, and the precipitate washed with hot water and dried. 3-Nitrophenothioxin crystallises from chloroform or a mixture of ligroin and chloroform in minute needles, m. p. 140° (Found: C = 58.45; H = 2.99; N = 5.77; S = 12.79. $C_{12}H_7O_3NS$ requires C = 58.45; H = 2.85; N = 5.71; S = 13.06 per cent.).

3-Nitrophenothioxin dioxide was prepared by heating nitric acid (d 1.4) with 3-nitrophenothioxin in glacial acetic acid solution for three hours on a water-bath, pouring the mixture into water, and crystallising the precipitate from acetic acid. The dioxide forms plates, m. p. $205-206^{\circ}$; its solution in concentrated sulphuric acid is yellow (Found : S = 11.40. $C_{12}H_7O_5NS$ requires S = 11.53 per cent.).

6-Chloro-3-nitro-4'-hydroxydiphenyl Sulphide,

—A solution of phenol (2 grams) and 6-chloro-3-nitrobenzenesulphinic acid (6 grams) in 20 c.c. of concentrated sulphuric acid was kept for three hours at room temperature, its deep blue colour changing to light green. The yellow solid formed on pouring the solution into water was collected, dissolved in cold 2N-sodium hydroxide, reprecipitated from the filtered solution with dilute sulphuric acid, washed with hot water, dried, and crystallised from acetone, a yellow powder, m. p. $165-167^{\circ}$, being obtained (Found : Cl = 13.00; S = 11.72. $C_{12}H_8O_3NClS$ requires Cl = 12.61; S = 11.50).

per cent.). In the above mixture, together with the diphenyl sulphide a product, quite insoluble in alkalis, was formed which probably has the constitution $\text{NO}_2 \cdot \text{C}_6\text{H}_4\text{Cl} \cdot \text{S}(\text{OH}) \cdot \text{C}_6\text{H}_4 \cdot \text{O}$.

The following compounds were prepared by methods similar to those described above.

* *4-Nitro-2-sulphino-4'-methyldiphenyl ether*, obtained from *p*-cresol, crystallised from water or dilute alcohol in colourless needles, m. p. 126° (Found : S = 11.25. $\text{C}_{13}\text{H}_{11}\text{O}_5\text{NS}$ requires S = 10.92 per cent.).

3-Nitro-6-methylphenothioxin crystallises from acetone or chloroform in minute, yellow needles, m. p. 156° (Found : C = 60.00; H = 3.61; N = 5.13; S = 12.22. $\text{C}_{13}\text{H}_9\text{O}_3\text{NS}$ requires C = 60.23; H = 3.47; N = 5.40; S = 12.35 per cent.).

6-Chloro-3-nitro-6'-hydroxy-3'-methyldiphenyl sulphide separates from acetone as a yellowish-grey powder, m. p. 198° (Found : Cl = 11.72; S = 11.01. $\text{C}_{13}\text{H}_{10}\text{O}_3\text{NClS}$ requires Cl = 11.97; S = 10.82 per cent.).

4'-Chloro-4-nitro-2-sulphinodiphenyl ether, obtained from *p*-chlorophenol, crystallised from alcohol in colourless prisms, m. p. 135° (Found : C = 45.73; H = 2.71; Cl = 11.29; S = 10.31. $\text{C}_{12}\text{H}_8\text{O}_3\text{NClS}$ requires C = 45.93; H = 2.55; Cl = 11.32; S = 10.20 per cent.).

6-Chloro-3-nitrophenothioxin crystallises from chloroform in orange-yellow needles, m. p. $128\text{--}129^\circ$ (Found : C = 51.30; H = 2.36; Cl = 12.53; S = 11.61. $\text{C}_{12}\text{H}_6\text{O}_3\text{NClS}$ requires C = 51.52; H = 2.14; Cl = 12.70; S = 11.45 per cent.).

6-Chloro-3-nitrophenothioxin dioxide was obtained on oxidation of the above phenothioxin with chromic acid in acetic acid solution. It crystallises from acetic acid in colourless plates, m. p. $183\text{--}185^\circ$ (Found : Cl = 11.29; S = 10.63. $\text{C}_{12}\text{H}_6\text{O}_5\text{NClS}$ requires Cl = 11.39; S = 10.27 per cent.).

6:6'-Dichloro-3-nitro-4'-hydroxydiphenyl sulphide, obtained from *o*-chlorophenol, separates from acetone as a yellow powder, m. p. 186° (Found : Cl = 22.10; S = 10.42. $\text{C}_{12}\text{H}_7\text{O}_2\text{NCl}_2\text{S}$ requires Cl = 22.40; S = 10.12 per cent.). A second substance, m. p. $262\text{--}264^\circ$, is obtained during the preparation. Attempts were made to obtain 8-chloro-3-nitrophenothioxin, but without success.

4-Nitro-2-sulphinophenyl β -naphthyl ether, obtained from β -naphthol, crystallises from hot water in light yellow needles, m. p. 101° (Found : N = 3.90; S = 9.57. $\text{C}_{16}\text{H}_{11}\text{O}_5\text{NS}$ requires N = 4.25; S = 9.72 per cent.).

3-Nitro- β -naphthaphenothioxin, $\text{NO}_2 \cdot \text{C}_6\text{H}_3 \begin{smallmatrix} \text{O} \\ \text{S} \end{smallmatrix} \text{C}_{10}\text{H}_6$, separates from acetone or chloroform as an orange-yellow powder, m. p. 128° .

It dissolves in concentrated sulphuric acid with a green colour (Found : C = 64.74; H = 3.51; S = 10.54. $C_{16}H_9O_4NS$ requires C = 65.68; H = 3.05; S = 10.84 per cent.).

3-Nitro- β -naphthaphenothioxin dioxide separates from alcohol as a yellow powder, m. p. 182°. It dissolves in concentrated sulphuric acid, giving a light yellow solution (Found : S = 9.49. $C_{16}H_9O_4NS$ requires S = 9.78 per cent.).

In conclusion, I wish to express my thanks to Professor Smiles, F.R.S., for the interest he has taken in this work, and to the Research Fund Committee of the Chemical Society for a grant in aid of this investigation.

KING'S COLLEGE, LONDON.

[Received, August 16th, 1923.]

CCXXII.—*Synthesis of Substituted Thianthrens.* *Part II.*

By SRI KRISHNA.

THE method by which thianthren was synthesised from 6-chloro-3-nitrobenzenesulphinic acid (this vol., p. 156) has now been applied to the preparation of its derivatives.

The requisite substituted diphenyl sulphides were prepared as before (*loc. cit.*), sodium 6-chloro-3-nitrobenzenesulphinate (20 grams) in water (50 c.c.) being added to a boiling alkaline solution of the mercaptan (10 grams in 25 c.c. of water containing 4 grams of sodium hydroxide). The substituted diphenyl sulphide obtained was washed, dried, and crystallised from a suitable solvent. If the sulphide was a viscous oil, it was found advantageous to convert it into its sodium salt.

The sulphides were converted into substituted thianthrens, $NO_2 \cdot C_6H_3 < \underset{S}{\text{C}} > R$, by treatment with concentrated sulphuric acid (*loc. cit.*), the period of digestion varying from thirty minutes to three hours according to the nature of the sulphide. The crude product obtained on dilution was treated with dilute sodium hydroxide solution, and the undissolved portion washed and dried in a desiccator. It usually contained nitrothianthren monoxide, which was converted into the thianthren by treating the mixture with hydrogen bromide in glacial acetic or formic acid for half an hour at room temperature, and for the same period on a water-bath, and pouring it into cold water; the solid was dried, and crystallised from a suitable solvent.

By treatment in acetic acid solution with zinc dust and concentrated hydrochloric acid, the nitrothianthrens were reduced to the amino-compounds, the hydrochlorides of which were precipitated on diluting the solution with water. The precipitate was dried, and crystallised from alcohol.

The tetroxides were obtained by the method previously described (*loc. cit.*).

The various nitrothianthrens described below develop blue or purple colorations in concentrated sulphuric acid; the solutions of the lower oxides have a redder tinge, and those of the tetroxides are colourless.

The ortho-position of the sulphur atoms in the 3-nitrothianthrens indicated by the method of synthesis is confirmed by the nature of the products obtained when 3-nitro-6-methylthianthren tetroxide is heated with phosphorus pentachloride, 3:4-dichlorotoluene and a substance, which is presumably the disulphonyl chloride, being formed:

This fission is similar to that described by Deuss (*Ber.*, 1908, 41, 2330), who obtained *o*-dichlorobenzene and benzene-*o*-disulphonyl chloride from thianthren tetroxide.

EXPERIMENTAL.

6-Chloro-3-nitrobenzenesulphinic acid has been obtained in 70 per cent. yield by a modification of the method of preparation previously described (*loc. cit.*). A mixture of 50 grams of sodium sulphite ($\text{Na}_2\text{SO}_3 \cdot 9\text{H}_2\text{O}$) and 100 grams of crushed ice is employed in the reaction and subsequently, by the addition of sodium chloride, sodium 6-chloro-3-nitrobenzenesulphinate is precipitated; it crystallises from absolute alcohol in short, lemon-yellow needles, and yields the sulphinic acid on acidification.

4-Nitro-2-sulphino-4'-methylidiphenyl sulphide, obtained from *p*-tolyl mercaptan, crystallised from chloroform in pale yellow needles, m. p. 125° (Found: N = 4.42; S = 21.09. $\text{C}_{13}\text{H}_{11}\text{O}_4\text{NS}_2$ requires N = 4.53; S = 20.78 per cent.).

3-Nitro-6-methylthianthren, $\text{NO}_2 \cdot \text{C}_6\text{H}_3 \begin{smallmatrix} \text{S} \\ < \\ \text{S} \end{smallmatrix} > \text{C}_6\text{H}_3\text{Me}$, crystallised from formic acid or a mixture of ligroin and glacial acetic acid in orange needles, m. p. 159–160°. It develops a bright purple colour with concentrated sulphuric acid and is precipitated unchanged on addition of water (Found: C = 56.83; H = 3.51; S = 23.18. $\text{C}_{13}\text{H}_9\text{O}_2\text{NS}_2$ requires C = 56.72; H = 3.28; S = 23.27 per cent.).

3-Amino-6-methylthianthren hydrochloride crystallised in colourless needles, m. p. 256° (Found: N = 12.45; S = 22.75. $C_{13}H_{12}NClS_2$ requires N = 12.61; S = 22.73 per cent.).

3-Nitro-6-methylthianthren Tetroxide.—A solution of 3-nitro-6-methylthianthren in acetic acid was warmed for five hours at 50–70° with the calculated quantity of potassium permanganate, the reaction having been started by means of a few drops of strong sulphuric acid. The mixture was poured into excess of sulphurous acid, and the cream-white or orange precipitate was washed, dried, and crystallised from acetic acid with the aid of animal charcoal; the tetroxide was obtained in colourless plates, m. p. 256° (Found: N = 4.00; S = 19.01. $C_{13}H_9O_6NS_2$ requires N = 4.14; S = 18.87 per cent.).

Three grams of the tetroxide were heated with 20 grams of finely powdered phosphorus pentachloride in a sealed tube for four hours at 250–280°. The brown oil obtained was poured over crushed ice, the resulting paste shaken with ether, and the semi-solid residue obtained after evaporation of the solvent was drained on porous plate. The absorbed oil was removed with ether and identified as 3:4-dichlorotoluene. The solid residue was presumably nitrobenzene-3:4-disulphonyl chloride, but has not yet been fully characterised. It crystallised in colourless needles, m. p. 125°, from benzene or ether, in which it was extremely soluble (Found: S = 19.62. $C_6H_3O_6NCl_2S_2$ requires S = 20.00 per cent.).

4-Nitro-2-sulphino-4':6'-dimethyldiphenyl sulphide, prepared from *m*-xylyl-4-mercaptan, was isolated as the sodium salt (Found: N = 4.22; S = 19.00. $C_{14}H_{12}O_4NS_2Na$ requires N = 4.05; S = 18.55 per cent.).

3-Nitro-6:8-dimethylthianthren separates from acetic acid, acetone, or alcohol as a yellow, crystalline powder, m. p. 142–144° (Found: C = 58.52; H = 4.21; S = 22.34. $C_{14}H_{11}O_2NS_2$ requires C = 58.13; H = 4.20; S = 22.14 per cent.).

4-Methoxy-*m*-tolyl Mercaptan,* $OMe \cdot C_6H_3Me \cdot SH$.—A mixture of 20 grams of 3-chlorosulphonyl-*p*-tolyl methyl ether (Stewart, T., 1922, 121, 2558) and 50 grams of granulated tin was heated under reflux with 120 c.c. of concentrated hydrochloric acid. When all the tin had dissolved, the mixture was distilled in steam, and the oily distillate frozen. The mercaptan was further purified by pouring its warm alcoholic solution over ice, when it separated in white plates, m. p. 40° (Found: C = 62.00; H = 4.62. C_9H_9OS requires C = 62.33; H = 6.48 per cent.).

4-Nitro-6'-methoxy-2-sulphino-3'-methyldiphenyl sulphide, pre-

* The experimental data were supplied by Mr. D. T. Gibson, to whom the author is indebted.

pared from the above mercaptan, crystallised from benzene in slender, yellow needles, m. p. 130—131° (Found: N = 4.35; S = 19.16. $C_{14}H_{13}O_3NS_2$ requires N = 4.13; S = 18.87 per cent.).

3-Nitro-8-methoxy-5-methylthianthren separated from acetic acid as an orange-yellow, microcrystalline powder, m. p. 189—190° (Found: C = 54.85; H = 3.72; N = 4.21; S = 21.30. $C_{14}H_{11}O_3NS_2$ requires C = 55.08; H = 3.60; N = 4.58; S = 20.98 per cent.).

3-Amino-8-methoxy-5-methylthianthren hydrochloride crystallised from alcohol in needles, m. p. 221°. It can be sublimed at 230°/10 mm. (Found: Cl = 11.54; S = 20.32. $C_{14}H_{11}ONClS_2$ requires Cl = 11.39; S = 20.54 per cent.).

4-Nitro-2-sulphino-5'(or 3')-carboxydiphenyl sulphide, obtained from *m*-thiobenzoic acid (Stewart, T., 1921, 119, 1792), crystallised from glacial acetic acid in yellow plates, m. p. 166—168° (Found: S = 18.84. $C_{13}H_9O_6NS_2$ requires S = 18.87 per cent.).

The ammonium salt crystallised in colourless prisms.

3-Nitrothianthren-7(or 5)-carboxylic acid was obtained from acetic acid as a crystalline powder, m. p. 272—273°. It dissolves in concentrated sulphuric acid, forming a red solution (Found: N = 4.84; S = 21.30. $C_{13}H_7O_4NS_2$ requires N = 4.59; S = 20.97 per cent.).

The hydrochloride of the amino-derivative crystallised from dilute acetic acid in plates, m. p. 239° (Found: Cl = 11.58; S = 20.69. $C_{13}H_{10}O_2NClS_2$ requires Cl = 11.39; S = 20.54 per cent.).

3-Nitrothianthren tetroxide 7(or 5)-carboxylic acid crystallised from dilute acetic acid or alcohol in colourless plates melting above 285° (Found: N = 3.60; S = 17.46. $C_{13}H_7O_8NS_2$ requires N = 3.79; S = 17.34 per cent.).

4'-Chloro-4-nitro-2-sulphinodiphenyl sulphide, obtained from *p*-chlorophenyl mercaptan (Ber., 1881, 14, 1437), crystallised from chloroform in feathery needles, m. p. 115° (Found: Cl = 10.42; S = 19.01. $C_{12}H_8O_4NClS_2$ requires Cl = 10.77; S = 19.42 per cent.).

6-Chloro-3-nitrothianthren crystallised from hot xylene in yellow prisms, m. p. 215° (Found: C = 48.71; H = 2.18; N = 4.92; Cl = 11.98; S = 22.01. $C_{12}H_6O_2NClS_2$ requires C = 48.73; H = 2.03; N = 4.73; Cl = 12.01; S = 21.99 per cent.).

6-Chloro-3-aminothianthren hydrochloride crystallised from hot dilute alcohol in colourless, feathery needles, m. p. 272° (Found: Cl = 23.42; S = 21.51. $C_{12}H_9NCl_2S_2$ requires Cl = 23.51; S = 21.19 per cent.).

6-Chloro-3-nitrothianthren tetroxide crystallised from acetic acid in colourless plates, m. p. 251—253° (Found: Cl = 10.21; S = 18.10. $C_{12}H_6O_6NClS_2$ requires Cl = 9.88; S = 17.80 per cent.).

2:5-Dichlorophenyl mercaptan was prepared by reducing 20 grams of 2:5-dichlorobenzenesulphonyl chloride (Stewart, *loc. cit.*) with tin (50 grams) and hydrochloric acid (100 c.c.) as in the case of 3-chlorosulphonyl-*p*-tolyl methyl ether (*vide supra*). The solid obtained after the distillation with steam crystallised from alcohol in needles, m. p. 28° (Found: Cl = 39.73; S = 18.10. Calc., Cl = 39.66; S = 17.91 per cent.). On oxidation with ferric chloride, it gave the corresponding disulphide, which was identified by the melting point of its mixture with a specimen obtained from another source.

3':6'-Dichloro-4-nitro-2-sulphinodiphenyl sulphide was isolated as the sodium salt, which crystallised on cooling its boiling alkaline solution; on recrystallisation from water, it formed orange plates (Found: Cl = 18.00; S = 16.63. $C_{12}H_6O_4NCl_2S_2Na$ requires Cl = 18.39; S = 16.58 per cent.).

5:8-Dichloro-3-nitrothianthren crystallised from acetic acid in small, orange prisms, m. p. 220° (Found: C = 43.31; H = 1.83; N = 4.52; Cl = 21.44; S = 19.72. $C_{12}H_3O_2NCl_2S_2$ requires C = 43.63; H = 1.51; N = 4.24; Cl = 21.51; S = 19.42 per cent.).

The tetroxide, prepared by oxidising 5:8-dichloro-3-nitrothianthren in boiling acetic acid with fuming nitric acid, crystallised from acetic acid in plates, m. p. 251–253° (Found: Cl = 17.88; S = 16.52. $C_{12}H_3O_6NCl_2S_2$ requires Cl = 18.02; S = 16.24 per cent.).

CCCXXIII.—Substituted Phenyldichloroamines.

By KENNEDY JOSEPH PREVITÉ ORTON and (the late) JOHN EDWIN BAYLISS.

INDICATIONS that anilines yield chloroamines as do aliphatic amines were obtained by Chattaway and Orton (T., 1901, 79, 461), who found that in anhydrous media such a chloroamine as acetylchloroamino-2:4-dichlorobenzene, $C_6H_3Cl_2 \cdot NClAc$, and *s*-trichloroaniline yielded hexachloroazobenzene, and an oily unstable by-product which was probably the chloroamine of the aniline. Further, more definite evidence of the formation of such chloroamines was obtained in the method used by Orton and M. Jones (T., 1912, 101, 1708) in analysing mixtures of anilines and anilides by converting the latter into chloroamines, which were frequently contaminated with phenylchloroamines. Later, Goldschmidt (Ber., 1913, 47, 2728) succeeded in isolating phenyldi-

chloroamine—an oil—and *s*-trichlorophenyldichloroamine—a glassy solid at -80° —by treatment of the anilines with an ethereal solution of hypochlorous acid at very low temperatures.

The great instability of the dichloroamines of substituted anilines seems to depend on the readiness with which they are hydrolysed, but it is questionable whether they exceed in this respect the *s*-trisubstituted phenylchloronitroamines, $C_6H_2X_3 \cdot NCl \cdot NO_2$, which can be prepared in the crystalline state at the ordinary temperature (Orton, T., 1902, **81**, 965). In the reversible equilibrium, $:NCl + H_2O \rightleftharpoons HClO + :NH$, which undoubtedly exists in aqueous solution (Orton and Gray, *Brit. Assoc. Reports*, 1913, 136), where the equilibrium constant, $K = [HClO][:NH]/[:NCl]$, the relative solubilities of the chloroamine and amine will play a very important part, if K is large, or in other words if the concentration of hypochlorous acid has a high value at the state of equilibrium. When the amine has a very low solubility and K is large, on bringing the chloroamine in contact with water, very extensive, or in limiting cases, even complete hydrolysis may result. Conversely, it may not be possible in a given case to attain a sufficiently high concentration of hypochlorous acid in water to convert completely the amine into chloroamine. The relatively high solubility of the nitroamines made possible the isolation of the chloronitroamines by use of dilute hypochlorous acid. Experiments with several *s*-trisubstituted anilines illustrate this aspect. Some dichloroamines can be prepared by treatment of the solution of the aniline in glacial acetic acid with aqueous bleaching powder. Thus the dichloroamines derived from 2:4-dichloro-6-nitro- and 2:6-dichloro-4-nitro-anilines are obtained pure by this method, whilst with others, *s*-trichloroaniline, 2-chloro-4:6-dinitroaniline, *s*-trinitroaniline, the dichloroamine is mixed with unchanged aniline and the corresponding azobenzene, which is possibly formed thus: $2C_6H_2X_3 \cdot NHCl = C_6H_2X_3 \cdot N:N \cdot C_6H_2X_3 + 2HCl$.

A purer product is obtained by shaking the chloroform solution of the aniline with a solution of potassium hypochlorite and potassium hydrogen carbonate, in which hypochlorous acid is at a higher concentration.

The chloroamines from brominated anilines, for example, *s*-tribromoaniline, rapidly decompose at the ordinary temperature with the appearance of bromine. Those derived from substituted toluidines also undergo very rapidly a profound decomposition.

Like all chloroamines, these dichloroamines of the anilines are reconverted quantitatively into the anilines by excess of reducing agents, but azo-compounds also are formed with small proportions of such agents.

2:4-Dichloro-6-nitrophenyldichloroamine and 2:6-Dichloro-4-nitrophenyldichloroamine, $\text{NO}_2 \cdot \text{C}_6\text{H}_2\text{Cl}_2 \cdot \text{NCl}_2$.—To 1 gram of the aniline dissolved in 100 c.c. of glacial acetic acid 150 c.c. of 1·1N. bleaching powder solution were added at intervals. The milky mixture was diluted with 250 c.c. of water and then extracted with chloroform three times (15, 10, and 5 c.c.). The extract was agitated with 100 c.c. of diluted bleaching powder solution and then evaporated at 0° under reduced pressure in a slow current of dust-free, dry pure air. The viscous, yellow oil was nearly pure dichloroamine (Found: for the former, Cl as $\cdot\text{NCl}_2 = 25\cdot4$; for the latter, Cl as $\cdot\text{NCl}_2 = 25\cdot0$. Calc. for $\text{NO}_2 \cdot \text{C}_6\text{H}_2\text{Cl}_2 \cdot \text{NCl}_2$, Cl = $25\cdot7$ per cent.). The product of reduction in both cases was the corresponding pure aniline (melting points 99° and 188°).

The shaking of the chloroform solution with a solution of potassium hypochlorite (ClO^\cdot at a concentration of $0\cdot3$ — $0\cdot4N$) and potassium hydrogen carbonate gave as good results with the above anilines. When the hypochlorite was in large excess, about an hour's shaking sufficed. By the latter method 2-chloro-4:6-dinitroaniline gave a product containing 93 per cent. of the dichloroamine. Owing to the low solubility of the aniline, which was at first mainly suspended in the chloroform, the shaking was much prolonged. The product from *s*-trichloroaniline contained at best about 50 per cent. of dichloroamine.

In dry atmospheres, the oils could be kept for some time without change, but later the colour deepened as decomposition increased.

CCCXXIV.—*The Colour of Monocyclic Substances Calculated by Assigning an Absorption Band to Each Possible Tautomeric Form.*

By JAMES MOIR.

IN the addendum to my paper on the azo-dyes (T., 1922, 121, 1562), I directed attention to the fact that the spectrum of ordinary hydroxyazobenzene shows closely overlapping double bands, and indicated that it is possible to calculate the position of each band *separately* on the assumption that the orbit in the case of the higher band goes from the oxygen to the nearer nitrogen atom [formula of the hydroxylated compound $\text{Ph} \cdot \text{NH} \cdot \text{N}(\text{OH}) \cdot \text{C}_6\text{H}_4 \cdot \text{OH}$], whereas for the lower band the oxygen and the outer nitrogen atom are concerned [$\text{Ph} \cdot \text{N}(\text{OH}) \cdot \text{NH} \cdot \text{C}_6\text{H}_4 \cdot \text{OH}$].

Surprise may be felt that the lower band belongs to the orbit which is apparently the larger of the two; but it may be pointed out that stereochemically both nitrogen atoms are at about the same distance from the other end of the molecule. Cain (T., 1907, 91, 1054) has even depicted the nitrogen atoms as superposed on the benzene ring, with the "outer" nitrogen atom nearer the auxochrome.

Continuing my investigations, I discovered that probably *all* the members of the azo- and azomethine families exhibit this double-banded spectrum; sometimes (as in acid solutions of methyl-red and dimethylaminoazobenzene) both bands are very distinct; sometimes, again, they so overlap that only the faintest luminosity appears in the middle, and the band has the semblance of a single very broad one. In this case, the position of the centres of the two bands can only be guessed at, with a possible error of 10 units.

Again, all the substances change colour if made acid or alkaline, and thus give three kinds of spectrum if the hydrion-concentration of the medium is varied.

Since all the absorption bands are double, each substance is capable of exhibiting six different bands. It is the object of this paper to calculate the position of all the six bands of each substance on the assumption that each of the six represents the orbit of an electron in the "active" part of the molecule, each band thus corresponding to a definite tautomeric formula of the substance.

In the case of *p*-hydroxyazobenzene and of *p*-dimethylaminoazobenzene, the six tautomeric formulæ and the band corresponding to each, respectively, are given in Table I.

TABLE I.

	λ .	Phase.
$\text{PhNH}\cdot\text{N}(\text{OH})\cdot\text{C}_6\text{H}_5\text{O}'$	433	Alkaline
$\text{PhN}(\text{OH})\cdot\text{NH}\cdot\text{C}_6\text{H}_5\text{O}'$	395	(deep yellow).
* $\text{PhN}\cdot\text{N}^+\text{HCl}\cdot\text{C}_6\text{H}_5\cdot\text{OH}$	491	Acid
* $\text{PhN}^+\text{HCl}\cdot\text{N}\cdot\text{C}_6\text{H}_5\cdot\text{OH}$	461	(salmon-orange).
$\text{PhN}\cdot\text{N}\cdot\text{C}_6\text{H}_5\cdot\text{OH}$	about 340	Neutral
$\text{PhNH}\cdot\text{N}\cdot\text{C}_6\text{H}_5\cdot\text{O}$	about 315	(pale yellow).
* $\text{PhN}\cdot\text{N}^+\text{HCl}\cdot\text{C}_6\text{H}_5\cdot\text{N}^+\text{Me}_2\cdot\text{HCl}$	543	Acid
* $\text{PhN}^+\text{HCl}\cdot\text{N}\cdot\text{C}_6\text{H}_5\cdot\text{N}^+\text{Me}_2\cdot\text{HCl}$	508	(rose-pink).
* $\text{PhNH}\cdot\text{N}(\text{OH})\cdot\text{C}_6\text{H}_5\cdot\text{N}^+\text{Me}_2\cdot\text{HCl}$	491	Acidic ($p_H = 6$)
* $\text{PhN}(\text{OH})\cdot\text{NH}\cdot\text{C}_6\text{H}_5\cdot\text{N}^+\text{Me}_2\cdot\text{HCl}$	460	(salmon-orange).
$\text{PhN}\cdot\text{N}\cdot\text{C}_6\text{H}_5\cdot\text{NMe}_2$	about 405	Alkaline
$\text{PhNH}\cdot\text{N}\cdot\text{C}_6\text{H}_5\cdot\text{N}^+\text{Me}_2(\text{OH}) (?)$	about 375	(pale yellow).

* The chlorine in these compounds in solution is, of course, ionised, but its symbol is inserted in the formulæ to preserve the conventional quinquevalency of nitrogen, this element being really quadrivalent when ionised (Lewis-Langmuir theory).

Calculation of the Position of the Six Bands.

A. Hydroxy-compounds.—The phenoxide-ion, $\text{C}_6\text{H}_5\cdot\text{O}'$, which has its band at λ 288 in water, is the parent-substance. If the oximino-

group, $\cdot\text{NOH}$, is interposed, we get $\text{H}\cdot\text{N}(\text{OH})\cdot\text{C}_6\text{H}_4\cdot\text{O}'$, which is the "hydroxylated" formula for (ionised) quinoneimine.

If the anilino-group, PhNH , be next substituted for hydrogen, we get $\text{PhNH}\cdot\text{N}(\text{OH})\cdot\text{C}_6\text{H}_4\cdot\text{O}'$, which is the first of the six formulae for hydroxyazobenzene.

The colour-factor for the α -oximino-interposition is 1.20 (T., 1922, 121, 1555, 1558), and the factor for the anilino-substitution is 1.25.

The calculation is, as before, factorial : quinoneimine (calculated λ) = $288 \times 1.20 = 346$; alkaline (ionised) hydroxyazobenzene (calc. λ) = $346 \times 1.25 = 432$.

To get the second tautomeric variety of hydroxyazobenzene, we proceed as above in the reverse order, namely, $\cdot\text{NH}\cdot$ is first interposed, giving $\text{H}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{O}'$ (ionised *p*-aminophenol); then the phenyloximino-group, $\text{PhN}(\text{OH})$, is substituted for hydrogen, giving $\text{PhN}(\text{OH})\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{O}'$, the required second tautomeride of hydroxyazobenzene.

The colour-factor for imino-interposition is 1.09, and for phenyl-oximino-substitution 1.26. The calculated λ of *p*-aminophenol is thus $288 \times 1.09 = 314$, and that of the second hydroxyazobenzene is $314 \times 1.26 = 396$.

To calculate the third and fourth (the acid) phases, we simply multiply the results already obtained by an "acid ionising factor," the value of which is 1.13 :

Calculated for $\text{PhN}\cdot\text{N}^+\text{HCl}\cdot\text{C}_6\text{H}_4\cdot\text{OH}$, $432 \times 1.13 = 488$.

" " $\text{PhN}^+\text{HCl}\cdot\text{N}\cdot\text{C}_6\text{H}_4\cdot\text{OH}$, $396 \times 1.13 = 447$.

To calculate the position of the remaining two bands (neutral phase) we simply multiply the results of the calculations for the ionised forms by the factor 0.8, giving $432 \times 0.8 (= 345)$ and $396 \times 0.8 (= 316)$. The positions of all six bands are thus calculated.

B. Amino-compounds.—An ionised (alkaline) hydroxy-compound having been thus investigated, it is found that the position of the bands of the corresponding amino-compound can be calculated by multiplying the figures for the alkaline hydroxy-compound by 1.2* when acid ionisation is compared with alkaline ionisation, that is, when NH_3Ac takes the place of O' . Thus acid *p*-aminoazobenzene has the calculated $\lambda = 432 \times 1.2 = 518$ for its highest band. When, however, an acid amino-compound is compared with the *acid* phase of the corresponding hydroxy-compound, the factor is less, being indeed $1.2 \div 1.13$ (the acid ionising factor). Comparing again a neutral (or acidic at $p_H = 6$) solution of an amino-compound with an acid solution of the corresponding hydroxy-

* Provisional value, probably rather too high.

compound, we find the positions of the bands to be nearly the same, the former being the lower and the factor being $1.2 \times 0.8 \div 1.13$.

C. Dimethylamino-compounds.—Similarly, the factor for calculating the position of the bands of the acid phase of these compounds from those of the alkaline phase of the hydroxy-compounds is 1.26 (factor for $\text{NHMe}_2\text{Ac/O'}$). Thus acid dimethylaminoazobenzene has the calculated $\lambda = 432 \times 1.26 = 544$ for its highest band.

When, however, the bands of *acid* phases in *both* substances are compared, the factor becomes $1.26 \div 1.13 = 1.12$. Apparently the factor 1.26 is the square of the "acid ionisation factor" within the limits of experimental error. The practical result is that the neutral solution (acidic at $p_H = 6$) of any dimethylamino-compound of this class shows the same bands as the acid solution of the corresponding hydroxy-compound, and these bands are halfway between those of the acid dimethylamino-compounds and those of the alkaline hydroxy-compound.

The Azomethines.

These are of two kinds, (1) the type $\text{PhN:CH}\cdot\text{C}_6\text{H}_4\text{A}$ and (2) the type $\text{PhCH:N}\cdot\text{C}_6\text{H}_4\text{A}$, in which A is any auxochrome.

The position of the bands of the former are calculated from the hydroxylated formulae $\text{PhCH(OH)}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\text{A}$ and

starting with (a) *p*-aminophenol and a hydroxybenzyl factor and (b) *p*-hydroxylaminophenol (quinoneiminc) and a benzyl factor, whilst those of the latter are calculated by the reverse process, which need not be specified in detail (see T., 1922, 121, 1558), starting with $\cdot\text{CH}_2\cdot$ and $\cdot\text{CH(OH)}\cdot$ interpositions. All agree sufficiently well with observation.

The following table gives all the colour-factors required :

TABLE II.
Monocyclic colour-factors.

Name.	Value.
α -Methylene-interposition, $\cdot\text{CH}_2\cdot$	0.93 *
α -Imino. " , $\cdot\text{NH}\cdot$	1.09 *
α -Carbinol. " , $\cdot\text{CH(OH)}\cdot$	1.017 *
α -Oximino. " , $\cdot\text{N(OH)}\cdot$	1.20 *
β -Benzyl, † PhCH_2	1.135
β -Anilino, PhNH	1.25
β -Phenylcarbinol (hydroxybenzyl), $\text{Ph}\cdot\text{CH(OH)}$	1.17
β -Phenyloximino, $\text{Ph}\cdot\text{N(OH)}$	1.26
α -Phenyl-substitution	1.135

* Practically the same as before (T., 1922, 121, 1555, 1558).

† The groups of the β -factors are substituents of the α -positions; their phenyl group is a substituent in the β -position from the ring.

We now proceed to calculate the position of the band in all the simple hydroxy-compounds. The simpler ones of course, not being azo- or azomethine compounds, have only one band.

TABLE III.

Calculation of the position of the bands of simple hydroxy-compounds.

Name.	Basis of calculation.	Result (A).
Quinol (ionised)	<i>p</i> -Hydroxybenzyl alcohol minus α -CH ₂	316
<i>p</i> -Hydroxybenzaldehyde	Quinol $\times \alpha$ -CH(OH)	321*
<i>p</i> -Hydroxybenzophenone	Foregoing $\times \alpha$ -Ph	364
<i>p</i> -Hydroxybenzyl alcohol	Phenoxide $\times \alpha$ -CH(OH)	293
<i>p</i> -Hydroxybenzhydrol	Foregoing $\times \alpha$ -Ph	332
Fuchsone	Foregoing again $\times \alpha$ -Ph	378
Quinoneanil	Quinoneimine $\times \alpha$ -Ph	390
<i>p</i> -Hydroxydiphenylamine	Aminophenol $\times \alpha$ -Ph	356

<i>p</i> -Hydroxybenzylideneaniline	Phenoxide $\times \alpha$ -CH(OH) $\times \beta$ -PhNH	366 (upper)
"	" $\times \alpha$ -CH ₂ $\times \beta$ -PhN-OH	338 (lower)
<i>p</i> -Benzylideneaminophenol	" $\times \alpha$ -NOH $\times \beta$ -PhCH ₂	393
"	" $\times \alpha$ -NH $\times \beta$ -PhCH(OH)	367
<i>p</i> -Hydroxystilbene	" $\times \alpha$ -CH(OH) $\times \beta$ -PhCH ₂	333
"	" $\times \alpha$ -CH ₂ $\times \beta$ -PhCH(OH)	314

* This value differs from the observed value (Table V) by 9 units.

It is to be noted that where the parent substance in the "basis of calculation" is not phenoxide, the position of its band can yet be derived immediately from that of the phenoxide-ion by use of the same set of colour-factors.

The positions of the bands of the monocyclic phthaleins also may be calculated from the foregoing results, by using the $C_6H_4 \cdot CO_2H / C_6H_5$ factor previously published.

All the possible hydroxy-compounds have thus been considered, excepting two, the absorption spectra of which have not been observed, namely, *p*-hydroxystilbene oxide (calc. λ 343) and *p*-hydroxyazoxybenzene (calc. λ 436), corresponding to the hydroxylated formulæ $Ph \cdot CH(OH) \cdot CH(OH) \cdot C_6H_4 \cdot OH$ and $Ph \cdot N(OH) \cdot N(OH) \cdot C_6H_4 \cdot OH$.

Amino- and Dimethylamino-compounds.

Table IV contains the calculated values of the position of the bands in the remaining amino- and dimethylamino-compounds, namely, those not already calculated under sections B and C.

The positions of the bands of most of the simpler members of the series are also calculable from the results for the hydroxy-compounds (Table III), but the method of calculation does not hold for the very simplest leuco-compounds. Thus the ratio of

the numbers for the bands of dimethyltoluidine and of the tolyloxide-ion is only 1.05 instead of 1.26. Perhaps agreement should not be expected when one of the groups on the ring is merely unoxidised methyl.

Observations.

All these calculated results may be compared with the following tables of observed values, almost all of which have been obtained from photographs, taken with a grating instrument of low dispersion (so as to get narrow bands). Nearly all the work of the pioneers in colour chemistry has been repeated, *water* having been used as the solvent, so that all observations should be comparable with the highly-ionised solutions of the dyes previously investigated.

Polymeric <i>p</i> -aminobenzaldehyde	415

* Another band visible at λ 320 probably belongs to the non-ionised substance.

† All the published spectroscopic work on azomethines (Hewitt and Pope, etc.) is useless for the present purpose because solutions were employed which were much too concentrated, and only one edge of the band was observed.

The absorption bands of phenolic substances were observed in presence of sufficient sodium hydroxide to give a fairly high ionisation, and amino-compounds in presence of 10 per cent. acetic acid; mineral acid should not be used, since fully ionised amino-compounds are rendered inactive and then display a spectrum similar to that of benzene (see Hartley's and Baly's work).

Apparent Exceptions.

Some substances, such as nitrosophenol, form apparent exceptions to the laws given above, inasmuch as they are unaffected in colour by a gross change of hydron concentration from strongly acid to strongly alkaline so long as the substance remains ionised either

as an alkaline or an acid ion. These substances, which contain either no nitrogen at all, or nitrogen incapable of assuming its higher valency, have only two (not six) bands, one of which belongs to the ionised, and the other to the non-ionised, condition. It is important to note that the ion of these substances has its band in the same position whether it is acid or alkaline. Thus *p*-hydroxybenzaldehyde exhibits a band at λ 330 when examined either in sodium hydroxide solution (ion $\text{CHO}\cdot\text{C}_6\text{H}_4\cdot\text{O}^-$), or in concentrated hydrochloric acid (ion $\text{CHO}\cdot\text{C}_6\text{H}_4\cdot\text{O}^+\text{H}_2^+$); whereas free (non-ionised) *p*-hydroxybenzaldehyde has its band at λ 285. Table VI gives examples of these substances.

* About λ 350 in water.

† Close to that of benzene α .

† Also another at about λ 730 in the red.

The substances of the nitrosophenol type show another abnormality, namely, that the factor to be used in calculating the positions of the bands of amino- or dimethylamino-compounds from those of hydroxy-compounds is only 1.13 instead of 1.26, taking the latter case. The normal factor 1.26 is approximately the square of 1.13, and apparently it comes into play only when nitrogen in the linking as well as the nitrogen in the dimethylamino-group assumes its higher valency. Examples are dimethylaminostilbene and dimethylaminobenzaldehyde.

Summary and Conclusions.

Such a substance as sodium phenoxide, consisting of a nucleus and an auxochrome, has not a strong absorption visible in great dilution (say $N/40000$), as the true colouring matters have. Technically, it is a *coloured substance* with a shallow absorption band in the ultra-violet. Its pentabromo-substitution product is faintly yellow, the "loading" having raised the absorption band from λ 288 to about λ 350 (author's observation), but the absorption band is not strong.

If a second group be substituted for hydrogen of the nucleus, such compounds as $\text{CH}_3\cdot\text{C}_6\text{H}_4\cdot\text{O}'$, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{O}'$, and $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{O}'$ will be obtained. These still remain "coloured substances," not "colouring matters." Such leuco-compounds have only shallow absorption.

p-Hydroxybenzaldehyde is the type of the simplest true *colouring matter*, giving a strong sharp absorption band even in high dilution. In order that a substance may be a colouring matter, therefore, it must contain a ring, an auxochrome, and a second substituent, and the whole must be oxidised. The formula $\text{HO}\cdot\text{C}_6\text{H}_4\cdot\text{CHO}$ refers to solid neutral hydroxybenzaldehyde, but the ion in the aqueous alkaline solution may be represented by $\text{O}'\cdot\text{C}_6\text{H}_4\cdot\text{CHO}$, $\text{O}'\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{O}'$, $\text{O}\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{O}'$, or half-a-dozen other formulae involv-

ing the valencies of the ring itself. This is the modern form of the Hewitt-Watson and Meek hypothesis.

Apparently the relation of the second substituent to the auxochrome may be either ortho, meta, or para, but the bands of meta-compounds appear to be slightly less pronounced.

The cause of colour (visible or invisible) is the existence of *two* positive points on the molecule with only one loose electron, which therefore, when set in motion by light, describes an orbit round the two positive points. Apparently no other factor is necessary. The old terms "chromophore" and "chromogen" are thus super-

sed. They connoted *two* elements and a double bond joining them, both of which are unnecessary. Only one element (and no double bond) is required besides the auxochrome. These views are merely a modernised version of those of Hartley promulgated between 1882 and 1886.

I propose the new term *hapton* for the second substituent which, when introduced into the molecule of phenol, aniline, and similar compounds consisting of nucleus and auxochrome alone, greatly intensifies the absorption band of such substances. The word hapton is intended to be a generic term for any group derived from the elements C, N, O, and S. The term "auxochrome" means either OH or NH₂ or NHAik or NAlk₂, but no other group derived from C, N, O, or S.

Some distinction between hapton and auxochrome is necessary, since, for example, the colour of benzoquinoneimine is not halfway between those of benzoquinone and benzoquinonedi-imine. The hapton is either non-ionisable or difficultly ionisable, whereas the auxochrome is easily ionisable. Examples of haptons are: -CH₂-OH, -CHO, -NH-OH, -NO, -NO₂, -O(OH), -S(OH), and sometimes apparently CO₂H and SO₃H in spite of their high ionisation.

In the case of a "coloured substance" as defined above, the requirements are even less than in that of a "colouring matter." Apparently the ring itself may be dispensed with, if a structure stereochemically obstructive to the moving electron is present, for example, (CH₃)₃C:N:O, in which I suggest that the electron goes from N to O round the molecule. These substances with shallow bands are, however, on a par with benzene and therefore are very different quantitatively from the colouring matters, although qualitatively the supposition of two positive centres and one loosely-held electron explains nearly all cases of absorption.

The matter may be extended, as has been done by other workers, to complex cases. The numerous bands of penta- and hexahydroxyanthraquinone probably each correspond to a calculable tautomeric form, and even the bands in solutions of the MnO₄'-ion could be explained by an asymmetric arrangement of the five atoms.

It thus appears that colour may become a very important quantitative instrument for the elucidation of problems of chemical constitution.

* I have to thank Professor G. T. Morgan and Mr. H. G. Reeves for this specimen (T., 1922, 121, 5).

Further Note on the Calculation of Dicyclic Azo- and Phenazine Derivatives.—If we assume that the NH colour-factor remains unchanged at 0.78, but that the NOH colour-factor has two values corresponding to the two valency-angles of 133° and 120° (the values being 0.47 and 0.43), we get for dihydroxyphenazine the calculated values $\lambda\lambda$ 506 and 462 [$1380 \times 0.78 \times (0.47 \text{ or } 0.43)$], practically the same as for dihydroxyazobenzene. Similarly, diaminophenazine and azoaniline have almost identical bands. Also applying these data to methylene-blue, we get the calculated $\lambda\lambda = 1380 \times (1.059)^2 \times 0.92 \times (0.47 \text{ or } 0.43) = 668$ and 611. This is a partial physical explanation of the occurrence of two bands and of two sets of colour-factors in the azo- and azine series.

CCCXXV.—*The Cyanine Dyes. Part VII. A New Method of Formation of the Carbocyanines. The Constitution of the Thioisocyanines and of Kryptocyanine.*

By WILLIAM HOBSON MILLS and WALTER THEODORE KARL BRAUNHOLTZ.

We have shown in a recent communication (T., 1922, **121**, 2004) that when a mixture of quinoline ethiodide (I) and 1-methylbenzothiazole ethiodide (II) is treated with alkali, a dye, containing one quinoline and one benzothiazole nucleus, corresponding in composition with the isocyanines is produced.

In this reaction, we regarded the 1-methylbenzothiazole ethiodide as playing the same part as the quinaldine ethiodide in the isocyanine condensation on account of the close correspondence in chemical character between the two salts conditioned by the similarly reactive methyl group which each contains. We accordingly concluded that quinoline ethiodide also reacted in the same way in both condensations and that therefore, in this mixed dye, the quinoline nucleus was attached to the rest of the molecule through the 4-position as it is in the isocyanines (Mills and Wishart, T., 1920, **117**, 597).

We thus assigned to the mixed dye the constitution III and proposed for the compounds of this series the name thioisocyanine.

It is shown in the present communication that this view is correct. If the dye has the constitution (III), then it should also be formed by a cyanine condensation between lepidine ethiodide (IV) and benzothiazole ethiodide (V). This, however, cannot be effected in the ordinary way by the action of alkali on the mixed alkyl-iodides. For in the isocyanine condensation, only the alkyl-iodide of quinaldine, and not that of quinoline, can be replaced by the

corresponding benzothiazole derivative, evidently on account of the peculiar behaviour of the benzothiazolonium base, which, as shown by Mills, Clark, and Aeschlimann (this vol., p. 2353), is converted by alkalis into the comparatively non-reactive metallic salts of *o*-formylethylaminophenyl mercaptan. An observation made some time previously indicated, however, a method by which the required condensation might be brought about.

One of us and Mr. E. J. Amies found that when 1-methylbenzothiazole ethiodide is heated with di-*o*-formylethylaminodiphenyl disulphide, $S_2(C_6H_4 \cdot NEt \cdot CHO)_2$ (Mills, Clark, and Aeschlimann, *loc. cit.*), in pyridine solution a mixture of diethylthiocyanine iodide (VI) and diethylcarbothiocyanine iodide (VII) is formed (compare Mills, T., 1922, 121, 455). Under these conditions, therefore, reactions of two distinct types take place between the disulphide and the 1-methylbenzothiazole alkylidide. On the one hand, the disulphide supplies the residue $C_6H_4 \langle \begin{smallmatrix} S \\ \diagup \diagdown \\ NEt \end{smallmatrix} \rangle C:$ which condenses with 1 mol. of the 1-methylbenzothiazole quaternary salt to give the thiocyanine VI (reaction of type I).

On the other hand, it provides a methenyl residue which condenses with 2 mols. of the quaternary salt to form the carbothiocyanine VII (reaction of type II).

Clearly the power of the 1-methylbenzothiazole alkylidide of reacting in each of these two ways is determined by the presence of the reactive 1-methyl group. It seemed probable, therefore, that the quaternary salts of quinaldine and lepidine, containing a similarly reactive group, would react with the disulphide in a corresponding manner. This expectation proved to be correct. Quinaldine ethonitrate was heated with the disulphide in pyridine solution and two dyes were produced. One of these was pinacyanole (IX). The other was an orange-brown compound which, from its composition and method of formation, could only have the structure VIII, and therefore was formed by a reaction of type I. It is a member of a new series of cyanine dyes for which

the name *thiopseudocyanine* is proposed. The pinacyanole was formed evidently by a reaction of type II.

The formation of pinacyanole in this manner very clearly demonstrates the analogy in constitution between the carbocyanines and the carbothiocyanines.

The corresponding reaction was then carried out with lepidine ethionitrate. In this case also, an orange-red and a blue dye were produced. The red dye was a mixed dye formed by a reaction of type I. The corresponding iodide was identical with the diethylthioisocyanine iodide previously obtained by the action of alkali on a mixture of quinoline ethiodide and 1-methylbenzothiazole ethiodide. The constitution (III) of the thioisocyanine (apart from the question of the linking of the acid radicle in this presumably virtually tautomeric monacid salt of a diacidic base) was thus established.

The other dye formed beautiful, pleochroic prisms, with a double green and golden lustre. Analysis showed it to be an isomeride of pinacyanole. The tint of the blue alcoholic solution was of a greener shade than that of pinacyanole. The compound proved to be a powerful photographic sensitiser, the band of extra sensi-

tisation lying considerably farther to the red than that due to pinacyanole.

There is thus an exact correspondence between the reactions which occur when quinaldine ethonitrate and when lepidine ethonitrate are heated with the disulphide and pyridine. In each case two dyes are formed which are respectively not only isomeric but show the closest correspondence in general characters.

The compounds obtained from quinaldine ethonitrate are quinoline derivatives in which the quinoline nuclei are linked through the 2-position. They owe their formation, therefore, to the reactive 2-methyl group in the quaternary salt. The isomeric compounds obtained from lepidine ethonitrate under the same conditions must be produced through the analogous reactivity of its 4-methyl group and therefore are the corresponding 4-derivatives of quinoline.

The orange dye, having, as has been shown, the constitution III, is formed by a reaction of type I. The blue dye is formed by a reaction of type II and must be related to lepidine in the same way as its isomeride pinacyanole is to quinaldine. It is therefore the 4:4'-carbocyanine of the constitution X.

Adams and Haller (*J. Amer. Chem. Soc.*, 1920, **42**, 2661) have described the preparation from lepidine ethiodide of a greenish-blue dye which they named "kryptocyanine." Since the method of preparation which they used—the action of alkali and formaldehyde, or chloroform, on the hot alcoholic solution of the salt—corresponds with that usually employed for preparing pinacyanole from quinaldine ethiodide, kryptocyanine would be expected to be analogous in constitution to pinacyanole and thus identical with 1:1'-diethyl-4:4'-carbocyanine iodide. Adams and Haller give no analyses of "kryptocyanine" and suggest tentatively the formula XI, but the characteristic optical and photosensitising properties which they describe leave no doubt that the product contained the 4:4'-carbocyanine as its essential constituent. It would appear that the dye is not readily obtained pure by means of alkali and formaldehyde, for Adams and Haller describe it as a purplish-black, crystalline powder. By recrystallisation from chloroform, Mees and Gutekunst (*Brit. J. Phot.*, 1922, **69**, 474) obtained it as small, bronze crystals. They give no analyses, but they state that even after repeated recrystallisation it still produced fogging of the plate when used at a dilution of 1 in 75,000, whereas the pure dye prepared with the disulphide and pyridine gives clean working plates at this dilution.

The power of reacting simultaneously with di-*o*-formylmethylaminodiphenyl disulphide, or its diethyl analogue in the two ways which have been referred to as reactions of type I and type II

seems to be a very general property of the quaternary salts of heterocyclic bases containing a reactive methyl group. In connexion with our experiments on the reactivity of methyl groups in heterocyclic bases (T., 1922, 121, 2724) the interaction of the dimethyl disulphide with 2-methyl-4-phenylthiazole methiodide (XII) and pyridine was examined by one of us and Dr. J. L. B. Smith. It was found that both the cyanine (XIII), produced by

a reaction of type I, and the carbocyanine (XIV), produced by a reaction of type II, were formed. These substances resemble in properties the compounds similarly obtained from the quaternary salts of quinaldine and lepidine, but are less deeply coloured.

We were exceedingly interested to find that there is formed in these condensations, besides the two dyes of cyanine and carbocyanine type, the spirocyclic compound bis-2-ethylbenzothiazoline-1:1-spiran (XV) described by Mills, Clark, and Aeschlimann (*loc. cit.*).

The molecular formula of this compound, $\text{C}_{17}\text{H}_{18}\text{N}_2\text{S}_2$, differs from that of the corresponding disulphide, $\text{C}_{18}\text{H}_{20}\text{O}_2\text{N}_2\text{S}_2$, by the elements of formic acid, CH_2O_2 , and the formyl group is actually eliminated in the transformation, for when the disulphide is heated with phenylhydrazine the spirocyclic compound and formylphenylhydrazine are produced. There can therefore be little doubt that the formation of, for example, pinacyanole by the method described in this paper is to be represented as follows,

the hydrogen iodide being fixed by the pyridine.

The source of the central methenyl group in the carbocyanines (printed in clarendon type in formulæ VII, IX, and X) would thus be one of the formyl groups of the disulphide.

EXPERIMENTAL.

The following condensations of di-*o*-formylethylaminodiphenyl disulphide and pyridine with quaternary salts of heterocyclic bases containing a reactive methyl group were investigated.

(1) *Condensation with 1-Methylbenzothiazole Ethiodide*.—The ethiodide (2.7 grams) and the disulphide (1.6 grams) were dissolved in pyridine (10 c.c.) and the solution was boiled for four hours. The changes observed agreed closely with those seen when a mixture of this ethiodide and benzothiazole ethiodide are similarly heated in pyridine solution, and a similar crystalline mass consisting of a mixture of the carbothiocyanine and the thiocyanine was obtained. These were separated by the method previously described (T., 1922, 121, 461) and 0.45 gram of each compound was isolated.

(2) *Condensation with 1:5-Dimethylbenzothiazole Ethiodide*.—The solution of the ethiodide (8.5 grams) and the disulphide (4.4 grams) in pyridine (50 c.c.) was heated for nine hours at 100°. The crystalline material which separated from the cold solution, together with that obtained by pouring the filtrate into an aqueous solution of potassium iodide and washing the precipitate with ether, was extracted with boiling chloroform. 5-Methyl-2:2'-diethylthiocyanine iodide remained undissolved and 5:5'-dimethyl-2:2'-diethylcarbothiocyanine was isolated from the chloroform solution as previously described (*loc. cit.*, p. 463) (Found: C = 53.0; H = 4.8; I = 24.12. $C_{23}H_{25}N_2IS_2$ requires C = 53.1; H = 4.8; I = 24.4 per cent.).

(3) *Condensation with Quinaldine Ethonitrate*.—Quinaldine ethonitrate, which was used on account of its ready solubility in pyridine, was obtained by adding to an aqueous solution of the ethiodide an equivalent quantity of an aqueous solution of silver nitrate, removing the precipitated silver iodide, and evaporating the clear filtrate to dryness under diminished pressure.

A solution of the ethonitrate (3.5 grams) and the disulphide (2.8 grams) in pyridine (30 c.c.) was heated at 100° for seven hours. A blue colour rapidly developed and the solution, after cooling, deposited a crystalline solid. This was collected after twenty hours and extracted with a little cold alcohol, which dissolved the thiopseudocyanine, leaving the carbo-cyanine for the most part undissolved. A fairly sharp separation of the two dyes was obtained in this way and by adding to the alcoholic solution of each a concentrated aqueous solution of potassium iodide the corresponding iodide was precipitated and could be obtained pure by crystallisation from methyl alcohol.

1':2-Diethylthiopseudocyanine iodide forms orange-brown needles

showing a faint blue lustre, melting and decomposing at 285° , and containing no water or methyl alcohol of crystallisation (Found: C = 55.05; H = 4.61; I = 27.77. $C_{31}H_{21}N_2SI$ requires C = 54.78; H = 4.57; I = 27.61 per cent.).

This *thiopseudocyanine* possesses marked photosensitising properties, its spectrograph being somewhat reminiscent of that of erythrosine. The extra-sensitisation extends, for moderate exposures, as far as about λ 5500, and has a well-defined maximum at λ 5280. The absorption spectrum shows two overlapping bands with maxima at λ 4930 and 4610 respectively, the former being the more intense. The yellowish-brown colour of the dilute aqueous alcoholic solution of the dye is discharged by the addition of mineral acid.

1:1'-Diethylcarbocyanine Iodide.—The ethiodide obtained from the less soluble nitrate was identified as diethylcarbocyanine iodide (pinacyanole) by the following characteristics. It formed small, lustrous, dark green crystals melting and decomposing at 286 – 287° and not depressing the melting point of the carbocyanine prepared in the usual way. It gave the characteristic absorption spectrum of pinacyanole. Dried at $100^{\circ}/12$ mm., the crystals lost 6.25 per cent. $C_{25}H_{25}N_2I \cdot CH_3 \cdot OH$ requires $CH_3 \cdot OH$ = 6.25 per cent. (Found: I = 26.48. $C_{25}H_{25}N_2I$ requires I = 26.46 per cent.).

(4) *Condensation with Lepidine Ethonitrate.*—A solution of the disulphide (7.1 grams) and lepidine ethonitrate (8.6 grams), prepared from the iodide similarly to quinaldine ethonitrate, in pyridine (40 c.c.) was heated for seven hours at 100° . A deep purplish-blue colour developed and a crystalline solid was deposited. After keeping for forty hours, the red solid was collected and washed with a little cold pyridine and ether (weight 3.4 grams). The deep blue filtrate was poured into an aqueous solution of potassium iodide, when a green solid was precipitated. This was collected, dried, extracted several times with hot benzene, and finally crystallised from methyl alcohol, from which it was obtained as lustrous, golden plates (yield 1.3 grams).

1':2-Diethylthioisocyanine Iodide.—The solid which separated from the original reaction mixture was a quaternary nitrate. It was converted by potassium iodide into the corresponding iodide, which, crystallised from methyl alcohol, formed bright red needles and was identical with the diethylthioisocyanine iodide formed by the condensation of quinoline ethiodide with 1-methylbenzothiazole ethiodide (*loc. cit.*, p. 2006). It melted and decomposed at 293° and did not depress the melting point of the previously obtained diethylthioisocyanine iodide (Found: C = 54.78; H = 4.56; I = 27.71. Calc., C = 54.78; H = 4.57; I = 27.61 per cent.).

1: 1'-Diethyl-4: 4'-carbocyanine Iodide (*Kryptocyanine*).—The blue dye obtained from the pyridine filtrate, when recrystallised from methyl alcohol, formed prisms showing a golden lustre on some faces and a green lustre on others.* Dried at 100°/12 mm., it lost solvent of crystallisation and changed into a green powder. The pure dye melted at 253–254° (Found: C = 62.45; H = 5.23; I = 26.55. $C_{25}H_{25}N_2I$ requires C = 62.50; H = 5.21; I = 26.46 per cent.).

The absorption spectrum was examined visually by means of a Hilger spectrophotometer, and was found to show a very strong double absorption band with maxima at λ 6900 and 6930 and a weaker band with a maximum at about λ 6400. The spectrograph obtained on a gelatino-bromide plate bathed with the dye is remarkable. The strong extra-sensitisation is almost completely confined, for moderate exposures, within the limits λ 6500–7900, rising gradually from either side to a well-marked maximum at about λ 7430. Addition of ammonia to the dye-bath enhances the extra-sensitisation, but the plate then shows some tendency to fog.

For comparison, a specimen of kryptocyanine was prepared as described by Adams and Haller (*loc. cit.*). The product was not homogeneous and could not readily be purified. The absorption and the sensitisation spectra of the dye were essentially the same as those of diethyl-4: 4'-carbocyanine iodide, although the impurities present caused considerable fogging of the plate.

Bis-2-ethylbenzothiazoline-1: 1-spiran.—The benzene washings of the crude 4: 4'-carbocyanine gave on evaporation a colourless, crystalline solid (1–1.5 grams) which after recrystallisation from alcohol melted at 134–135° and was found to be identical with the spirocyclic compound obtained by the action of phenylhydrazine on diformylethylaminodiphenyl disulphide.

(5) *Condensation with 6-Ethoxylepidine Ethonitrate*.—6-Ethoxylepidine was converted into its ethiodide by heating for sixteen hours at 100° with the equivalent quantity of ethyl iodide (yellow prisms, m. p. 187°. Found: I = 37.05. $C_{14}H_{18}ONI$ requires I = 37.02 per cent.). The nitrate was prepared from this in the same way as the quaternary nitrates previously used.

6-Ethoxylepidine ethonitrate (4.3 grams) and the disulphide (4.0 grams) were heated together in pyridine solution (20 c.c.) for seven hours at 100°. The resulting deep purplish-red solution was kept for forty hours and the colourless, crystalline solid which had separated was collected (0.7 gram). This melted at 134–135° and was identified as bis-2-ethylbenzothiazoline-1: 1-spiran.

* A specimen showing a third crystalline habit was obtained from methyl alcohol. It resembled brass shavings.

6'-Ethoxy-1':2-diethylthioisocyanine Iodide.—The pyridine filtrate was poured into an aqueous solution of potassium iodide and a red solid (3 grams) was precipitated. This was a mixture of a further quantity of the spiran and the thioisocyanine. The former was removed by extraction with benzene and the dye crystallised from methyl alcohol. A mixture of bright red needles and short dark red, lustrous prisms was obtained. Both forms melted and decomposed at 262° and were identical with thioisocyanine previously prepared (*loc. cit.*) from 6-ethoxyquinoline ethiodide and 1-methylbenzothiazole ethiodide (Found: I = 25.53. Calc., I = 25.20 per cent.). The corresponding 4:4'-carbocyanine could not be isolated, and had evidently been produced in very small quantity. Its presence could, however, be inferred from the deep blue colour of the aqueous pyridine filtrate after removal of the precipitated thioisocyanine.

(6) *Condensation with 2-Picoline Ethonitrate.*—A solution of the ethonitrate (5 grams) and the disulphide (5 grams) in pyridine (30 c.c.) was heated for seven hours at 100°. The resulting deep red solution was poured into an aqueous solution of potassium iodide, and the precipitate thus obtained was extracted with hot benzene to remove a considerable quantity of unchanged disulphide and of the spirocyclic base which had been produced. The residue (0.3–0.4 gram) thus obtained consisted of the mixed cyanine dye.

1':2-Diethylthiopseudopyridocyanine Iodide,

—This residue, crystallised from methyl alcohol, gave the pure dye as golden-yellow needles, m. p. 265° (decomp.) (Found: C = 49.92; H = 4.83; I = 30.83. $\text{C}_{17}\text{H}_{19}\text{N}_2\text{I}$ requires C = 49.76; H = 4.63; I = 30.97 per cent.). The absorption spectrum of the dye shows two rather ill-defined bands in the blue between λ 4000 and 4600. The deep red aqueous pyridine filtrate showed a weak absorption band at about λ 6000, presumably due to the pyridocarbocyanine, which appears to be an easily soluble compound, and formed only in very small quantity.

(7) *Condensation of 4-Phenyl-2-methylthiazole Methiodide with Di-o-formylmethylaminodiphenyl Disulphide* [with J. L. B. SMITH].—A solution of the methiodide (8.5 grams) and the disulphide (4.5 grams) in pyridine (50 grams) was heated for ten hours at 100°. The solution rapidly developed a deep purple colour and, on cooling, a crystalline precipitate was deposited.

4-Phenyl-2-methylbenzothiazolenzylmethylthiazole Methiodide.—The above precipitate, twice recrystallised from methyl alcohol, gave the pure dye as pale yellow needles, m. p. 270° (decomp.) (Found:

$l = 27.53$; $S = 13.92$. $C_{19}H_{17}N_2IS_2$ requires $I = 27.37$; $S = 13.79$ per cent.).

4:4'-Diphenyl-3:3'-dimethylthiazolocarbocyanine Iodide.—The pyridine filtrate from the mixed cyanine dye was poured into an aqueous solution of potassium iodide. A tarry precipitate was formed which, extracted with ether and benzene, left a red powder. This, twice recrystallised from methyl alcohol, gave the carbocyanine as red needles with a brassy lustre, m. p. 244° (decomp.) (Found: $I = 24.20$; $S = 12.40$. $C_{23}H_{21}N_2IS_2$ requires $I = 24.58$; $S = 12.43$ per cent.).

One of us (W. T. K. B.) is indebted to the Department of Scientific and Industrial Research for a grant for which he desires to express his thanks.

CCCXXVI.—*The Solubility of the Phenylenediamines and of their Monoacetyl Derivatives.*

By NEVIL VINCENT SIDGWICK and JAMES ACHESON NEILL.

THE boiling points of the phenylenediamines (ortho 252° , meta 287° , para 267°) not only differ widely, but are in an unusual order, the para-compound coming between the other two, and much nearer to the ortho. This peculiarity, which is found also among other amino-derivatives, but nowhere else (Sidgwick, T., 1920, 117, 395), led us to measure the solubility of these substances, and of their acetyl derivatives, in water and benzene.

Preparation of Materials.

o-Phenylenediamine. Made by the reduction of *o*-nitroaniline with cast-iron turnings and 2 per cent. calcium chloride solution, a method suggested to us by Prof. T. S. Moore, to whom we wish to express our thanks. The hydrochloride was recrystallised from water, and the free base twice recrystallised from chloroform in the absence of air; m. p. 103.8° . The meta-diamine was twice recrystallised from alcohol; m. p. 62.8° . The para-diamine was made by the reduction of *p*-nitroaniline or better of *p*-nitroacetanilide with iron and calcium chloride. The hydrochloride was recrystallised from water, and the free base twice from alcohol; m. p. 139.7° .

Monoacetyl-diamines. Ortho: twice recrystallised from water; m. p. 144.8° . Meta: made by the action of acetic acid on the

diamine (Wallach and Schulze, *Ber.*, 1882, 15, 3020); twice recrystallised from water; m. p. 279°. Para: by the reduction of *p*-nitroacetanilide with iron and acetic acid (Nietzki, *Ber.*, 1884, 17, 343) or calcium chloride (Moore). The brown product was boiled with animal charcoal and twice recrystallised from water. Colourless; m. p. 160.5°.

Dotted lines: in benzene.

Determination of Solubility.

This was measured synthetically in corked or sealed bulbs, the point being observed at which the liquid became cloudy on cooling, or, when the solid phase was present, at which the last crystals disappeared on slow warming.

m-Phenylenediamine was found to be dimorphic. The two forms are enantiotropic, with a transition point at 36°; this was determined from the solubility curves, and also by special experiments with a dilatometer. The α -form (stable above 36°) consists of brown needles, the β - (stable below 36°) of mauve plates. The colour is no doubt due to traces of decomposition products, but the difference is easily recognised. The α -form appears to be the usual one at the ordinary temperature; the first point obtained

with a tube lay always on the α -curve; but if the tube was frozen with ice and salt, and the solubility redetermined, it gave a point on the β - (stable) curve.

Measurements with the *o*- and *p*-diamines at temperatures above 80° were difficult on account of the darkening of the liquid, which was not wholly prevented by filling the tubes with hydrogen. No such difficulty occurred with the acetyl derivatives, for which very

high temperatures could be reached by the use of specially thick sealed bulbs, the observer being protected by a plate-glass screen.

The results are given in Tables I and II, and plotted on Figs. 1 and 2, the concentrations being expressed in grams of amine to 100 grams of solution. Two-liquid points are marked L, and metastable points with an asterisk.

The nominal heats of solution, given in Table III, are calculated by means of the usual formula $Q = \log \frac{S}{S_1} \cdot \frac{RT_1 T}{T - T_1}$. Since none of these compounds forms two liquid layers with water, the heats of solution were calculated for the water curves as well as for those in benzene. The values obtained for water are not comparable with those in benzene, on account of the uncertainty as to the molecular weight of the water, which was assumed to be 18, but is no doubt larger than this, and is affected both by the concentration and by the temperature. But they are comparable with one another, and enable us to form an approximate idea of the relative miscibility of the different isomerides with water. The values in benzene have also been calculated for those substances which do not form two liquid layers with this solvent; when this occurs, the nominal heat of course becomes infinite.

Discussion of Results.

The results show that these substances are not only abnormal, but have marked peculiarities of their own. Their behaviour in benzene can be compared by means of the critical solution temperatures, which can be observed directly for three of the compounds (*m*-diamine, *m*- and *p*-acetyldiamine) and for the other three can be calculated approximately by the rule of Flaschner and Rankin (*Sitzungsber. K. Akad. Wiss. Wien*, 1909, **118**, IIb, 695). This rule states that the slope of the S-L solubility curve (increase in weight per cent. solute for 1° rise of temperature) at 40 per cent. solute, multiplied by the difference in degrees between the S-L and the L-L curves at this concentration, is equal to a constant, the value of which for benzene was found (Sidgwick and Ewbank, T., 1921, **119**, 991) to be 190. In water, the increase of *Q*, the nominal heat of solution, affords a method of comparison. The values so obtained are as follows (calculated critical solution temperatures are enclosed in brackets):

Diamines.

	Ortho.	Meta.	Para.
Crit. sol. temp. in benzene.....	(18°)	69°	(91°)
Increase of <i>Q</i> in water	89.1	α 25.9 β 58.2	5.2
Boiling point (760 mm.).....	252°	287°	267°

Acetyl-diamines.

	Ortho.	Meta.	Para.
Crit. sol. temp. in benzene.....	(-20°)	266°	188°
Increase of <i>Q</i> in water	5.7	0	22.3

The usual behaviour of abnormal isomerides is that in benzene the ortho is the most miscible (lowest crit. sol. temp. and smallest increase in *Q*) and the para the least miscible, the meta coming near the para: and that in water these relations are reversed. The peculiarities of these amino-compounds are of two kinds, (1) the exceptional position of the meta-series and (2) the anomalous behaviour of the acetyl compounds in water. Disregarding the latter for the moment, the relation of ortho to para is what we should expect: the ortho-series is the more volatile, the more soluble in benzene, and the less soluble in water. The meta-diamine is exceptional in that its solubility in benzene and in water comes nearer to that of the ortho than is usual; its volatility also, instead of being greater than that of the para, is less. The meta-acetyl-diamine is less soluble in benzene than the para, whereas we should expect it to be more so. The behaviour of the acetyl derivatives in water

is wholly anomalous; instead of getting the order of solubilities $o \ll m < p$, we get $p \ll o < m$.

The fact that the para-diamine is more volatile than the meta is to be noticed. It has already been pointed out (Sidgwick, *loc. cit.*) that this behaviour is confined to compounds in which at least one substituent is an amino- or substituted amino-group, the only observed cases being those in which the substituents are CH_3 , $\text{N}(\text{CH}_3)_2$; CH_3 , $\text{N}(\text{C}_2\text{H}_5)_2$; CH_3O , NH_2 ; Cl , $\text{N}(\text{CH}_3)_2$; $\text{N}(\text{CH}_3)_2$, $\text{N}(\text{CH}_3)_2$; and NH_2 with NH_2 , $\text{NH}\cdot\text{CH}_3$, $\text{NH}\cdot\text{C}_2\text{H}_5$, $\text{N}(\text{CH}_3)_2$, and $\text{N}(\text{C}_2\text{H}_5)_2$.

The phenylenediamines are the most basic compounds which have had their solubilities examined from this point of view, and this may well be the cause of some of their peculiarities. The remarkable behaviour of the diamines and their acetyl derivatives in water is no doubt connected with the power of the amino-groups to form stable hydrates. This would not, however, explain their behaviour in benzene, or their anomalous volatility, which seem to point to association in the pure liquid.

[Received, October 11th, 1923.]

CCCXXVII.—*The Solubility of the Hydroxybenzaldehydes and the Hydroxytolualdehydes.*

By NEVIL VINCENT SIDGWICK and ERIC NEWMARCH ALLOTT.

THE hydroxybenzaldehydes are already known to differ widely in boiling point, which is an indication of abnormality, but their behaviour has not been examined in detail. In this paper, the solubilities of these substances and of three of the hydroxytolualdehydes are recorded and discussed. The preparation of a new hydroxytolualdehyde ($\text{CHO}:\text{OH}:\text{CH}_3 = 1:3:4$) is also described.

Preparation of Materials.

Salicylaldehyde.—This was redistilled, and the fraction boiling at $196.5^\circ/760$ mm. was used.

m-Hydroxybenzaldehyde.—Prepared from benzaldehyde by nitration, reduction, and diazotisation (Meister, Lucius, & Brüning, D.R.-P. 66241; Friedländer, III, 61); after recrystallisation from benzene it melted at 106.0° (corr.).

p-Hydroxybenzaldehyde.—Recrystallised from water and dried on a water-bath. It melted at 116.0° (corr.). Previous observers give values from 115° to 118° .

Hydroxytolualdehydes.—The aldehydes $\text{CHO}:\text{OH}:\text{CH}_3 = 1:2:5$, $1:4:5$, $1:4:6$ (the substituents are arranged in the order of their influence on the solubility) were prepared from the three cresols by the Tiemann-Reimer reaction (Tiemann and Schotten, *Ber.*, 1878, **11**, 770) and were purified as follows. $1:2:5$: Recrystallised from alcohol until its m. p. was constant at 55.1° (corr.); Tiemann and Schotten give 56° . $1:4:5$: Recrystallised from water and benzene; m. p. 117.4° (corr.). Tiemann and Schotten give 115° ; Gattermann and Berchermann (*Ber.*, 1898, **31**, 1765) give 118° . $1:4:6$: After repeated crystallisation from water and benzene it melted (not sharply) at 108.9° (corr.); Tiemann and Schotten and Gattermann and Berchermann give 110° . Further recrystallisation did not alter the m. p.

As the yields in the Tiemann-Reimer reaction are always small, attempts were made to discover better methods of preparation, but without success. For example, Moritz and Wolfenstein (*Ber.*, 1899, **32**, 433, 2533), in oxidising benzene hydrocarbons with potassium persulphate, obtained small quantities of aldehydes as by-products; and it seemed possible that by treating the tolyl ester with enough persulphate for complete oxidation to the aldehyde, a reasonable yield of the latter might be obtained. It was found, however, that after treating *o*-tolyl acetate in this way, most of the ester was recovered unchanged, and the only oxidation product isolated was a small quantity of a substance giving a phenylhydrazone which melted at 220° , and had a composition corresponding to the formula $\text{C}_{26}\text{H}_{38}\text{O}_{12}\text{N}_8$ (Found: C = 47.2; H = 5.99; N = 17.7. Calc., C = 46.8; H = 5.92; N = 17.5 per cent.); this was not further examined.

Hydroxytolualdehyde 1:3:4 (2-Hydroxy-p-tolualdehyde).—Since no isomeride with the hydroxyl in the meta-position to the aldehyde group is known, this substance was prepared from *p*-tolualdehyde. The aldehyde was nitrated in the usual way (Hanzlik and Bianchi, *Ber.*, 1899, **32**, 1288), and the nitro-compound (obtained in fairly good yield) reduced as described by Meister, Lucius, & Brünig (D.R.-P. 66241, 62950). The only successful method was to add the bisulphite solution of the aldehyde to a boiling ferrous sulphate solution, and run in a solution of sodium carbonate. Even then a large amount of unchanged nitroaldehyde was recovered. On diazotisation and concentration of the solution, a small amount of the new *hydroxytolualdehyde* was obtained as pale yellow needles melting at 73° (Found: C = 69.9; H = 5.9. $\text{C}_8\text{H}_8\text{O}_2$ requires C = 70.6; H = 5.9 per cent.). Owing to the smallness of the yield, the solubility of this aldehyde was not measured.

Determination of Solubilities.

These were measured synthetically in sealed bulbs. The results are given in Tables I and II, the concentrations being expressed in grams per 100 grams of solution. The points at which a second liquid phase separates are marked L, those at which solid benzene

FIG. 1.

separates B, and the metastable points with an asterisk. The results are plotted on Figs. 1 and 2. The nominal heats of solution in benzene, calculated on the usual formula

$$Q = \log_e \frac{S}{S_1} \cdot \frac{RTT_1}{T - T_1},$$

are given in Table III.

Discussion of Results.

It is obvious that the hydroxybenzaldehydes form a highly abnormal group of compounds. Their relations resemble very closely those of the nitrophenols (Sidgwick, Spurrell, and Davies, T., 1915, 107, 1202; Sidgwick and Aldous, T., 1921, 119, 1001)

FIG. 2.

Solubilities in benzene.
 Hydroxybenzaldehydes: Ortho —○— Meta —+— Para —x—
 Hydroxytolualdehydes: 1:2:5 —○— 1:4:5 —x— 1:4:6 —x—

and those of the hydroxybenzoic acids (Sidgwick and Ewbank, T., 1921, 119, 979). The resemblance to the nitrophenols is of peculiar interest, since Hantzsch (*Ber.*, 1906, 39, 3089) has already directed attention to the resemblance between these two groups of compounds in their power of forming coloured salts.

The effect of the methyl group is the same as was found (Sidgwick

and Ewbank, *loc. cit.*) in the comparison of the hydroxybenzoic and the hydroxytoluic acids; its introduction always diminishes the solubility in water, but its influence is little affected by its position on the ring, and is wholly subordinate to that of the relative position of the two active groups. These facts are illustrated by the following table, giving the critical solution temperatures of these compounds in water; values in brackets are indirectly determined, and are only roughly accurate. The compounds are classified by the relative positions of the two active groups.

Critical solution temperatures in water.

Substituents.	Ortho.	Meta.	Para.
NO ₂ ,OH	>200°	98·7°	92·8°
CHO,OH	>200	66·2	64·4
CHO,OH,CH ₃	>200	—	125 (1 : 4 : 6)
CO ₂ H,OH	89·5	V. low	136·8 (1 : 4 : 5)
CO ₂ H,OH,CH ₃	153·5 (1 : 2 : 3)	(+ 9°)	V. low
	145·2 (1 : 2 : 4)		(17°)
	142·8 (1 : 2 : 5)		

The same resemblance is found in the behaviour of the isomerides in benzene as indicated by the heats of solution, the values for the ortho-compounds being nearly constant, whilst those for the meta and para show a marked increase with dilution. The amount of this increase (in kgr.-cals. per gr.-mol.) is as follows :

Substituents.	Ortho.	Meta.	Para.
NO ₂ ,OH	2·2	18·7	26·4
CHO,OH	—	26·6	45·0
CHO,OH,CH ₃	2·3	—	23·6 (1 : 4 : 6)
CO ₂ H,OH	8·0	65·6	49·0 (1 : 4 : 5)
CO ₂ H,OH,CH ₃	5·5 (1 : 2 : 3)	35·4	69·8
	7·6 (1 : 2 : 4)		29·4
	6·4 (1 : 2 : 5)		

Auwers (*Z. physikal. Chem.*, 1895, **18**, 605) has measured the depression of the freezing point of naphthalene by the three hydroxybenzaldehydes, and finds that in equimolecular solutions the effect is much less for the meta- and para- than for the ortho-compound. If we calculate from his results the nominal heat of solution of the naphthalene on the hypothesis that the molecular weight of the aldehyde is constant (which is as justifiable as the assumption that the difference is due to the association of the solute), we get the following values for the heat of solution of naphthalene at 95 molecules per cent. naphthalene in the three aldehydes, the value for 100 per cent. (heat of fusion) being 4·55 kgr.-cals. :

Ortho 5·14 : Meta 8·34 : Para 11·5.

96.5° and the meta at 240°. The difference is not so large as that 30° found with the nitrophenols, but is sufficiently striking.

These three groups of compounds—the nitrophenols, the hydroxyaldehydes, and the hydroxy-acids—show in a very high degree the

typical behaviour of abnormal benzene derivatives. They all contain two active groups, one of which is hydroxyl. In all cases, the ortho-compound differs widely from the meta and para, which are similar to one another. The ortho-compound is always the most volatile, and in the liquid state the least miscible with water and the most miscible with benzene. In every way, the ortho-compounds behave as the less polar, and the meta and para as the more polar.

CCCXXVIII.—A *New Absorption Pipette for Gas Analysis.*

By SIDNEY WALTER SAUNDERS.

IN most types of gas analysis apparatus, the glass-to-glass connexion between the measuring vessel and the absorption pipette is made by means of wired-on rubber pressure-tubing. Apart from the inconvenience caused by making these connexions, air is always liable to be trapped in the junction, causing an error in the analysis, which may be considerable if several such junctions have to be made. Part of these difficulties have been eliminated by Bone (P., 1898, 14, 154), who makes use of metal-to-metal joints. The apparatus to be described was designed to eliminate such joints, and thus increase the accuracy of the analysis. In the method adopted, the measuring vessel and the absorption pipette were rigidly connected together and mixing of the gas and reagent was secured by spraying the reagent through the gas.

The diagram shows the arrangement for analysis at constant volume. The apparatus consists of a water-jacketed measuring bulb, *A*, forming part of one limb of a U manometer, the other limb, *P*, being immediately in front of a glass scale. The gas to be measured is confined in *A* between the tap, *L*, and a blue pointer, *O*, and its pressure is measured by the manometer. The absorption pipette consists of two bulbs, *B* and *C*, the capacity of each being approximately equal to that of *A* (about 30 c.c.), connected to each other by a piece of capillary tubing, *Q*, constricted a little at the middle, and by a piece of ordinary tubing, *N*, drawn out to rather a wide jet at the end inside *B*. The remainder of the apparatus will be clear from the diagram.

In order to make an analysis, the apparatus is filled with mercury by raising the reservoirs *E* and *F*. The gas is introduced through

D, the apparatus being washed out by passing the gas into *A* and expelling it from *A* through *K*, which is then filled with mercury. Gas is then introduced into *A* and followed through the capillary tube with mercury from *K*, tap *L* is closed, and the temperature and pressure of the gas are noted. The reagent is then sucked into *B* through a piece of glass tubing attached to *D*. No glass-to-glass contact is necessary, nor is an air-tight joint. Having obtained the required amount of reagent in *B*, any air present is expelled *via D*; and to drive all the reagent into *B*, mercury is allowed to run into *B* from *K*, and tap *M* is closed. *A* now contains

FIG. 1.

gas, *B* reagent, and *C* mercury. The gas is then transferred to *B*, the reagent being forced into *C*, and tap *L* is closed. After a few moments, the gas will be in *B* and the reagent in *C*. If the mercury reservoir, *F*, is now raised, the reagent is forced through *N* (only a little will pass through *Q*) and sprayed through the gas, running down the side of the bulb. *F* is then lowered, when some gas will pass through *N* into *C*, and the reagent will run through the capillary and through the gas in *C*, causing further absorption as it is displaced, until all the gas is in *B* and reagent in *C*. The cycle can then be repeated. This requires about three minutes. The gas is then transferred to *A* and followed through with mercury

from *K*, and the reagent is expelled through *D*. Water is then sucked into *B* and *C* and, *D* being open, mercury is sprayed through it by raising *F*, ensuring a rapid washing. The mercury having been washed, *B* is filled with water, and the gas washed and transferred to *A* for pressure measurement. No reagent is ever allowed to enter *A*. The process is then repeated with other reagents.

The apparatus cannot be used as above with reagents which attack mercury, but it can be used as an ordinary form of constant-volume apparatus by filling *B* and *C* with mercury and closing *G*. For these reagents connexion must be made at *D* in the ordinary manner. An improvement might be made by replacing the capillary *Q* by a capillary tap. The absorption pipette can be employed with either a constant-pressure or constant-volume apparatus.

The author wishes to express his thanks to Mr. W. E. Garner for helpful advice and criticism.

CCCXXIX.—Reduction of *m*-Methoxybenzyl Bromide by Hydrogen Iodide.

By JOHN BALDWIN SHOESMITH.

In a recent paper (Lapworth and Shoesmith, T., 1922, 121, 1391), the ease of replacement of bromine in the three isomeric methoxybenzyl bromides was considered from the point of view of the principle of induced alternate polarities. It was shown that whilst the halogen in *m*-methoxybenzyl bromide was less readily removed by alkali than was the halogen in the *o*- and *p*-isomerides, yet the *m*-isomeride was the most readily attacked by hydrogen iodide, iodine being especially rapidly liberated when *m*-methoxybenzyl bromide was dissolved in glacial acetic acid containing hydrogen iodide at 25°. The liberation of free iodine was interpreted as due to reduction of the methoxybenzyl bromide in accordance with the equations—

The quantity of iodine liberated corresponded with that expected from such a reduction.

The result, namely, that the lability of the halogen atoms in *m*-methoxybenzyl bromide is least when alkali but greatest when hydrogen iodide is the reagent, is one that could not have been foreseen with the aid of any general principles enunciated prior to the principle of induced alternate polarities, and therefore was one to which the authors attached great importance. They had considered all other explanations of the course of the reaction and were satisfied that the preceding equations were the only ones which could account for the liberation of iodine in the experiment with hydrogen iodide. Since the publication of the original paper, however, the conclusions were privately criticised on the ground that it had not been established that the equations given represented the true course of the reaction; the assumed reduction product, namely, *m*-tolyl methyl ether, had not been isolated. In view of this, the experiments described in the present paper were made and the results are now communicated, as they remove any serious doubt which might otherwise be entertained of the course of the reaction in question.

When *m*-methoxybenzyl bromide is dissolved in a solution of hydriodic acid in glacial acetic acid (0.46 gram of HI per c.c.), iodine is at once liberated. In an hour's time the amount of iodine present represents complete reduction of the $-\text{CH}_2\text{Br}$ group to $-\text{CH}_3$. From such a reduction mixture *m*-tolyl methyl ether and *m*-cresol may be isolated. The ether, which is obviously the intermediate compound in the scheme $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\text{Br} \xrightarrow{\text{HI}} \text{OMe}\cdot\text{C}_6\text{H}_4\text{Me} \xrightarrow{\text{HI}} \text{OH}\cdot\text{C}_6\text{H}_4\text{Me}$, is demethylated in the solution with no liberation of iodine.

EXPERIMENTAL.

A solution of 6.06 grams of *m*-methoxybenzyl bromide in glacial acetic acid, containing 0.46 gram of HI per c.c. (compare Lapworth and Shoesmith, *loc. cit.*), the total volume being 50 c.c., was maintained at 25°. After the reaction had proceeded for twenty minutes, 1 c.c. of the mixture was withdrawn and the iodine which had been liberated titrated in about 100 c.c. of water with standard sodium thiosulphate solution; 93.5 per cent. of the bromide had been reduced. Samples withdrawn after the reaction had proceeded for an hour and an hour and a half were identical and indicated that reduction was complete (97.5 per cent.) and the liberation of iodine had ceased.

Separation of the Reaction Products.—The solution was poured into 200 c.c. of water containing 17 grams of sodium thiosulphate,

neutralised with solid sodium carbonate (during this operation the odour of methyl iodide was very marked), and then extracted with ether. The ethereal solution was extracted thrice with 10 per cent. caustic potash solution, dried over anhydrous sodium sulphate, the ether removed, and the residual oil fractionated. The main fraction, b. p. 180—200°, weighed 0.90 gram. On refractionating, 0.50 gram boiled between 175° and 185°. This alkali-insoluble oil was *m*-tolyl methyl ether (b. p. 177°) and was further identified by oxidising a small portion with alkaline permanganate to *m*-methoxybenzoic acid, and by demethylating to *m*-cresol as described below.

From the caustic potash solution 0.70 gram of *m*-cresol, b. p. 190—200°, was isolated in the usual way. It gave a bluish-violet colour with ferric chloride solution, and a precipitate with bromine water which crystallised from aqueous alcohol in white needles melting at 81—82°, alone or mixed with an authentic specimen of tribromo-*m*-cresol.

Demethylation of the m-Tolyl Methyl Ether.—The 0.50 gram of ether obtained in the first experiment was mixed with 5 c.c. of the acetic acid-hydriodic acid solution and kept for five hours at 25°. No iodine was liberated. The mixture was neutralised, etc., as before and a small trace of the ether was still unchanged; 0.17 gram of *m*-cresol was isolated and identified as previously described.

No liberation of iodine took place when a mixture of 0.50 gram of methyl iodide with 5 c.c. of the acetic acid-hydriodic acid solution was kept for four hours.

The author wishes to thank Prof. A. Lapworth for valuable suggestions *re* the communication of this note, and also the Earl of Moray Research Fund Committee for a grant which defrayed the cost of some of the chemicals and apparatus used.

CCCXXX.—*Organic Derivatives of Silicon. Part XXIX. Preparation, Properties, and Condensation Products of Di-p-tolylsilicanediol.*

By HERBERT SHEPPARD PINK and FREDERIC STANLEY KIPPING.

THE silicohydrocarbons formed by the action of sodium on dichlorodiphenylsilicane are of such an interesting character (Kipping and Sands, T., 1921, **119**, 830) that it was decided to study the

corresponding reaction in the case of dichlorodi-*p*-tolylsilicane. In the present paper, the preparation of this di-*p*-tolyl derivative from silicon tetrachloride is described, but its behaviour towards sodium has not yet been investigated, as it was desirable in the first place to characterise the corresponding diol, $\text{Si}(\text{C}_6\text{H}_4\cdot\text{CH}_3)_2(\text{OH})_2$, and its condensation products.

Di-p-tolylsilicanediol is easily produced by hydrolysing the dichloride, but its isolation is very troublesome, because, like diphenylsilicanediol (Kipping, T., 1912, **101**, 2125), it readily undergoes condensation in presence of acids and alkalis, giving both open- and closed-chain compounds, corresponding with those obtained from the diphenyl derivative. When, for example, the dichloride is treated with water, it gives a glue-like mass of these condensation products: when treated with a 5 per cent. solution of sodium hydroxide, it gives a clear solution of the sodium derivative, but as soon as the diol is liberated by the addition of dilute acetic acid it begins to condense before it can be isolated. By following closely the method of purification which was successful in the case of diphenylsilicanediol (Kipping, T., 1912, **101**, 2121), the di-*p*-tolyl derivative is obtainable in needles completely soluble in a 5 per cent. solution of sodium hydroxide and it can then be recrystallised in the ordinary way from various organic solvents.

Two or three crystalline condensation products of the diol have been obtained up to the present. So far as can be established by analysis, molecular-weight determinations, and analogy with the diphenyl derivatives, the products are *dianhydrotrisdi-p-tolylsilicanediol* (I), $\text{HO}\cdot\text{Si}(\text{C}_7\text{H}_7)_2\cdot\text{O}\cdot\text{Si}(\text{C}_7\text{H}_7)_2\cdot\text{O}\cdot\text{Si}(\text{C}_7\text{H}_7)_2\cdot\text{OH}$, m. p. 141° , and *trianhydrotrisdi-p-tolylsilicanediol* (II), $\text{O}\left\langle\begin{smallmatrix}\text{Si}(\text{C}_7\text{H}_7)_2\text{O} \\ \text{Si}(\text{C}_7\text{H}_7)_2\text{O}\end{smallmatrix}\right\rangle\text{Si}(\text{C}_7\text{H}_7)_2$, m. p. 261° . A third crystalline product obtained in small quantity is probably *tetra-anhydrotetrakisdi-p-tolylsilicanediol*, but possibly a mixture of the trianhydrotris and tetra-anhydrotetrakis compounds corresponding with that (m. p. $185\text{--}186^\circ$) obtained from the diphenyl derivative (Kipping, T., 1912, **101**, 2040). Attention may be directed to the results of the cryoscopic determinations, recorded below, made with these condensation products; although they differ widely from the theoretical values, their very abnormality seems to supply evidence in support of the molecular formulae respectively assigned to the compounds.

EXPERIMENTAL.

Dichlorodi-p-tolylsilicane, $(\text{C}_6\text{H}_4\text{Me})_2\text{SiCl}_2$.—A solution of *p*-bromotoluene (195 grams; $2\frac{1}{4}$ mols.) in dry ether (600 c.c.) was added

gradually to magnesium (27 grams; $2\frac{1}{2}$ atoms) covered with ether (100 c.c.), the reaction mixture being kept at about 10° ; if when the reaction is at an end the solution is cooled to 0° , it changes into an olive-green, jelly-like mass, which liquefies again at 12° . The reagent was added in the course of one and a half hours to silicon tetrachloride (85 grams; 1 mol.) cooled to 0° . Having been stirred during about eight hours longer, the mixture was heated on a reflux apparatus for three hours, the ether distilled, and the residue kept at 100° for three hours and then extracted with ether in the absence of moisture (Kipping, T., 1907, **91**, 216). On evaporation, the ethereal extract deposited, as is usual, a considerable quantity of magnesium salt. After filtration, the brown oil was distilled under 50 mm. pressure, the receiver being changed at intervals of 100° until the thermometer registered 300° . The considerable residue could not be distilled even at 15 mm. and set to a hard, brittle, non-crystalline mass when cooled.

The small first fraction ($10-100^{\circ}$) contained traces of toluene and a little *p*-bromotoluene; the second fraction ($100-200^{\circ}$) on redistillation gave about 25 grams of trichloro-*p*-tolylsilicane, which passed over at about 125° , and liquids of higher boiling point, which were added to the third fraction. The third fraction ($200-300^{\circ}$) was essentially a mixture of di-*p*-tolyl and dichlorodi-*p*-tolylsilicane. It gave on redistillation a small quantity of di-*p*-tolyl boiling at about 208° , which partly solidified when cold, and then a large fraction boiling from about 210° to 220° . The latter still contained a considerable proportion of di-*p*-tolyl, which could be partly removed by cooling the liquid to -10° , filtering rapidly and again fractionating, but even after these operations had been repeated several times, analysis showed that the product, which boiled at $225-226^{\circ}/50$ mm., contained about 7 per cent. of di-*p*-tolyl.*

The average yield of dichlorodi-*p*-tolylsilicane in several experiments carried out as described above was 23 per cent. of the theoretical, and did not seem to be improved by varying the proportion of the Grignard reagent. Attempts to increase the yield by using the modified method of applying the Grignard reagent, so successful in certain other cases (Kipping and Davies, T., 1911, **99**, 296), gave even less satisfactory results: there was a much larger proportion of non-volatile matter, which, treated with water, gave a colourless, non-crystalline solid partly soluble in 5 per cent. sodium hydroxide solution with evolution of hydrogen. Similar products are obtained in the preparation of many alkyl and aryl derivatives of silicon tetrachloride (compare Martin and Kipping,

* The boiling point of di-*p*-tolyl was found to be 168° (20 mm.), 178° (35 mm.), 181° (41 mm.), 188° (50 mm.), and 198° (76 mm.).

T., 1909, 95, 314), but not as a rule in such large proportions as in this particular instance.

Trichloro-p-tolylsilicane (see above) is a colourless, fuming liquid, b. p. 210—215°. When treated with water, it gives an oily product, doubtless a condensation product of *p*-tolylsiliconic acid.

Dichlorodi-p-tolylsilicane, b. p. 225—226°/50 mm., fumes only slightly in moist air. In spite of the difference in the boiling points,* its complete separation from di-*p*-tolyl is not easy, and being unnecessary for the immediate purpose in view, was not seriously attempted.

Hydrolysis of Dichlorodi-p-tolylsilicane.—Preliminary experiments having shown that the decomposition of the dichloride with water gave a very unsatisfactory product, which, moreover, was contaminated with di-*p*-tolyl, the oil was hydrolysed by adding it slowly to a well-stirred, ice-cold, 5 per cent. aqueous solution of potassium hydroxide. The turbid solution was rapidly filtered from the insoluble yellow oil (di-*p*-tolyl) and then immediately acidified with dilute acetic acid, which precipitated the diol in colourless, very bulky masses having the appearance of cotton wool: the precipitate was then rapidly separated by filtration and well washed with water.

The filtrate contained a small quantity of what seemed to be *p*-cresol. As this compound could not have been present in the fractionated dichlorodi-*p*-tolylsilicane and could scarcely have been produced from the dichloride or the diol by the action of alkali (which would give toluene), it is probable that the fractionated dichloride contained some dichloro-*p*-tolyl-*p*-tolylsilicane, $C_7H_7SiCl_2O \cdot C_7H_7$, formed from oxidised magnesium *p*-tolyl bromide.

Another by-product is obtained in the preparation of the diol; when the acidified filtrate is evaporated to dryness, it gives a residue consisting essentially of potassium chloride and acetate, but which contains a small proportion of organic matter insoluble in water. This product is soluble in ethyl acetate or chloroform, and on evaporation of the solutions is obtained as a brittle residue which does not melt at 360°; possibly it is a condensation product of *p*-tolylsiliconic acid formed from the substance formulated above.

Isolation of Di-p-tolylsilicanediol.—The precipitated diol was not completely soluble in 5 per cent. potassium hydroxide solution and when kept in a desiccator became very sticky and could not then be obtained from solution in a crystalline form. The roughly air-dried preparation was readily soluble in cold ether, chloroform, acetone, and many other solvents, from all of which it separated

* See footnote on previous page.

at the ordinary temperature in silky needles mixed with pasty, cauliflower-like masses; such deposits were obviously impure and melted at 90–110°. After repeated failures to purify the diol by ordinary fractional crystallisation, the method used to obtain pure diphenylsilicanediol was applied.

A solution of the impure substance in acetone was diluted with a small proportion of water; on the surface of the milky liquid thus produced, a skin of long, silky, transparent needles formed after two or three days; this was removed and its acetone solution again treated with water. These operations were repeated and as purification proceeded, the milkiness of the liquid produced by the addition of water to the acetone solution gradually diminished until finally a crystalline precipitate of pure diol was deposited and the supernatant liquid remained clear.

The milky suspensions from the diol contain mixtures of condensation products: they will remain unchanged in appearance over a period of six weeks or more, but the addition of a little sodium hydroxide solution, dilute acetic acid, or ammonium chloride causes coagulation of the suspended matter, which can then be separated by filtration.

Di-p-tolylsilicanediol, $(C_7H_7)_2Si(OH)_2$, crystallises in small, transparent prisms and melts at 113–116°, according to the rate of heating, with evolution of steam. It dissolves freely in cold acetone, chloroform, ether, ethyl acetate, or the lower alcohols, but is only sparingly soluble in cold benzene, carbon disulphide, or carbon tetrachloride, and practically insoluble in cold petroleum. When pure, it is precipitated in slender needles from its chloroform solution on the addition of carbon tetrachloride (Found: C = 68.3; H = 6.47; Si = 11.65. $C_{11}H_{15}O_2Si$ requires C = 68.7; H = 6.54, Si = 11.57 per cent.).

It dissolves readily and completely in 5 per cent. aqueous sodium hydroxide, but the solution soon becomes turbid, even when it is kept in a desiccator over soda-lime, and in the course of some twenty-four hours practically the whole of the diol is precipitated as a glue, from which the condensation products melting at 186–187° and 260–261° can be isolated.

Attempts to methylate the diol with methyl sulphate in pyridine solution were unsuccessful; the product consisted of trianhydrotris-di-p-tolylsilicanediol (p. 2836), the yield of which was practically theoretical.

Dianhydrotrisdi-p-tolylsilicanediol (Formula 1).—The first condensation product of di-p-tolylsilicanediol, corresponding with anhydrobisdiphenylsilicanediol, $HO\cdot SiPh_2\cdot O\cdot SiPh_2\cdot OH$, has not yet been characterised, a result which is doubtless due to the

difficulty of separating it from the oily mixtures produced from the diol under various conditions.

Dianhydrotrisdi-*p*-tolylsilicanediol, the second condensation product, has also not yet been isolated from the glues produced by the action of alkalis on the diol, but it can be obtained in other ways. When the diol is heated at 100°, it liquefies in about thirty minutes, and after three hours the loss of weight remains constant at about 4.67 per cent., the calculated value for the loss of one molecule of water being 4.92. The product, which becomes opaque and brittle when cold, is dissolved in chloroform and the solution diluted with light petroleum (b. p. 70–80°); after some time, crystals of dianhydrotrisdi-*p*-tolylsilicanediol are deposited, but the yield is poor and the mother-liquors contain a considerable quantity of a glue-like mixture of other condensation products, from which the components have not been isolated. Dianhydrotrisdi-*p*-tolylsilicanediol crystallises well from a mixture of chloroform and light petroleum in rectangular plates melting at 141° (Found: Si = 12.34, 12.22; *M*, in freezing benzene, = 799. $C_{42}H_{44}O_4Si_3$ requires Si = 12.17 per cent.; *M* = 697.5). This experimental result obviously indicates the presence of associated molecules and is closely comparable with the high values obtained in the case of dianhydrotrisdi-phenylsilicanediol, which gave *M* about 750 (Calc., *M* = 613. Kipping, T., 1912, 101, 2134); that the compound has the structure given above seems to be clearly established by the fact that it is easily converted into trianhydrotrisdi-*p*-tolylsilicanediol (p. 2836).

Dianhydrotrisdi-*p*-tolylsilicanediol is readily soluble in most of the common organic media, including carbon disulphide, but it is only sparingly soluble in cold alcohol or light petroleum. Like the corresponding diphenyl derivative, it is not appreciably soluble in 5 per cent. aqueous potassium hydroxide, but it is gradually dissolved by alcoholic potassium hydroxide, being converted into the potassium derivative of di-*p*-tolylsilicanediol. It can also be obtained by treating an acetone solution of the diol with a very small proportion of concentrated hydrochloric acid and leaving the liquid to evaporate at the ordinary temperature. The glue-like product, which is partly crystalline, is dissolved in chloroform and the solution diluted with light petroleum; from the crystalline deposit which is ultimately obtained pure dianhydrotrisdi-*p*-tolylsilicanediol is easily isolated.

When pure di-*p*-tolylsilicanediol is heated at temperatures above 100°, the loss of weight is far more than corresponds with the loss of one molecule of water (7.4 per cent.); thus after forty-eight hours at 105° the loss was 16.2 per cent. and after sixteen hours at 110° it was 17 per cent. and a constant weight had not been attained.

Similar results were obtained by Robison and Kipping in the case of dibenzylsilicanediol (T., 1912, 101, 2149) and were attributed to the formation and volatilisation of benzaldehyde; in the present case, the loss might possibly be due to the formation of toluene in consequence of hydrolysis by the liberated water.

Trianhydrotrisdi-p-tolylsilicanediol (Formula II).—The dianhydro-compound just described seems to be stable at 100°, but when heated at 150° it loses water and is very largely converted into the trianhydro-derivative. The glassy product thus obtained (after heating during four hours) was dissolved in chloroform and the solution diluted with light petroleum. The crystalline precipitate was further purified by recrystallisation from ethyl acetate. The chloroform-petroleum mother-liquors on evaporation gave only a small proportion of a glue-like residue, showing that the trianhydro-compound is formed in approximately theoretical quantity.

Trianhydrotrisdi-p-tolylsilicanediol crystallises from warm ethyl acetate in rhomboidal plates, m. p. 261–262° (Found: Si = 12.59, 12.60. $C_{42}H_{42}O_3Si_2$ requires Si = 12.49 per cent.).

The molecular weight in benzene solution by the cryoscopic method was found to be 626, 607, 637. These results do not agree with the theoretical (679) and, in fact, are much lower than those given by dianhydrotrisdi-*p*-tolylsilicanediol; the two sets of values, however, correspond closely with those which were obtained in the case of dianhydrotris- and trianhydrotris-diphenylsilicanediol (Kipping, T., 1912, 101, 2125) and therefore their irregularity does not cast any serious doubt on the suggested formulæ: a series of other determinations was made with the trianhydro-compound by the camphor method (Rast, *Ber.*, 1922, 55, [B], 1051), but the results, although fairly concordant, were even lower (540–560) than those obtained with benzene. Trianhydrotrisdi-*p*-tolylsilicanediol is readily soluble in chloroform or ethyl acetate, very sparingly soluble in cold acetone or ether, and practically insoluble in alcohol or light petroleum. It does not dissolve when it is heated during a short time with 5 per cent. aqueous potassium hydroxide, but it is hydrolysed by alcoholic potash, giving the potassium derivative of di-*p*-tolylsilicanediol.

Action of Piperidine on Di-p-tolylsilicanediol.—It seems highly probable that the two crystalline compounds described above are not the only condensation products formed from di-*p*-tolylsilicanediol under the action of heat, acids, or alkalis, because under very varied conditions the diol yields a considerable proportion of non-crystalline matter which is not appreciably soluble in cold aqueous alkalis. In the hope of isolating some of the missing members of the series, the pure diol was treated with a trace of piperidine in acetone

solution. On evaporation at the ordinary temperature, the only product was a very viscous oil, from which, with the aid of chloroform and light petroleum, a small proportion of trianhydrotrisdi-*p*-tolylsilicanediol was first isolated; the remaining glue, left in an ice-chest with acetone during several days, gave crystalline deposits which consisted of trianhydrotrisdi-*p*-tolylsilicanediol and a substance of lower melting point. After the former had been separated as far as possible by fractional crystallisation and extraction with acetone, there was obtained what seemed to be a definite compound melting at 186–187° which crystallised from ethyl acetate in long slender prisms (Found: Si = 12.45. *M*, in freezing benzene, = 738, 737. $C_{50}H_{96}O_4Si_4$ requires Si = 12.49 per cent.; *M* = 906).

This substance is practically insoluble in light petroleum, carbon tetrachloride, or alcohol, but dissolves freely in most of the other ordinary organic solvents. It is not appreciably changed by hot 5 per cent. potassium hydroxide solution.

From the evidence available this compound is probably *tetra-anhydrotetraakisdi-p-tolylsilicanediol*, but it seems not impossible from the relatively low melting point that it is a mixture (compare p. 2831); sufficient material was not available for further experiments.

The authors express their gratitude to the Government Grant Committee of the Royal Society for a grant in aid of the investigation. One of them (H.S.P.) is indebted to the Education Committee of the Nottinghamshire County Council for a grant which enabled him to continue his studies.

CCCXXXI.—*Separation of Octoic and Decoic Acids from Coconut Oil.*

By ERIC EVERARD WALKER.

SOME years ago the author required a small quantity of decoic acid for some physical measurements, and as at that time the acid itself and the material for its synthesis were difficult to obtain, its isolation from coconut oil was attempted. The difficulty experienced in effecting this separation indicated that there was less of this acid present in the oil than was generally believed. The author intended to investigate this matter further in Ceylon, but circumstances led to the abandonment of the work, and as there is no probability of its being resumed in the near

future, such information as is available is published in the present note.

Georgey isolated decoic acid from cocoanut oil in 1875 by fractionating the barium salt. He stated that only traces of the acid were present which might be easily overlooked. In 1907, Paulmeyer (*La Savonnerie Marseillaise*, 1907, No. 78) fractionated the mixed acids in a current of steam. He found 0.25 per cent. of octoic acid and 19.5 per cent. of decoic acid. In 1913, Elsdon (*Analyst*, 1913, 38, 8) fractionated the methyl esters and concluded that they contained 9 per cent. of octoic acid and 10 per cent. of decoic acid. The author's observations do not support either of these analyses.

The first attempt to isolate decoic acid was by fractionation of the ethyl esters. The mixed acids (750 grams) were converted into the esters and fractionated. Only 3.5 grams (0.47 per cent.) of a very impure acid melting at 24–25° were obtained after a prolonged fractionation of the esters.

In the second attempt 2.5 kilograms of the mixed acids were roughly fractionated under diminished pressure. All fractions between practically pure octoic acid and practically pure dodecoic acid were collected and converted into the lithium salts. The product was fractionally crystallised from water. The readiness with which the acids can be separated by this means is illustrated by the following details of the fractional crystallisation of the lithium salts prepared from one portion of the distillate.

Equivalent of acid.		
1st crop	12 grams 218 (dodecoic acid 200.2)
2nd crop	5 " 172 (decoic acid 172.2)
3rd crop	3 " 147 (octoic acid 144.1)

In all, 14 grams (0.58 per cent. of the original mixed acids) of the lithium salt were obtained having an equivalent of 174. This was dissolved in 1500 c.c. of water and 15 per cent. of it was precipitated as the barium salt and separated. The remainder was then precipitated, and recrystallised from 75 per cent. alcohol. Nine grams of the clean crystalline salt were obtained (0.2010 gram of decoate gave 0.0830 gram of BaCO_3 . Calc., 0.0827 gram. Equivalent wt. 172.6).

The salt was decomposed and gave an acid, m. p. 31.0°. This is a trifle low (Lewkowitsch gives 31.3° to 31.4°), but the acid is considerably purer than that obtained by Georgey after numerous fractionations of the barium salt in large volumes of alcohol and water. One hundred and fifty grams (6.0 per cent.) of octoic acid, m. p. 14.5°, were obtained from the same sample of mixed acids, and this furnished a good yield of pure acid melting at 16.5°.

Thus there cannot have been less than 6 per cent. of octoic acid, or less than 0.5 per cent. of decoic acid, and bearing in mind the readiness with which these acids can be separated by the method just described, it is difficult to believe that there can have been more than 1 per cent. or at the outside 2 per cent. of decoic acid in the original sample. This is entirely at variance with the analyses quoted in the first part of the paper, but is in agreement with Georgy's observations. Whether this disagreement represents real differences in the composition of different samples of oil or whether the analyses were inaccurate cannot be stated definitely. The author had hoped to settle this point by analyses of oils from different sources in India and Ceylon, but these analyses were not completed. So far as the author is aware, no one has separated pure decoic acid from cocoanut oil in quantities which would indicate its presence in anything approaching 10 or 20 per cent. in the original sample.

The author desires to thank Professor Lowry for permitting him to carry out this work in his laboratories.

CCCXXII.—*Substitution in Vicinal Trisubstituted Benzene Derivatives. Part II.*

By WILLIAM DAVIES and LEON RUBENSTEIN.

IN Part I (Davies, this vol., p. 1575), a preliminary attempt was made to ascertain from the position of nuclear substitution in substances of type (1), whether the conception of intermediate formation of an additive compound of the reactant with one or more of the ethereal oxygen atoms can be used as a guide in predicting the position of substitution. If the hypothesis of addition preceding substitution is correct, it is to be expected that the oxygen attached to R_1 will be prevented by the well-known hindering effect of two adjacent groups from forming such an intermediate compound. In that case $-OR_1$ will have no directing influence, and the substitution taking place will be in the para-position (since the directing influence of an aldehyde group is almost negligible compared with that of an alkyloxy-group) to $-OR$, which is spatially free to form the intermediate compound. As previously pointed out, this view might be used to explain the nitration of 2:3-dimethoxybenzaldehyde, where substitution takes place apparently entirely in the position ortho to the aldehyde group (Perkin and Robinson, T., 1914, 105, 2389).

The point at issue has been further investigated by examining the effect of substitution when R and R₁ are alternately methyl and ethyl, and when they are both ethyl radicles. In the case where R and R₁ are different, the value of this method is more open to doubt, since the two groups (quite independently of questions of mechanism of reaction) may differ considerably in orientating power. Professor Robinson, however, to whom one of us (W. D.) is much indebted for suggestions on these and kindred problems, has informed us (private communication) that in 2-ethoxyanisole one group is not much more powerfully directive than the other. Consequently, information is to be obtained bearing on the problem under discussion when R and R₁ are methyl and ethyl, as well as when they are both ethyl radicles.

In the nitration of 2-methoxy-3-ethoxybenzaldehyde (Davies, *loc. cit.*, p. 1590), a mixture of two isomerides is formed of which (III) is probably the chief, as it can be isolated in about 40 per cent. yield, whilst (IV) cannot be isolated as such in a pure condition. A similar result is obtained by the nitration of 3-methoxy-2-ethoxybenzaldehyde (V), when the two isomerides (VI) and (VII) are produced. The proportions are very difficult to ascertain, but 5-nitro-3-methoxy-2-ethoxybenzaldehyde (VII) is the only one to be obtained in a pure state, and when the nitration product is oxidised, the acid corresponding to (VII) is obtained in a yield of more than 30 per cent., even when the mixture of acids produced has not been completely resolved. The constitution of (VII) has been determined by the ethylation of 5-nitro-2-hydroxy-3-methoxybenzaldehyde (VIII), the constitution of which is known (Davies, *loc. cit.*, p. 1584).

Both these cases furnished no evidence of the formation of the intermediate compound (on the middle oxygen atom) being sterically prevented, and the nitration of 2 : 3-diethoxybenzaldehyde has accordingly been carried out. Here also a mixture of derivatives of *o*- and *m*-nitrobenzaldehydes is formed. In this instance, it has

not been possible to separate either isomeride from the nitration product, although the presence of each has been conclusively

proved. The formation of the *o*-nitrobenzaldehyde derivative (IX) has been shown, as in all these cases, by the production of an indigotin derivative by the action of acetone and sodium hydroxide solution. When the nitration product is oxidised, the main acid (XI) isolated from the mixture melts at 118°, and is converted by boiling with dilute sodium hydroxide solution into 5-nitro-2-hydroxy-3-ethoxybenzoic acid (XII), the constitution of which has been shown by its production from 5-nitro-2-methoxy-3-ethoxybenzoic acid (XIII). Moreover, 5-nitro-2:3-diethoxybenzaldehyde (X) has been synthesised by the ethylation of 5-nitro-3-ethoxysalicylaldehyde (XIV), and the pure aldehyde formed gives on oxidation the 5-nitro-2:3-diethoxybenzoic acid (XI) mentioned above as melting at 118°. The proportion of aldehydes in the nitration product or of the acids formed on oxidation of this has not been determined. It must, however, be remembered that the conversion of these heavily-substituted aldehydes into the corresponding acids is far from quantitative. The method of estimating the *o*-nitrobenzaldehyde derivative by conversion into an indigotin has been tried in all these cases, and is far from satisfactory (pages 2845 and 2846). The proportion of 5-nitro-2:3-diethoxybenzoic acid formed by the oxidation of the nitration mixture is large, however, and the experiment shows that the nitration of 2:3-diethoxybenzaldehyde does not follow the surprising course of that of 2:3-dimethoxybenzaldehyde.

2:3-Diethoxybenzoic acid (XV) is converted by nitration into 5-nitro-2:3-diethoxybenzoic acid (XI) in good yield, and no other isomeride has been isolated. This experiment is completely analogous to the nitration of *o*-veratric acid, whereby 5-nitro-*o*-veratric acid is produced.

These experiments show clearly that either steric hindrance does not play an interfering rôle in the formation of intermediate

additive compounds with the ethereal oxygen, or else more probably that such preliminary addition is not necessary for nuclear substitution to take place. It will, however, be noticed that in all cases some *o*-nitrobenzaldehyde derivative is formed, which may be accounted for on the unsatisfactory hypothesis that steric hindrance has been only partly effective. The fact that both methoxy- and ethoxy-groups are powerfully para-directive is the simpler and alternative explanation. To test this point, 3-chloro-2-methoxybenzaldehyde (XVI), in which the 3-group (chlorine) has a much weaker directing influence than the 2-group (methoxyl), has been nitrated, when no trace of the *o*-nitrobenzaldehyde derivative is produced. The only isomeride obtained is 3-chloro-5-nitro-2-methoxybenzaldehyde (XVII), which is formed in good yield. The proof of the formula assigned to this substance follows from the scheme, and from the fact that the corresponding 3-chloro-5-nitro-2-methoxybenzoic acid (XVIII) is almost quantitatively converted by alkaline hydrolysis into 3-chloro-5-nitrosalicylic acid (XIX), no hydrolysis of chlorine being produced in the process. (For the value of this type of proof, see Davies, *loc. cit.*, p. 1578.)

Thus 3-chloro-2-methoxybenzaldehyde is substituted exactly in the position which would be predicted from the knowledge that methoxyl is a much more strongly directing group than the chlorine atom. The present investigation, therefore, does not bear out the original conception of the possible influence of steric hindrance on substitution in compounds of this type, and, on the one hand, rather supports the view of Kurt Meyer and Schoeller (*Ber.*, 1919, 52, 1468) that preliminary addition takes place at the ends of a system of conjugated linkings, and, on the other, makes it doubtful whether in the nitration of alkyl aryl ethers, the common assumption of the intermediate oxonium compound is really justified.

This research, therefore, leaves the remarkable result of the nitration of *o*-veratraldehyde (XX) unexplained. There are several authenticated cases extant of other remarkable and unexpected substitutions in compounds where two or more groups are adjacent. For example, 2:3-dinitrochlorobenzene (XXI) is largely converted by nitration into 2:3:5-trinitrochlorobenzene (Holleman, *Proc. Acad. Amsterdam*, 1922, 25, 223; *Chemical Abstracts*, 1922, 16, 4193), which is quite inexplicable. Usually chlorine has a far stronger directing power than nitroxy, but the reverse holds in this case. Again, von Braun (*Ber.*, 1916, 49, 1101) shows that changes in the substituent X (Me, Cl, Br, OMe) in ortho-substituted dimethylaniline derivatives (XXII) cause great variation in the yield of the quaternary ammonium iodide (XXIII) produced, and that the same changes in X bring about the same variations, at any rate of the same order, in the yield of the *p*-dimethylaminobenzyl alcohol derivative (XXIV). This furnishes a very good instance of the

apparent effect of steric hindrance on substitution, but its value is much diminished by the fact that the oxidation of the benzyl alcohol derivatives (XXIV) to the benzoic acid is affected in the same way by changes in the now remote substituent X. This unexpected result may be explained by the presence of a linking between the -NMe₂ and -CH₂-OH groups, but such an assumption raises debatable points which are out of place in this communication. These and several other remarkable instances that have attracted our attention show that the juxtaposition of groups in the benzene nucleus sometimes causes quite unexpected further substitution to take place.

With the exception of the bromine derivatives, the formulæ of almost all the new compounds (apart from the two probable *o*-nitrobenzoic acid derivatives described on pages 2847 and 2849) have been rigidly proved. In the bromination of *o*-veratraldehyde, 2-methoxy-3-ethoxy-, 3-methoxy-2-ethoxy-, and 2:3-diethoxybenzaldehyde, only one compound has been isolated in each case, and this, on nitration, is convertible into a derivative of *o*-nitrobenzaldehyde, as shown by the production of an indigotin in the usual way. Moreover, in every case, the same bromo-2:3-dialkylxybenzaldehydes have also been produced by methylating or ethylating bromo-*o*-vanillin or bromo-3-ethoxysalicylaldehyde.

Now in the course of this research the nitroxyl in nitro-*o*-vanillin and nitro-3-salicylaldehyde has been proved to be in the 5-position, where it would be expected to go. There is consequently no reason to doubt that the bromine is similarly directed by the hydroxyl group to the para-position, in preference to the 4-position. No instance of 4-substitution has, in fact, been encountered in the course of this work. Hence, as the bromine has been proved not to be

in the 6-position, the cumulative evidence is very strong that all the bromination products are 5-bromo-derivatives. The scheme given summarises the evidence obtained of the constitution of the bromination products of *o*-veratraldehyde (XXV) and of 3-methoxy-2-ethoxybenzaldehyde (XXVI). Precisely similar evidence of the formulæ of the bromination products of 2-methoxy-3-ethoxybenzaldehyde and of 2:3-diethoxybenzaldehyde is to be found in the experimental portion of the paper.

The new compounds described are normal in behaviour. It may, however, be here mentioned that both 3-methoxy-2-ethoxy- and 2:3-diethoxy-benzaldehydes are pungent sternutatory liquids at the ordinary temperature, and on distillation at ordinary pressures are partly converted into derivatives of phenol, migration of an alkyl group into the nucleus having taken place under these conditions (compare Claisen and Eisleb, *Annalen*, 1913, **401**, 112).

EXPERIMENTAL.

Nitration of 2-Methoxy-3-ethoxybenzaldehyde (continued).

A partly successful attempt has been made to separate the *o*-nitro-benzaldehyde derivative present in the nitration product of 2-methoxy-3-ethoxybenzaldehyde (this vol., p. 1590). After remaining for an hour at 0°, the nitrated mixture is filtered, the filtrate diluted with water, and the precipitate (0.4 gram from 4.0 grams of the aldehyde) repeatedly crystallised from methyl alcohol. The fraction melting at 93–96° can be converted in very large pro-

portion into an indigotin derivative and on oxidation in the usual way is converted into a trace of 5-nitro-2-methoxy-3-ethoxybenzoic acid (m. p. 177°), but mostly into the more soluble acid already described melting at 157·5°, which is doubtless 6-nitro-2-methoxy-3-ethoxybenzoic acid.

The proportion of the isomerides formed in the nitration of the above methoxyethoxybenzaldehyde has not been accurately determined. The method of estimating *o*-nitrobenzaldehyde derivatives by conversion into *o*-nitrosobenzoic acids by the action of ultra-violet light is not very suitable here, and conversion into an indigotin leaves much to be desired, owing to oxidation of one or more of the nitroaldehydes to the corresponding acid during the condensation, and probably also to the formation of *m*-nitrobenzylideneacetone derivatives. The following is an example of the procedure adopted. The nitration product (3·5 grams), which is not kept in the presence of nitric acid when the reaction has finished, is dissolved in warm acetone (20 c.c.), 10 per cent. sodium hydroxide solution (9 c.c.) added, and the solution after five minutes diluted with water (70 c.c.), heated on the water-bath for an hour, and kept over-night. The indigoid precipitate is washed with dilute sodium hydroxide solution and then with water, the total filtrate treated with excess of carbon dioxide and evaporated to dryness under reduced pressure, and the residue treated with water (50 c.c.) (solution A). The crude indigo, after digestion with benzene (25 c.c.), is obtained as a beautifully crystalline substance with bronze glance (1·05 grams; m. p. 270° uncorr.). The benzene solution is evaporated, the residue (1·7 grams) mixed with solution A, to which excess of potassium bicarbonate has been added, and oxidised with dilute potassium permanganate solution. Even when 4·5 grams of potassium permanganate are used, some carbonyl compound is still present. The reaction product is filtered, the manganese dioxide washed with a little hot water, and the filtrate concentrated and acidified, practically pure 5-nitro-2-methoxy-3-ethoxybenzoic acid (0·8 gram) melting at 168° to 176° being produced. These figures show that about 50 per cent. of the nitroaldehydes is not accounted for. This fact must be partly attributable to the excess of potassium permanganate used, which rarely gives even approximately quantitative yields of acids by the oxidation of pure vicinal aromatic aldehydes of this type (see Davies, *loc. cit.*, 1591; this vol., p. 2847). This indigotin method has been tried with the other 2:3-dialkyloxybenzaldehyde nitration products, but is very unsatisfactory. However, as considerable quantities of the 5-nitro-derivative have been detected in every case, the method has not been further elaborated.

Nitration and Bromination of 3-Methoxy-2-ethoxybenzaldehyde.

3-Methoxy-2-ethoxybenzaldehyde (V).—A mixture of *o*-vanillin (17.5 grams), ethyl alcohol (120 c.c.; 97 per cent.), ethyl iodide (12.5 c.c.), and 2 c.c. of a sodium hydroxide solution (6 grams of sodium hydroxide in 12 c.c. of water) is boiled during fourteen hours, 1 c.c. of the sodium hydroxide solution being added about every hour, so that the amount of free alkali present at any time is very small and the Cannizzaro reaction is prevented from taking place. Five c.c. of ethyl iodide are now added and five hours later most of the alcohol is distilled off, the product poured into water, extracted with ether, and the ethereal solution washed with sodium hydroxide solution and with water, dried over potassium carbonate, and evaporated. The residual oil distils almost completely at 140°/18 mm., the yield being 15.5 grams. **3-Methoxy-2-ethoxybenzaldehyde** is a colourless, highly refractive liquid heavier than water, and solidifies at 0° to colourless needles which melt at room temperature. It is pungent and sternutatory, although less so than 2:3-diethoxybenzaldehyde. Both these ethers, when distilled at ordinary pressures, are partly converted into derivatives of phenol, as is shown by the distillate giving an intense blue coloration with ferric chloride solution. The *phenylhydrazone* of 3-methoxy-2-ethoxybenzaldehyde consists of colourless prisms melting at 122°, and the *p*-nitrophenylhydrazone of intense orange-red needles which turn light yellow at a temperature a few degrees below the m. p. 192°.

Repeated attempts to ethylate *o*-vanillin with ethyl iodide and silver oxide were unsuccessful.

Nitration of 3-Methoxy-2-ethoxybenzaldehyde.—The nitration mixture of methoxyethoxybenzaldehyde (6 grams) and nitric acid (20 c.c.; *d* 1.42), having reacted at 10–20°, is kept for two hours at 0° and filtered. The solid is crystallised from ethyl alcohol, from which 1.5 grams of 5-nitro-3-methoxy-2-ethoxybenzaldehyde (see below) separate in light yellow plates melting at 137° (Found: *N* = 6.3. $C_{10}H_{11}O_5N$ requires *N* = 6.2 per cent.). The nitric acid filtrate on dilution with water yields 5.35 grams of a product, melting indefinitely at 60–100°, which can be largely converted into an indigotin derivative.

Attempted Separation of the Isomerides.—Separation of the *o*-nitrobenzaldehyde derivative by conversion into the corresponding indigotin is even less satisfactory than is the case with the nitroderivatives of 2-methoxy-3-ethoxybenzaldehyde (page 2845). The amount of indigoid substance formed is less than 10 per cent., and the small proportion of organic acid produced melts, after purification, at 169°. A very partial separation can be effected

as follows: 2 grams of the initial nitration product, melting at 50–100° (from which none of the isomeride melting at 137° had been removed), are converted by oxidation with excess of permanganate in the presence of potassium bicarbonate into two acids. The less soluble one (0.75 gram; m. p. 162–168°) consists of 5-nitro-3-methoxy-2-ethoxybenzoic acid (see below) melting, after recrystallisation, at 169°. The more soluble acid (0.15 gram) separates from water in plates, m. p. 132°, and is doubtless 6-nitro-3-methoxy-2-ethoxybenzoic acid (Found: equivalent = 240. $C_{10}H_{11}O_6N$ requires equivalent = 241). When the mother-liquor is concentrated, a mixture of acids (0.4 gram) melting from about 105° to 130° is isolated.

Synthesis of 5-Nitro-3-methoxy-2-ethoxybenzaldehyde (VII).—5-Nitro-2-hydroxy-3-methoxybenzaldehyde (Davies, *loc. cit.*, p. 1578) is ethylated with ethyl iodide and silver oxide in chloroform solution, when an almost theoretical yield of 5-nitro-3-methoxy-2-ethoxybenzaldehyde, m. p. 137°, identical with the product (m. p. 137°) formed by direct nitration of 3-methoxy-2-ethoxybenzaldehyde (see above), is obtained.

5-Nitro-3-methoxy-2-ethoxybenzoic acid, prepared by oxidising 5-nitro-3-methoxy-2-ethoxybenzaldehyde with potassium permanganate (yield 65 per cent.), forms minute needles, m. p. 169°, and is moderately soluble in hot and sparingly soluble in cold water (Found: equivalent = 240.9. $C_{10}H_{11}O_6N$ requires equivalent = 241).

Bromination of 3-Methoxy-2-ethoxybenzaldehyde (XXVI). Three grams of this substance are brominated in the way described on page 2849 (yield 3.35 grams). 5-Bromo-3-methoxy-2-ethoxybenzaldehyde consists of colourless needles melting at 84.5°. The nitro-derivative separates from alcohol in thick, colourless plates melting at 101°, turns greenish-blue on exposure to light, and is readily converted into an indigotin derivative.

The product of ethylation of bromo-*o*-vanillin (Davies, *loc. cit.*, p. 1586), which is effected almost quantitatively by ethyl *p*-toluenesulphonate and sodium hydroxide in aqueous ethyl-alcoholic solution, melts at 84° and is identical with the bromo-3-methoxy-2-ethoxybenzaldehyde described above. The position of the bromine atom in this compound is therefore established with some degree of certainty.

Nitration and Bromination of 2:3-Diethoxybenzaldehyde.

2:3-Diethoxybenzaldehyde, which is not easily obtained by the ethylation of 3-ethoxysalicylaldehyde by means of ethyl iodide and silver oxide, but is readily formed in almost theoretical yield by

the method used in the preparation of 3-methoxy-2-ethoxybenzaldehyde (page 2846), is a colourless liquid with an extremely pungent odour and boils at 169°/37 mm. (Found: C = 67.5; H = 7.3. $C_{11}H_{14}O_3$ requires C = 68.0; H = 7.2 per cent.).

Nitration.—Carried out in the usual way (2.5 grams of the aldehyde and 12 c.c. of nitric acid, d 1.42), nitration yields a light yellow substance which, when washed and dried, melts at 40–50°. The product is purified for analysis by dissolution in a little alcohol, reprecipitation, and thorough washing with water (Found: C = 54.2; H = 5.45. $C_{11}H_{13}O_5N$ requires C = 55.2; H = 5.4 per cent.).* It is thus clear that there is little if any dinitro-derivative formed. The nitration product is partly convertible into an indigotin derivative in the usual way.

Attempted Separation of the Isomerides.—Crystallisation from organic solvents and even from nitric acid is ineffective. The separation by conversion of the *o*-nitrobenzaldehyde into an indigotin derivative has been tried with the following results. The mixture of isomerides (2.9 grams) is converted into 0.4 gram of a pure indigotin (high-melting needles with bronze glance). The filtrate, when treated as in the method described on page 2845, gives 0.8 gram of slightly impure 5-nitro-2:3-diethoxybenzoic acid (see below), melting at 115–117°. This method of separation is very unsatisfactory.

The oxidation of the nitration product of 2:3-diethoxybenzaldehyde with excess of potassium permanganate in potassium carbonate solution results in the formation of considerable quantities of an acid (colourless needles, m. p. 118°), and of a small amount of a much more soluble acid consisting of small, compact crystals

* *Note on the Analysis of Ethoxy-derivatives.*—It was noticed in the course of this work that nitroethoxy- and especially nitrodiethoxy-derivatives tend to give low carbon and very high nitrogen values. For example, the nitration mixture the analysis of which is recorded above gave a nitrogen value of 7.7 per cent. when carried out as usual (calc., N = 5.9 per cent. for one nitro-group and 9.9 per cent. for two nitro-groups). The analysis was repeated, the tube being heated at a higher temperature (Found: N = 6.85 per cent.). Accordingly, pure 2-methoxy-3-ethoxybenzaldehyde (0.1705 gram) was analysed for nitrogen in the usual way (Dumas's method with pure magnesite), and 2.9 c.c. of "nitrogen" were obtained at 19° and 758 mm. This gas decolorised dilute potassium permanganate solution, being partly absorbed in the process, and very probably contained ethylene. Its production can be entirely avoided by carrying out the combustion at considerably higher temperatures than usual and using larger quantities of copper oxide. In this way, no "nitrogen" was produced from the same specimen of 2-methoxy-3-ethoxybenzaldehyde. The lowering of the carbon value in ethoxy- and (where it is generally greater) in diethoxy-derivatives can be similarly prevented.

melting at about 102° . This is very probably a more or less pure form of 6-nitro-2:3-diethoxybenzoic acid, but has not been further examined. A mixture of two or more acids is also formed. The acid, m. p. 118° (Found: equivalent = 253. $C_{11}H_{13}O_6N$ requires equivalent = 255), when boiled for eight hours with excess of 2N-sodium hydroxide, is converted into 5-nitro-2-hydroxy-3-ethoxybenzoic acid (Davies, *loc. cit.*, p. 1589), and therefore is 5-nitro-2:3-diethoxybenzoic acid.

5-Nitro-2:3-diethoxybenzaldehyde, obtained in good yield by the ethylation of 5-nitro-2-hydroxy-3-ethoxybenzaldehyde by means of ethyl iodide and silver oxide, consists of pale yellow needles melting at 71° . It is converted by oxidation into the nitrodiethoxybenzoic acid (m. p. 118°) already described, the identity being established by the method of mixed melting points.

Nitration of 2:3-Diethoxybenzoic Acid.—2:3-Diethoxybenzaldehyde (2.4 grams), suspended in 25 c.c. of a boiling 10 per cent. potassium bicarbonate solution, is gradually oxidised with potassium permanganate (2.4 grams) in hot water (30 c.c.), the oxidising solution being added in very small amounts at a time. Even when this large excess of permanganate has been used, the pungent odour of the aldehyde is still perceptible. The acid is worked up in the usual way, when 1.5 grams of colourless crystals are obtained. 2:3-Diethoxybenzoic acid melts at 55.5° , is very soluble in boiling water and moderately soluble in cold water.

Nitrated in the usual way (10 c.c. of nitric acid, *d* 1.42), the acid (1.1 grams) yields 0.75 gram of needles (recrystallised from hot water) melting at 118° . Beyond the fact that the melting point of the uncrystallised acid is rather low, there is no evidence of the presence of an isomeric acid. The acid isolated does not depress the melting point of specimens of the nitrodiethoxybenzoic acid (m. p. 118°) already obtained.

Bromination of 2:3-Diethoxybenzaldehyde.

The aldehyde (2 grams), dissolved in glacial acetic acid (15 c.c.), is treated with a solution of bromine (1.9 grams) in acetic acid (5 c.c.). The temperature rises, and the reaction product, having been maintained under anhydrous conditions for three days, is poured into water, when an oil is produced which solidifies after long standing. This substance (2.1 grams) crystallises from ethyl alcohol in long, colourless needles melting at 46° . The *p*-nitrophenylhydrazone crystallises from alcohol, in which it is sparingly soluble, in orange-red hairs melting at 207° . The free aldehyde when nitrated is converted into a substance, light yellow plates, m. p. 110° (Found: C = 41.3; H = 4.0. $C_{11}H_{12}O_5NBr$ requires C = 41.5; H = 3.8

per cent.), which is readily transformed into a derivative of indigo-tin.

The bromo-derivative of 3-ethoxysalicylaldehyde is ethylated by means of ethyl *p*-toluenesulphonate (compare page 2847), the product slowly solidifying to give 5-bromo-2:3-diethoxybenzaldehyde, identical with the substance described above which melts at 46°. The *p*-nitrophenylhydrazone consists of orange-red hairs melting at 206° (Found : Br = 19.5. $C_{11}H_{14}O_4N_3Br$ requires Br = 19.7 per cent.).

Nitration of 3-Chlorosalicylaldehyde and its Derivatives.

3-Chlorosalicylaldehyde has already been prepared by the reduction of 3-chlorosalicylic acid (D.R.-P. 228838) and is described as a solid melting at 54°. The material required in this investigation has been made from *o*-chlorophenol by the Reimer-Tiemann reaction. The yield is only 10 to 15 per cent. of the *o*-chlorophenol taken, partly owing to the formation of a large proportion of 3-chloro-*p*-hydroxybenzaldehyde, which is non-volatile in steam. The required hydroxy-aldehyde is separated from the large amount of unchanged *o*-chlorophenol in the steam distillate by means of its sodium bisulphite compound, and crystallises from methyl alcohol in long, colourless needles, which melt at 55° and are readily soluble in the usual organic solvents.

Nitration of 3-Chlorosalicylaldehyde.—This phenolic derivative is not nitrated by a cold glacial acetic acid solution of nitric acid. The aldehyde (2 grams) in glacial acetic acid (10 c.c.) is treated at 45° with nitric acid (0.8 c.c.; d 1.42) in 4 c.c. of acetic acid, the temperature being maintained at 40–45° for a quarter of an hour, when crystals begin to separate. After an hour at room temperature, the product is poured into water, when 2.15 grams of the nitro-derivative, m. p. 125–127°, are obtained. 3-Chloro-5-nitro-2-hydroxybenzaldehyde crystallises from dilute alcohol in yellow needles, m. p. 129°, and gives a deep violet coloration with alcoholic ferric chloride solution (Found : N = 6.7. $C_7H_4O_4NCl$ requires N = 6.9 per cent.).

3-Chloro-5-nitro-2-methoxybenzaldehyde (XVII).—The methylation is conveniently carried out by Purdie's method (see below). Pure ether has been used as solvent in this case, the time required being three hours and the yield practically quantitative. When crystallised from methyl alcohol, the product is obtained in faintly yellow needles, m. p. 90°. The melting point of this substance changes on keeping (Found : C = 44.4; H = 3.06. $C_8H_6O_4NCl$ requires C = 44.5; H = 2.8 per cent.).

3-Chloro-5-nitro-2-methoxybenzoic Acid (XVIII).—The preceding

aldehyde, oxidised in the way described on page 2849, yields an *acid*, colourless needles, which is moderately soluble in water and melts at 155.5° (Found: equivalent = 231. $C_8H_6O_5NCl$ requires equivalent = 231.5).

3-Chloro-2-methoxybenzaldehyde.—The methylation of 3-chloro-salicylaldehyde does not proceed smoothly with methyl sulphate, but is almost quantitatively carried out by Purdie's method. *3-Chloro-2-methoxybenzaldehyde* is a fragrant, limpid liquid, b. p. about 255° , which solidifies at 0° in colourless needles. It is readily oxidised to the corresponding acid by atmospheric oxygen, and the low carbon result in the following analysis is attributed to slight oxidation (Found: C = 55.5; H = 4.0. $C_8H_7O_3Cl$ requires C = 56.3; H = 4.1 per cent.). This ether is converted in the usual way into the corresponding *3-chloro-2-methoxybenzoic acid*, white leaves, m. p. 117° , readily soluble in hot and slightly soluble in cold water (Found: equivalent = 189. $C_8H_7O_3Cl$ requires equivalent = 186.5).

Nitration of 3-Chloro-2-methoxybenzaldehyde.—This derivative of anisole is not nitrated by cold concentrated nitric acid, and even at 90° the nitration is very slow. A mixture of concentrated nitric acid (0.5 c.c.: d 1.50) and concentrated sulphuric acid (1 c.c.), cooled to -10° , is stirred vigorously while the methyl ether (1.0 gram) is very gradually added. After being stirred for four hours, the product is poured into water, when it solidifies, and after washing and drying weighs 1.1 grams. No trace of an indigotin derivative is obtained by the action of acetone and sodium hydroxide solution.

In order to separate any nitro- or dinitro-derivatives of *o*-chloro-anisole from the nitro-aldehyde, the nitration product is dissolved in ether, an almost saturated solution of sodium bisulphite added, and the mixture vigorously shaken. The bisulphite compound is collected after several hours, washed with ether, and then decomposed with hydrochloric acid. The aldehyde obtained (0.75 gram) is recrystallised from methyl alcohol, from which it separates in pale yellow needles melting at 90° , and also at this temperature when mixed with the methyl ether prepared from the nitration product of 3-chlorosalicylaldehyde (page 2850).

Nitration of 3-Chloro-2-methoxybenzoic Acid.—This acid, like the corresponding aldehyde, is not readily nitrated by nitric acid alone, but is attacked by excess of a mixture of equal parts of nitric acid (d 1.5) and concentrated sulphuric acid. The temperature should be kept between 20° and 30° throughout, during the latter part of the reaction by external heating. Five minutes after all the benzoic acid derivative has been added, the solution is poured into water, and the nitrated acid is obtained in almost quantitative

yield in colourless needles melting at 155.5° ; it is identical with the chloronitromethoxybenzoic acid already described.

It is clear from the above experiments that in the nitration of 3-chlorosalicylaldehyde, its methyl ether, and of 3-chloro-2-methoxybenzoic acid, the nitroxyl in each case enters the same position relative to the chlorine atom. The position actually taken up is shown by the action of alkali on the chloronitromethoxybenzoic acid.

3-Chloro-5-nitro-2-hydroxybenzoic Acid (XIX).—The preceding acid (m. p. 155.5°) (1.5 grams), dissolved in 40 c.c. of 2*N*-sodium hydroxide, is heated on the water-bath for fifteen hours, and the solution acidified with dilute sulphuric acid, when a new acid (1.3 grams) is deposited. The filtrate contains no trace of chloride. The acid, freed from inorganic material by conversion into its sodium salt or by dissolution in ether, in which it is very soluble, crystallises from methyl alcohol in clusters of minute, colourless needles which sinter above 250° (Found: Cl = 16.4. $C_7H_4O_5NCl$ requires Cl = 16.3 per cent.). The alcoholic solution of 3-chloro-5-nitro-2-hydroxybenzoic acid gives with ferric chloride solution a reddish-violet coloration which soon becomes brown. When treated with alkali, the acid forms a deep orange solution.

This experiment shows that in all these nitro-derivatives the nitroxyl is in the position meta to the chlorine atom.

The authors are indebted to the Research Fund Committee of the Chemical Society for a grant which has defrayed some of the expenses of this investigation.

CCCXXXIII.—*Ring-chain Tautomerism. Part VII.* *The $\alpha\beta\beta$ -Trisubstituted Glutaric Acid Type.*

By KANTILAL CHHAGANLAL PANDYA and JOCELYN FIELD
THORPE.

IN Part I of this series (T., 1922, **121**, 650) attention was directed to the probable occurrence of ring-chain tautomerism between the three forms I, II, and III, of a trisubstituted glutaric acid derivative,

and it is in this way that the peculiar properties of the acid $C_8H_{12}O_5$, which Balbiano had obtained by the oxidation of camphoric acid (*Rend. Accad. Lincei*, 1892, I, 278; *Ber.*, 1894, 27, 2133), were explained.

It will be remembered that Balbiano at first suggested the presence of a hydroxyl group in the acid, but that later Mahla and Tiemann (*Ber.*, 1895, 28, 2151) brought forward evidence showing that the acid reacted as if it had the keto-acid formula (type II), and eventually Balbiano, rejecting both these, gave the butylene-oxide formula $Me_2C \begin{smallmatrix} \diagup CMe \cdot CO_2H \\ \diagdown CH - CO_2H \end{smallmatrix} O$ (IV) (*Ber.*, 1897, 30, 289, 1901).

A general review of the arguments in favour of both formulæ (II and IV) was given in Part I, and the conclusion drawn that, whereas the oxide formula of Balbiano should be discarded, there was evidence to warrant the assumption that, in the trimethyl series, there is actual tautomeric interchange between the three individuals, I, II, and III. Care was taken, however, not to emphasise the tautomeric character of the hydroxy-ring form (I), because, although there was ample evidence to show that Balbiano's acid reacted both as a keto-acid (II) and a hydroxy-lactonic acid (III), the only experimental evidence justifying the inclusion of the hydroxy-ring form (I) in the scheme of interchange was the fact that the formation of Balbiano's acid (in either keto- or hydroxy-lactone form) from camphoric acid rendered it necessary that the dihydroxy-acid (V) should intervene as an intermediate product thus :

for it is only through the hydroxy-ring form (I) that it is possible to pass from this dihydroxy-acid (V) to the individuals II and III.

It is evident, however, that the change may be a non-reversible one, in which case the hydroxy-ring acid would merely act as an

intermediary in the production of a more stable complex. If this is the case, and the general experimental evidence brought forward in this paper strongly supports it, we are dealing with two fundamentally distinct phenomena when we discuss the ring-chain tautomerism possessed by a structure such as Balbiano's acid and that shown by the *gem*-substituted glutaric acids investigated by Deshapande and Thorpe (T., 1922, 121, 1430) and Bains and Thorpe (this vol., p. 1206).

In the former case, ring-chain tautomerism occurs between the hydroxy-lactonic acid and the keto-acid, and is of the "direct" type involving the opening and the closing of a five-membered ring ($\text{II} \rightleftharpoons \text{III}$).

In the latter instance, tautomerism occurs between the hydroxy-ring form (I) and the keto-form (II), but is probably due (Lanfear and Thorpe, this vol., p. 1683) to the intermediate formation of a bridged five-membered ring (VI).

If it could be shown (as indeed is the case in this paper) that in Balbiano's acid there is no tautomerism between the keto- and the hydroxy-ring form, it would follow that the entrance of a methyl group on the α -carbon atom profoundly affects the tautomerism to which the complex is liable, giving in fact a preference to ring-chain tautomerism between an open-chain (II) and its five-membered ring isomeride (III) instead of between a three-membered ring (I) and its bridged five-membered prototype (VI).

It is too early yet to suggest any reason why this should be so, and more evidence must be obtained by a study of other α -substituted glutaric acids before the true cause can be discovered. It must be remembered, however, that the conditions in the two series are widely different. For, whereas the determining cause in the *gem*-series is undoubtedly the alteration in the tetrahedral angle, the entrance of an alkyl group in the α -carbon atom introduces conditions which must completely alter the tendency towards tautomerism, because, in order to bring about hydroxy-ring-keto-acid change, the hydrogen atom has, in this case, to pass to a carbon atom already bearing an alkyl group.

Meanwhile, it seemed desirable to ascertain whether the preference for open-chain-five-ring tautomerism in an acid of Balbiano's

type showed itself in any of the simpler derivatives of analogous composition, such as, for example, $\alpha\beta\beta$ -trimethylglutaric acid itself. It is evident (compare T., 1921, 119, 308) that the deflection of the tetrahedral angle in the *gem*-series of substituted glutaric acids increases the tendency to anhydride formation and the stability of the anhydride thus produced. If then there is open-chain-five-ring tautomerism in the $\alpha\beta\beta$ -series, it is to be expected that there might be tautomerism between the forms

in which the six-membered ring is involved.

The experiments in this direction are not conclusive, but there is a marked tendency for the anhydride of $\alpha\beta\beta$ -trimethylglutaric acid to combine with water to form a compound, rather difficult to isolate, which is not the acid. There can be little doubt that this "hydrated" anhydride is the individual (VIII), although the acid (VII) and the hydrated anhydride (VIII) do not appear to be tautomeric.

The experimental evidence regarding Balbiano's acid brought forward by Kon, Stevenson, and Thorpe (*loc. cit.*) was obtained from a study of Balbiano's acid itself, which had been prepared by the slow oxidation of camphoric acid, according to the method adopted by Balbiano and by Mahla and Tiemann (*loc. cit.*). The present work deals with derivatives of $\alpha\beta\beta$ -trimethylglutaric acid (VII), which has been prepared synthetically for this purpose.

Balbiano was the first to obtain the acid (VII), by reducing the acid $\text{C}_8\text{H}_{12}\text{O}_6$ (the chief oxidation product of camphoric acid) by hydrogen iodide and red phosphorus (*Ber.*, 1894, 27, 2136), as well as, later on, by the further reduction of the lactonic acid, $\text{C}_8\text{H}_{12}\text{O}_4$ (XIV), which was itself another reduction product of the compound $\text{C}_8\text{H}_{12}\text{O}_5$ (*Rend. Accad. Lincei*, 1899, [v], 8, 422). A more suitable method was then made available by Perkin and Thorpe (T., 1899, 75, 61), who synthesised it and established its constitution. This was followed by another synthesis by Crossley (T., 1901, 79, 141), which, when this work was taken up, was certainly the best method available. About 500 grams of $\alpha\beta\beta$ -trimethylglutaric acid were prepared by this method, which was followed, with a few modifications described in the experimental portion.

A shorter and easier method was subsequently discovered by Kon and Thorpe (T., 1922, 121, 1795). Guareschi's imide, $\alpha\alpha'$ -dicyano- $\beta\beta$ -dimethylglutarimide (IX), was methylated to give the imide (X) and this, on hydrolysis with strong sulphuric acid, passed into $\alpha\beta\beta$ -trimethylglutaric acid (VII):

This method had the additional advantage that the costly methyl iodide, necessary in Crossley's process, could be replaced by the cheaper methyl sulphate. When used on the large scale, however, this reagent proved to be uncertain in its action and, ultimately, methyl *p*-toluenesulphonate was used with good results; the yield of methylated imide obtained in this way was equal to the best reached by means of methyl sulphate.

The mono-bromination of the acid proceeds normally, although, when the product is esterified with ethyl alcohol, there is always an appreciable portion, from 20 to 49 per cent., of acid fraction. This acid fraction invariably contains, together with the liquid acid esters, a quantity of solid crystalline matter which does not contain bromine, and is evidently produced by the hydrolysis of a mono-halogen derivative; it consists of the lactone of α' -hydroxy- $\alpha\beta$ -trimethylglutaric acid (XI) and is identical with the lactonic acid obtained by Balbiano by reduction of the acid $\text{C}_8\text{H}_{12}\text{O}_6$, and named by him $\gamma\delta$ -trimethylpentane- $\beta\epsilon$ -olidoic acid (*Ber.*, 1894, 27, 2136). The formation of this lactonic acid in the manner described has also been noted by Balbiano (*Rend. Accad. Lincei*, 1899, [v], 8, 422), who, by heating $\alpha\beta\gamma$ -trimethylglutaric anhydride (from camphor) with bromine, obtained bromotrimethylglutaric anhydride, and, after esterifying the bromo-derivative with absolute alcohol, found the lactonic acid (XI) in the alkaline extract.

After removal of the crystals of this lactonic acid by filtration, a syrup is left, the composition of which corresponds with that of the pure monobromo-acid ester. It appears to be a mixture of the acid esters of the two isomeric monobromo-acids (XII and XIII), because, by the action of alkalis, it yields a mixture of two

lactonic acids, $\text{C}_8\text{H}_{12}\text{O}_4$, one of which is Balbiano's lactonic acid (XI) and the other, obtained in smaller proportion, Blanc's isomeric acid (XIV). The latter is the lactone of α -hydroxy- $\alpha\beta\gamma$ -trimethylglutaric acid, whilst the former (XI) is the lactone of the corresponding α' -hydroxy-acid.

The acid (XIV) is identical with the $\beta\beta\gamma$ -trimethylpentan- $\beta\epsilon$ -olidoic acid of Blanc, who obtained it from $\beta\beta$ -dimethyl-lævulinic

acid in his unsuccessful attempt at a new synthesis of $\alpha\beta\beta$ -trimethylglutaric acid (*Bull. Soc. chim.*, 1901, [iii], 25, 68). It may be noted that Balbiano afterwards found that this lactonic acid (XIV) was also a reduction product of the acid $C_8H_{12}O_5$, and, in fact, was formed from it simultaneously with the isomeric lactone (XI) (*Gazzetta*, 1902, 32, i, 485).

Similarly, the neutral product of monobromination is a mixture of the two monobromo-esters (XV) and (XVI), because it gives a mixture of the same lactones (XI) and (XIV) on hydrolysis with alkalis.

Dibromination leads to the formation of the dibromo-ester (XVII), the acid fraction, which is always considerable, consisting of the monobromo-acid ester together with a certain quantity of Balbiano's lactone (XI), which soon separates out in a crystalline form. The dibromo-ethyl ester cannot be purified, as on distillation under reduced pressure it passes into the lactonic ester (XVIII).*

By pouring the dibromination product into anhydrous formic acid, two dibromo-acids were obtained which must be related as *cis*- and *trans*-forms (XIX and XX):

The number of possible bromolactonic acids derived from these two acids, as well as from the third, unsymmetrical dibromo-acid (XXI), supposing it to be formed, would be six, of which two were isolated in a state of purity.

There are also, of course, six possible hydroxy-lactones, and only one of these would be the hydroxy-lactone (III) which is one

* It has not yet been possible to decide between the two alternative formulæ.

of the tautomeric individuals of Balbiano's acid. Unfortunately, it has not been found possible to isolate this lactone, mainly because all the dibromo-derivatives of $\alpha\beta\beta$ -trimethylglutaric acid, when treated with alkaline hydroxides, undergo hydrolytic fission and partial oxidation with extraordinary readiness, the products being $\alpha\beta\beta$ -trimethylacrylic and oxalic acids :

This was also Balbiano's experience with his bromolactonic acid, although he did not recognise the trimethylacrylic acid formed (*loc. cit.*).

A hydroxy-lactonic acid is actually obtained by the action of sodium carbonate on the dibromo-ester or acid, or the bromo-lactonic acid, but it is a very stable substance of high melting point (217.5–218°) and has, up to the present, withstood every attempt to convert it into the lower-melting isomeride.

The hydrolysis with sodium carbonate invariably yields, in addition to this lactonic acid, another substance, $\text{Me}_2\text{C} \begin{array}{c} \diagup \text{CMe} \\ \diagdown \text{C}(\text{CO}_2\text{H}) \end{array} \text{CO}$ (XXIII), which is the lactone of the hydroxy-ring acid (I).

This must be the lactone of the *trans*-modification, and therefore of the acid which would be tautomeric with Balbiano's acid. That this *trans*-form does not actually pass into Balbiano's acid by the non-reversible process discussed on p. 2854 must be due to the fact that the dihydroxy- and hydroxy-ring acids produced from γ -camphoric acid, which could do so, would necessarily be *cis*-forms ($\text{V} \rightarrow \text{I}$).

The lactone of the *trans*-form (XXIII) which we have obtained evidently does not pass into Balbiano's acid, because it does not give the characteristic condensation product with *o*-phenylenediamine and is recovered unchanged after boiling with a variety of reagents such as water, barium hydroxide, 10 per cent. sodium hydroxide, 64 per cent. potassium hydroxide, and dilute or concentrated hydrochloric acid.

Thus it is clear that the hydroxy-ring acid cannot be tautomeric with the keto-acid and the hydroxylactonic acid in the compound known as Balbiano's acid.

EXPERIMENTAL.

Preparation of $\alpha\beta\beta$ -Trimethylglutaric Acid.

1. *Crossley's Method*.—Crossley's instructions (*loc. cit.*) were followed, but larger quantities of material were employed; this

necessitated heating the mixture of mesityl oxide and ethyl sodio-methylmalonate for sixteen hours instead of ten. We also find that it is advantageous to use 10 per cent. more hypobromite solution than is recommended by Crossley, to avoid the formation of brominated by-products during the oxidation of the dihydroresorcinol derivative to $\alpha\beta$ -trimethylglutaric acid.

2. *Modification of Kon and Thorpe's Method.*—The imide (IX) was prepared by the usual method (Kon, T., 1921, **119**, 818). The methylation of the imide by means of methyl sulphate in presence of sodium methoxide did not always lead to good results when used on a large scale, and for this reason methyl *p*-toluenesulphonate was the methylating agent adopted.

To a solution of 35 grams of sodium in 500 c.c. of methyl alcohol, 96 grams of imide (IX) in 550 c.c. of hot methyl alcohol were added and the red solution was warmed for half an hour; 280 grams of methyl *p*-toluenesulphonate were then gradually added with vigorous shaking. Much heat was evolved and crystals began to separate. The reaction was completed by heating the mixture under reflux for one to one and a half hours, when it became neutral or faintly acid. Most of the alcohol was then evaporated off and water was added to the residue. The methylated imide gradually separated and the precipitation was completed by the addition of hydrochloric acid; the solid was collected after a few hours and found to be identical with that obtained by Kon and Thorpe (*loc. cit.*); it melted at 143–144° after purification. The mother-liquor deposited more of the same substance on standing; on evaporation, sodium *p*-toluenesulphonate was recovered and identified by converting it into the corresponding acid chloride (m. p. 69°) and the methyl ester (m. p. 28°; Ullmann and Wenner, *Annalen*, 1903, **327**, 120).

When hydrolysed by means of sulphuric acid in the usual way, the methylated imide gave a good yield (about 80 per cent.) of $\alpha\beta$ -trimethylglutaric acid.

Bromination of $\alpha\beta$ -Trimethylglutaric Acid.

The bromination of trimethylglutaric acid was carried out in the manner described in previous communications (compare this vol., p. 113). The products of mono- as well as di-bromination were treated either with absolute alcohol to obtain the corresponding esters, or with anhydrous formic acid to prepare the bromo-acids. The acid esters obtained in the first case were separated from the neutral bromination products by means of 2*N*-aqueous sodium carbonate.

It was observed that when phosphorus pentachloride was used

in the preparation of trimethylglutaryl chloride the bromination products were but faintly coloured and clean, but an appreciable amount of triethyl phosphate was always produced, so that the yield of bromo-esters apparently exceeded the theoretical. The use of thionyl chloride did not present this disadvantage, although the rate of absorption of bromine was considerably slower and the products were somewhat coloured.

Monobromination.—2.1 Atoms of bromine were used for 1 molecule of acid chloride, the temperature being maintained at about 60° during the reaction; the crude bromo-acid chloride was poured into ethyl alcohol. The *neutral* bromination product constituted from 50 to 70 per cent. of the total yield. An estimation of the bromine content showed a deficit of about 5 per cent. of bromine in the crude substance, which was due to the presence of ethyl trimethylglutarate (see p. 2863); it was not found possible to purify it further, as it decomposed when distilled under reduced pressure, and it was therefore used as such for further experiments. The reactions of the substance showed that it was composed of a mixture of α - and α' -monobromo-esters (XV and XVI).

The *acid* bromination product also showed a low bromine content (Found: Br = 23.96 per cent.), but on keeping in an evacuated desiccator it slowly deposited crystals of the bromine-free lactone (XI) (see p. 2856). After these had been removed, the residual oil was analysed again and gave figures in good agreement with those required for the acid monobromo-ester (Found: Br = 27.96. $C_{10}H_{17}O_4Br$ requires Br = 28.47 per cent.); it has already been mentioned that the substance was doubtless a mixture of α - and α' -bromo-acid esters.

Dibromination.—In the preparation of dibromo-derivatives 4.5 to 5 atoms of bromine were used for every molecule of acid chloride, the addition of bromine being made in four stages; the reaction mixture was maintained at 80–100° towards the end of the reaction.

The crude *neutral* dibromo-ester, which constituted 60–80 per cent. of the reaction product, was analysed after keeping in an evacuated desiccator for some time, but the bromine content was always 5 to 7 per cent. too low. On distillation under reduced pressure, it gave a small fraction boiling at 160°/25 mm., a large fraction boiling at 190°/25 mm., and a smaller high fraction, b. p. 196–200°/25 mm.

The *acid* dibromination product was found to be identical in every respect with that obtained in the monobromination of trimethylglutaric acid; it deposited crystals of the lactonic acid (XI) on keeping, whilst the residual oil consisted of a mixture of

the two monobromo-acid esters, as shown by the products obtained on alkaline hydrolysis.

Lactone of Ethyl α (or α')-Bromo- α' (or α)-hydroxy- $\alpha\beta$ -trimethylglutarate (XVIII).—The bromine content of the fraction of the neutral dibromination product boiling at $190^{\circ}/25$ mm. showed that the substance must be the bromolactone formed by elimination of ethyl bromide from the original dibromo-ester (Found: Br = 28.85. $C_{12}H_{20}O_4Br_2$ requires Br = 41.23 per cent. $C_{10}H_{15}O_4Br$ requires Br = 28.67 per cent.).

cis- and trans- $\alpha\gamma$ -Dibromo- $\alpha\beta\beta$ -trimethylglutaric Acids.—When the crude dibrominated acid chloride (see p. 2860) was poured into formic acid and the solution allowed to evaporate, crystals separated in several successive crops; these were collected and freed from oil by pressing on porous tiles and washing with cold benzene. The solid was twice extracted with boiling dry chloroform, when the greater part passed into solution. The insoluble residue was recrystallised three times from a mixture of chloroform and acetone. In this way crystals melting and decomposing at 196 – 197° were obtained (Found: Br = 51.08; equiv. = 152.5. $C_8H_{12}O_4Br_2$ requires Br = 48.19 per cent.; equiv. [dibasic] = 166). In spite of repeated purification, the bromine content was always found to be too high. This acid constitutes only about 5 per cent. of the total crystalline material isolated; by analogy with the other dibromo-acids of the glutaric series, this acid is assumed to be the *trans*-modification.

The chloroform solution obtained above deposited a crop of crystals on cooling and these were found to consist of both *cis*- and *trans*-acids in addition to the bromolactonic acids. The small quantity of *trans*-acid was removed owing to its sparing solubility in hot chloroform and the remaining acid purified by repeated treatment with cold benzene and cold chloroform, then crystallised alternately from these solvents. The acid so obtained separated from a large quantity of hot benzene in lustrous leaflets, m. p. 158 – 159° (decomp.) (Found: Br = 50.76; equiv. = 159.3), and evidently represented the *cis*-modification of the same acid.

Lactones of Bromohydroxytrimethylglutaric Acids.—The chloroform mother-liquors from which the preceding *cis*- and *trans*-dibromo-acids had been separated were mixed with light petroleum and allowed to stand, when a considerable amount of solid material was gradually precipitated. This was subjected to a long and tedious process of fractional crystallisation, but only a small quantity of pure substance could be isolated owing to the similar solubilities of the constituents of the mixture in various solvents. Eventually a compound was isolated which melted at 155° and

did not change its melting point on crystallisation from hot water, benzene, or chloroform and petroleum. It appears to be a bromolactonic acid (Found: Br = 32.92; equiv. = 245.6. $C_8H_{11}O_4Br$ requires Br = 31.87 per cent.; equiv. [monobasic] = 251).

This substance was also obtained when crude dibromotrimethylglutaryl chloride was treated with 80 per cent. formic acid instead of the anhydrous reagent; no dibromo-acids were isolated, but another isomeric bromolactonic acid, soluble in cold benzene, was present in small amount. It melted sharply at 132° (Found: Br = 32.01 per cent.).

Lactone of α' -Hydroxy- $\alpha\beta\beta$ -trimethylglutaric Acid.—As already stated, the crude monobromo-acid ester which is obtained in the mono- or di-bromination of trimethylglutaryl chloride deposits crystals of a bromine-free product. These crystals were purified by pressing on porous porcelain and washing with cold benzene, in which they were sparingly soluble; they dissolved readily in hot benzene, ethyl acetate, alcohol, or ether; after repeated crystallisation from benzene, the compound melted constantly at 165.5 — 166° . It was evidently identical with the lactonic acid prepared by Balbiano by the reduction of the acid $C_8H_{13}O_5$ (*loc. cit.*); and by Chandrasena, Ingold, and Thorpe (T., 1922, 121, 1550) by the oxidation of α -campholytic acid; its identity with the latter was confirmed by a mixed melting-point determination (Found: C = 55.62; H = 6.64; Ag in silver salt = 39.7; equiv., by titration with $Ba(OH)_2$ = 173.2. Calc., C = 55.8; H = 6.9; Ag = 38.7 per cent.; equiv. [monobasic] = 172).

Action of Dilute Sodium Carbonate Solution on the Monobromo-acid Ester.—The monobromo-acid ester (20 grams), freed from the solid lactone melting at 165.5 — 166° , was dissolved in 2*N*-sodium carbonate solution and boiled until a test-portion no longer gave a turbidity on acidification, care being taken that an excess of alkali was present throughout. The solution was cooled, acidified, and repeatedly extracted with ether; the ethereal solution on drying and distillation yielded 11 grams of a brown syrup. An additional amount of syrup (about 4 grams) was obtained by evaporating the aqueous solution to dryness with hydrochloric acid and extracting the solid residue with ether. The syrup crystallised and the solid, freed from oil by draining on porous porcelain, was subjected to crystallisation from hot benzene, when it was noticed that a small amount remained undissolved. This residue was repeatedly boiled with benzene and finally crystallised from dry ether, from which it separated in small, transparent, prismatic needles melting at 163 — 164° . It was not identical with Balbiano's lactonic acid, because a mixture of the two melted at

about 125°, but was doubtless Blanc's lactonic acid (XIV) [Found: C = 55.4; H = 6.7 per cent.; equiv., by titration with $\text{Ba}(\text{OH})_2$, 172.2; after boiling with excess of $\text{Ba}(\text{OH})_2$, equiv. = 85.8]. The crystalline material which remained after the separation of the lactonic acid melted indefinitely at 115–138°; titration with barium hydroxide showed that it was probably a mixture of the lactonic acids, m. p.'s 163–164° and 165.5–166°.

Action of Concentrated Alkalis on the Monobromination Products.

—Twenty grams of the acid ester were poured in a thin stream into a boiling solution of 60 grams of potassium hydroxide in 50 c.c. of water; the mixture was allowed to boil a few minutes longer, cooled, diluted, strongly acidified, and extracted with ether. The dried ethereal solution gave, on evaporation, 12 grams of a syrup which soon solidified; the solid was drained on porous porcelain, yielding 6 grams of a white solid, which was purified by crystallisation from benzene and found to consist of Balbiano's lactonic acid (XI) melting at 165.5–166°. The same substance, mixed with some of the isomeride melting at 163–164° (XIV), was also produced when a stronger alkali (70 grams of potassium hydroxide in 40 c.c. of water) was used to hydrolyse the acid or neutral monobromo-esters; in the latter case, a small amount of $\alpha\beta$ -trimethylglutaric acid was also found, which was doubtless due to the presence of unbrominated ester in the monobromo-ester used.

Action of 2N-Sodium Carbonate on the Dibromination Products.

—Forty grams of the neutral dibromo-ester were boiled with 250 c.c. of 2N-aqueous sodium carbonate for twenty-four hours. After a small amount of unchanged ester had been removed by means of ether, the liquid was strongly acidified and extracted six times with an equal volume of ether; the aqueous solution was evaporated to dryness, the residue treated with hydrochloric acid, and the solution evaporated to dryness; finally the residue was thoroughly dried and extracted with ether and with acetone. These latter extracts, however, contained very little organic matter, but the first ethereal extract gave, on drying and evaporating, a considerable amount of syrup which partly solidified on keeping for some time. The solid which had crystallised out was drained on porous porcelain and separated, by repeated crystallisation from hot benzene and hot chloroform alternately, into two acids. The less soluble was finally obtained pure by crystallisation from benzene and acetone, from which it separated in needles melting at 217.5–218°; it could also be recrystallised from dry ether and benzene, dry ether and chloroform, or acetone and chloroform. The acid did not give a silver salt, but behaved on titration as a

monobasic acid even on boiling with excess of *N*/25-barium hydr. oxide; on heating with stronger alkali (*N*/10), however, the lactone ring was broken (Found: C = 50.47; H = 6.2; equiv. 187.5 and 96.1. A lactonic acid $C_8H_{12}O_5$ requires C = 51.0; H = 6.5 per cent.; equiv. 188 and 94).

The more soluble acid separated from benzene in prismatic needles and melted at 136.5–137°. It was the lactone of trans-1:3:3-trimethylcyclopropan-2-ol-1:2-dicarboxylic acid (XXIII) (Found: C = 56.06; H = 5.98; equiv. 171.1 and 84.9. A lactonic acid $C_8H_{10}O_4$ requires C = 56.47; H = 5.88 per cent.; equiv. 170 and 85). The substance is soluble in water and effervesces with sodium hydrogen carbonate, but does not give a silver salt under the usual experimental conditions.

The syrup accompanying the above compounds was recovered from the porous plates used in their purification, but no individual substance could be isolated from it.

The same two lactonic acids were obtained when either *cis*- $\alpha\alpha'$ -dibromo- $\alpha\beta\beta$ -trimethylglutaric acid or the bromolactonic acid (p. 2862), m. p. 155°, was boiled with 2*N*-sodium carbonate for two hours. They were separated by rubbing with a mixture of benzene and dry ether (6:1), in which the lactonic acid melting at 217.5–218° is sparingly soluble.

Action of Concentrated Alkalis on the Dibromination Products.—Thirty grams of neutral dibromo-ester were slowly poured into a boiling solution of potassium hydroxide (105 grams) in water (60 c.c.). The reaction mixture was cooled and a small amount of unchanged ester removed by means of ether. The solution on acidification deposited 1.5 grams of an acid crystallising in long needles; the mother-liquor was extracted with ether and the extract dried and evaporated, yielding about 12 grams of a brown syrup.

The solid after two crystallisations from warm water melted at 70.5–71° and proved to be $\alpha\beta\beta$ -trimethylacrylic acid (Perkin, T., 1896, 69, 1480) (Found: C = 62.77; H = 8.56. Calc., C = 63.15; H = 8.77 per cent.). More of this acid could be obtained from the syrupy portion of the reaction mixture, which, in addition, contained considerable quantities of oxalic acid, identified in the usual manner. No trace of Balbiano's acid could be discovered in any portion of the reaction product, although a careful search was made.

The same two products were obtained when the dibromo-ester was hydrolysed by means of 56, 15, or even 10 per cent. potassium hydroxide, also when either the bromolactonic acid or the bromolactonic ester (XVIII) was subjected to the action of this reagent.

Experiments with the Lactonic Acids $C_8H_{10}O_4$ and $C_8H_{12}O_5$.

1. *Acid $C_8H_{10}O_4$.*—The acid was warmed in acetic acid solution with an excess of *o*-phenylenediamine in the hope of obtaining the *o*-phenylenediamine derivative of Balbiano's acid (see Part I, *loc. cit.*). No precipitate was formed.

Boiling with water for three hours, with an equivalent of barium hydroxide, or an excess of 10 per cent. sodium hydroxide or 64 per cent. potassium hydroxide, produced no change; heating in a sealed tube with 10 per cent. hydrochloric acid and boiling with the concentrated reagent were equally unsuccessful, whilst boiling with 48 per cent. hydrobromic acid produced partial resinification, but no trace of Balbiano's acid could be isolated from the product by means of *o*-phenylenediamine.

2. *Acid $C_8H_{12}O_5$.*—The same tests were applied to the lactonic acid melting at $217.5-218^\circ$ without success.

Our thanks are due to the Chemical Society for a grant which has partly defrayed the cost of this investigation.

CCCCXXIV.—*Ring-chain Tautomerism. Part VIII.*

The Effect of the cycloHexane Nucleus on the Carbon Tetrahedral Angle.

By ERIC WILLIAM LANFEAR and JOCELYN FIELD THORPE.

EVIDENCE has been given in the previous parts of this series which shows that two isomeric substances of types (I) and (II) may be

tautomeric when conditions are present which cause the carbon atoms (a) and (b) to be sufficiently close together. The distance apart of these two carbon atoms is, according to our general hypothesis, determined by the value of the carbon tetrahedral angle (x), which is controlled by the size of the corresponding angle (y), the value of the angle (y) being dependent on either the molecular

volumes of the groups represented by RR, or by the fixation of the value of (y) by the inclusion of the groups RR in a ring complex, the carbon-to-carbon angles of which are known. It follows, therefore, that if the conditions present do not cause the carbon atoms (a) and (b) to be sufficiently close together to render the two compounds (I) and (II) tautomeric, they must be either (1) so far apart that ring closure does not occur in compound (I) under the experimental conditions which lead to the formation of the equilibrium mixture of (I) and (II) when the two compounds are tautomeric, or (2) they must be so close together that the ring form (II) does not undergo fission under the same experimental conditions. The following table shows the series which have been investigated up to the present and gives the equilibrium mixtures which are attained in aqueous potash at 145° :

RR'.	Calculated angle.	Equilibrium.	
	$\begin{matrix} R \\ R' \end{matrix} > C < x.$	Keto acid per cent.	Hydroxy-ring acid per cent.
2 Hydrogens	115.3°	100	0
2 Methyls	109.5	100	0
<i>cyclo</i> Pentane	109.4	100	0
Methylethyl	$109.5-x$	100	0
2 Ethyls	$109.5-y$	38	62
2 <i>n</i> -Propyls	$109.5-z$	29	71
<i>cyclo</i> Hexane	107.2	0	100

In other words, it has now been experimentally verified that the keto-acids belonging to the first four series given in the above table are stable towards strong aqueous potash, that the keto-acids and the hydroxy-ring acids in the diethyl and di-*n*-propyl series are tautomeric under these conditions and that, in the *cyclo*hexane series, the hydroxy-ring acid is stable to strong potash. It only remains, therefore, to show that in the first four series given in the table the hydroxy-ring acids are unstable and that in the *cyclo*hexane series the keto-acid is unstable in order completely to establish the truth of our hypothesis.

The evidence that the hydroxy-ring form is unstable in the first three series is quite definite and convincing. The compounds are not formed in any of the reactions which lead to the formation of the homologue in the *cyclo*hexane series, such as, for example, the action of aqueous potash on the dibromo-ester (III). Moreover, any attempts made to hydrolyse the methoxy-derivatives (IV) either in the *cis*- or the *trans*-forms yield only the keto-acid. It is evident, therefore, that as soon as the necessary mobile hydrogen atom is introduced the ring breaks and the keto-acid is formed. It follows also that the formation of the methoxy-derivatives in these series must have taken place through the bromo-ring com-

pound (V), a reaction course which is probably pursued to some extent in every case.

It is only in the *cyclopentane* series that it was found possible to isolate a hydroxy-ring acid (this vol., p. 1683), but unlike the stable hydroxy-ring acid of the *cyclohexane* series and those of the diethyl and di-*n*-propyl series, which are tautomeric, this hydroxy-ring acid was a *cis*-form, readily giving an anhydride. The *cis*-hydroxy-ring acid was stable to strong aqueous potash, but when treated with hydrobromic acid it passed into the keto-acid. It was therefore clear that the change from the hydroxy-form to the keto-form took place only through the *trans*-modification of the hydroxy-ring acid, and on this account we suggested a mechanism which explained the manner in which the hydrogen atom passed from one carbon atom to the other (*loc. cit.*, p. 1686). It is, however, the absence of the *trans*-modifications in these series which indicates that it is this form which is unstable and that it is the one through which the keto-cyclol change takes place. It does not, of course, follow that, because the *cis*-hydroxy-ring acid yields the keto-acid when it is treated with hydrobromic acid, the conversion is preceded by a change from the *cis*- to the *trans*-configuration. It is evident that the transformation may have taken place through the addition and elimination of hydrogen bromide thus:

Indeed, the experiments described in this paper show that this is, in all probability, one of the courses which the reaction follows. Having, therefore, proved conclusively that the hydroxy-ring form is unstable in the first four series enumerated in the table, it became necessary to settle the final point, namely, whether the keto-acid is unstable in the *cyclohexane* series.

In the first place it is significant that no trace of this acid was found by Beesley, Ingold, and Thorpe (T., 1915, 107, 1080) in their experiments on the action of aqueous potash on the dibromo-ester (III) in the *cyclohexane* series, although it was obtained in small amount some years later by an indirect method (Ingold, Sealey, and Thorpe, this vol., p. 867). This method is, however,

too costly and difficult for practical purposes and therefore we decided to repeat the work of Beesley, Ingold, and Thorpe in order carefully to study the reaction in the light of experience which had been gained during the past eight years. When this was done, it was found possible to isolate both the *cis*- and the *trans*-form of the hydroxy-ring acid (VI) and to find that, whereas both forms were stable to strong aqueous potash as we anticipated they would be, yet both could be split by strong hydrobromic acid. In this way, the *cis*-form is completely transformed into the keto-acid, whilst the *trans*-modification yields under the same conditions a mixture of the keto-acid and the bromolactone. It is evident that the scheme representing these changes can be expressed as follows:

In this way, it is possible to prepare the keto-acid in considerable quantity. The keto-acid is completely converted into the hydroxy-ring acid when heated at 140° with aqueous caustic potash.

EXPERIMENTAL.

Hydrolysis of Ethyl α'-Dibromocyclohexane-1:1-diacetate: cis- and trans-cycloHexanespiro-1-hydroxycyclopropane-1:2-dicarboxylic Acids (VII and VI).—Ten grams of the dibromo-ester, prepared as described previously (Beesley, Ingold, and Thorpe, *loc. cit.*, p. 1083), were added as quickly as was consistent with safety to 60 c.c. of boiling 6*N*-methyl-alcoholic potassium hydroxide, and the boiling was continued for twenty minutes. The alcohol was then evaporated off entirely, and the filtered aqueous solution was acidified with hydrochloric acid and extracted eight times with its own volume of ether. On evaporating the ethereal solution, a gummy residue consisting of a mixture of the *cis*- and *trans*-acids remained. This

was triturated with dry ether, in which the *trans*-acid is insoluble, and filtered. The insoluble portion was recrystallised from undried ether, from which it separated in small crystals melting at 217°. Its identity was proved by comparing it with a specimen prepared from the bromolactone (Beesley, Ingold, and Thorpe, *loc. cit.*). Yield 3 grams (Found: C = 55.8; H = 6.7. Calc., C = 56.1; H = 6.6 per cent.).

The *disilver* salt was prepared from silver nitrate and the ammonium salt in aqueous solution (Found: Ag = 50.3. $C_{10}H_{12}O_5Ag_2$ requires Ag = 50.5 per cent.).

The filtrate from the *trans*-acid was evaporated to dryness and the residue recrystallised from a mixture of ether and light petroleum, the *cis*-acid separating in small plates melting at 163°. Yield 2 grams (Found: C = 56.3; H = 6.7. Calc., C = 56.1; H = 6.6 per cent.).

The *disilver* salt was prepared from silver nitrate and the ammonium salt in aqueous solution (Found: Ag = 50.2. $C_{10}H_{12}O_5Ag_2$ requires Ag = 50.5 per cent.).

Anhydride of cis-cycloHexanespiro-1-hydroxycyclopropane-1:2-dicarboxylic Acid.—The *cis*-hydroxy-ring acid (1 gram) was warmed with acetyl chloride (5 grams) for two hours and the excess of acetyl chloride evaporated. The viscous residue was left in an evacuated desiccator over potassium hydroxide, and solidified after a week. It was recrystallised from ether, from which it separated in long prisms melting at 102°. On treatment with dilute alkali and subsequent acidification, it yielded the original *cis*-hydroxy-ring acid. Yield 0.7 gram (Found: C = 61.3; H = 6.4. $C_{10}H_{12}O_4$ requires C = 61.3; H = 6.1 per cent.).

α -Ketocyclohexane-1:1-diacetic acid (IX) was obtained by the action of boiling strong hydrobromic acid on either of the ring hydroxy-acids.

A solution of 1 gram of the *cis*-hydroxy-ring acid in 10 c.c. of hydrobromic acid (*d* 1.49) was boiled under a reflux condenser for two hours. On cooling, the solution was diluted to 20 c.c. and extracted ten times with its own volume of ether. The ethereal solution was evaporated and the viscous residue placed over potassium hydroxide in an evacuated desiccator. After ten days, it solidified and was recrystallised from a mixture of ether and light petroleum, crystals melting at 130° being obtained. Yield 0.9 gram (Found: C = 56.0; H = 6.7. $C_{10}H_{14}O_5$ requires C = 56.1; H = 6.6 per cent.).

The quinoxaline derivative was prepared by heating the keto-acid and *o*-phenylenediamine in glacial acetic acid; on diluting the solution with water, the compound separated as a crystalline

precipitate melting with decomposition at 247° (Ingold, Seeley, and Thorpe, *loc. cit.*, p. 867) (Found: N = 9.7. Calc., N = 9.9 per cent.).

The keto-acid was also formed to the extent of about 40 per cent. when the *trans*-acid was heated with hydrobromic acid.

A solution of 1 gram of the *trans*-hydroxy-ring acid in 10 c.c. of hydrobromic acid (*d* 1.49) was boiled for two hours under a reflux condenser. On cooling, crystals of the bromolactonic acid (VIII) separated and were filtered off. The filtrate was diluted and extracted ten times with its own volume of ether. The ethereal solution was evaporated and the gummy residue seeded with a crystal of the keto-acid, when it solidified. It was recrystallised from a mixture of ether and light petroleum, yielding crystals (0.4 gram) melting at 130° .

The bromolactonic acid was recrystallised from boiling water, needles melting at 161° separating on cooling. Yield 0.6 gram (Found: C = 43.0; H = 4.7; Br = 28.6. Calc., C = 43.3; H = 4.7; Br = 28.8 per cent.).

The keto-acid was converted into the potassium salt of the *trans*-hydroxy-ring acid on boiling for half an hour with concentrated aqueous potassium hydroxide (b. p. $140-145^{\circ}$) under a reflux condenser.

The thanks of the authors are due to the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the expenses of this investigation.

CCCXXXV.—*The Preparation and Properties of Selenium Trioxide and Chloroselenic Acid.*

By RICHARD ROBERT LE GEYT WORSLEY and HERBERT BRERETON BAKER.

ALTHOUGH selenic acid in the pure state has been known for nearly thirty-five years, its anhydride, selenium trioxide, has not previously been isolated. Attempts have been made at various times to prepare it from selenic acid by means of dehydrating agents, diminished pressure, and heat, but in every case the acid decomposed to the dioxide or was unaffected. Attempts to combine the dioxide with oxygen in presence of a catalyst also failed. Jannek and Meyer, having noticed that moist ozone attacked

selenium to form selenic acid, unsuccessfully attempted to form the trioxide by using dry ozone.

It appeared possible that if a suitable solvent could be found for selenium or the dioxide, dry ozone might attack these substances more readily when in solution than in the solid state. Selenium oxychloride, SeOCl_2 , was chosen, since it dissolves considerable quantities of both selenium and the dioxide, and was also found to be unaffected by ozone after sixty hours' treatment. Accordingly about 200 c.c. of this substance were prepared by combination of selenium tetrachloride and dioxide, as described by Lenher (*J. Amer. Chem. Soc.*, 1920, **42**, 2498), great care being taken to obtain it free from water, seven distillations under considerably diminished pressure being carried out. The final distillate

FIG. 1.

was at once sealed off, in two portions, with excess of selenium and the dioxide, respectively.

The apparatus in which the oxidation was carried out consisted of a cylindrical glass vessel, *A* (see diagram), of about 200 c.c. capacity, with a well ground-in tap at the bottom. A centre tube, *B*, fused through the ground-in stopper, *L*, reached to within 2 mm. of the bottom, and acted as the delivery tube for the ozone. A side tube, *C*, acted as the exit tube, and was joined by a ground joint to a wider tube, *F*, about 3 feet long (to collect a sublimate which formed), which itself was joined to a sealed tube of manganese dioxide, *E*, which decomposed the excess of ozone. A side tube, *D*, was used to admit the selenium oxychloride. The ozoniser, *J*, was made entirely of glass and took the form shown in the diagram, water being used as the conducting medium. The oxygen was dried by bubbling through concentrated sulphuric acid and then by passing through a U-tube, *G*, of phosphorus

pentoxide, a piece of glass wool preventing any solid being carried over. By keeping the ozoniser cool, at 15° , 7 to 8 per cent. of the oxygen was converted into ozone, a 4-inch sparking coil being employed. As it was essential that no moisture should be allowed to enter, the whole apparatus consisted of glass fused together, or ground-in, at every joint, and was tested for leaks by leaving at diminished pressure for forty-eight hours.

In order to dry the apparatus, warm air, dried by the bubbler, *H*, of sulphuric acid and the U-tube, *G*, of phosphorus pentoxide, was slowly drawn through for seventy-two hours, the air being finally swept out by oxygen. The selenium oxychloride, saturated with selenium dioxide, was then rapidly introduced from its sealed tube, through the tube *D*, and the stopper replaced at once. The ozonised oxygen was then bubbled through at the rate of two bubbles per second. As no apparent change took place after forty hours, and as the liquid on testing gave no tests for a selenate, it was run out through the tap at the bottom and sealed off in a tube.

The oxychloride, saturated with selenium, was then introduced and ozonised oxygen passed through it. After thirty-five hours' treatment, the red colour of the solution, caused by the selenium, began to disappear and in a few hours longer the liquid was colourless. At the same time, a white solid began to form in the liquid and to sublime down the side tube, *C*, which in this experiment was connected directly with the U-tube, *E*. After forty hours, all action appeared to have ceased and the oxychloride, together with the majority of the white solid, was run out into a well-stoppered bottle.

After various solvents had been tried, it was found possible to obtain the white solid completely free of oxychloride by washing, first with carbon tetrachloride, which had been standing over phosphorus pentoxide for several weeks and distilled immediately before use, and then with ether, which had been standing over sodium for some weeks and also distilled immediately before use. The ether was finally removed by warm air dried by strong sulphuric acid and phosphorus pentoxide.

About 0.15 gram was obtained (Found: Se = 62.34. SeO_3 requires Se = 62.26 per cent.).

The quantity of white sublimate in the side tube was insufficient for analysis.

A second experiment, in which the long side tube, *F*, was introduced, yielded 0.23 gram of the solid (Found: Se = 62.01 per cent.). Again insufficient sublimate was formed for analysis, but when dissolved in water it yielded nothing but selenic acid, so that it is probable that it also was selenium trioxide.

In the third experiment, freshly distilled selenium oxychloride was introduced into the oxidation tube and sticks of fused selenium were placed in it. As the selenium dissolved, the ozone attacked it and thus a continuous formation of the trioxide went on. Fifteen grams were obtained by passing the ozonised oxygen for one hundred and forty hours.

Analysis.—The solid was weighed in a stoppered bottle and dissolved in water. Hydrochloric acid was added, the solution gently boiled for about an hour, so as to reduce the selenic acid to selenious acid, and while still hot, sulphur dioxide was bubbled through it to precipitate the selenium in the red amorphous form; the solution was boiled again for fifteen minutes, the selenium turning black. To make certain that no selenium was left in solution, a small amount of hydrazine sulphate was added, and if no further precipitate was formed the liquid was filtered through a weighed Gooch crucible and the precipitate washed with hot water, with absolute alcohol, and with ether, and finally dried at 105° for two hours. The Gooch crucible had previously been similarly treated before weighing. The increase in weight of the Gooch crucible gives directly the weight of selenium present. The results obtained show that the selenium trioxide obtained was practically in the pure state (Found: with different samples, Se = 62.34, 62.01, 62.30 per cent.).

Molecular Weight.—The molecular weight was determined by the cryoscopic method using phosphorus oxychloride as the solvent. The phosphorus oxychloride was shaken with, and left standing over, phosphorus pentoxide, and was distilled immediately before use, and care was taken to avoid any moisture entering. The depressions obtained corresponded to a molecular weight of (1) 136, (2) 135, which indicates that the selenium trioxide is represented by the formula SeO_3 .

An attempt to determine the molecular weight of the white solid which sublimed led only to inconsistent results, probably largely due to the very small quantity available.

Physical Properties.—The selenium trioxide obtained was a very pale yellow, amorphous solid of density 3.6. On heating, it decomposed at about 120° without melting or subliming. It would thus appear that the "sublimation" in the preparation was either due to the substance having been carried over in a very fine form or to an allotropic modification. Selenium dioxide was the only product of decomposition which could be detected. The trioxide was readily soluble in water with evolution of heat and also in alcohol, but was insoluble in ether, benzene, chloroform, or carbon tetrachloride.

Chemical Properties.—Selenium trioxide appeared to be similar to sulphur trioxide, dissolving in water to form selenic acid and in alkalis to form selenates. It also dissolved in selenic acid (melted under diminished pressure). It combined directly with dry hydrogen chloride, forming a fuming liquid, which proved to be *chloroselenic acid*, analogous to chlorosulphonic acid.

Chloroselenic Acid.

Considerable heat was evolved by the combination of hydrogen chloride and selenium trioxide and partial decomposition occurred, red selenium being formed. If, however, the temperature was kept down by immersing the reaction vessel in ice, no decomposition took place and a nearly colourless liquid was formed. It was analysed by dissolving carefully a weighed quantity in ice-cold silver nitrate solution and weighing the mixture of silver selenate and chloride formed; this gave the total selenium and chlorine. A second weighed portion was dissolved in water, boiled with hydrochloric acid, and precipitated with sulphur dioxide as in the analysis of the selenium trioxide. The chlorine was estimated by difference (Found: $\text{SeO}_3 = 77.18$; $\text{HCl} = 22.53$. HClSeO_3 requires $\text{SeO}_3 = 77.71$; $\text{HCl} = 22.28$ per cent.).

The chloroselenic acid obtained was a nearly colourless liquid which slowly turned pale yellow. It fumed in the air, evolving hydrogen chloride. Its density was 2.26 and it solidified at -46° . On heating, it decomposed, evolving hydrogen chloride and leaving selenium dioxide and selenium. Its molecular weight was determined by depression of the freezing point of phosphorus oxychloride, as for selenium trioxide, and yielded the values 349 and 341, showing it to be probably represented by the formula $(\text{HClSeO}_3)_2$, which requires a molecular weight of 327.

The chloroselenic acid dissolved very readily in water, evolving considerable heat, and forming selenic and hydrochloric acids. It was also decomposed by alcohol, heat being evolved and selenium precipitated. It was insoluble in ether, benzene, chloroform, or carbon tetrachloride, but dissolved readily in selenium oxychloride without decomposition.

Perselenic Acid.

Both selenium trioxide and chloroselenic acid appeared to react with hydrogen peroxide to form a perselenate, but as no anhydrous hydrogen peroxide was available at the time only qualitative results were obtainable. A distinct blue colour was obtained with alcoholic benzidine solution and the subject is being further investigated.

Summary.

Selenium trioxide and chloroselenic acid have been prepared in a pure state, and some of their physical and chemical properties have been examined. They appeared to be very similar to the analogous sulphur compounds, but less stable.

CCXXXVI.—*Optical Activation of Racemic Acid by d-Malic Acid.*

By ALEX. MCKENZIE, HAROLD JAMES PLENDERLEITH, and
NELLIE WALKER.

THE addition of *l*-malic acid to an aqueous solution of potassium racemate causes the deposition of crystals which are dextrorotatory and which consist of potassium hydrogen racemate with a small admixture of potassium hydrogen *d*-tartrate. A similar mixture is obtained when potassium hydrogen racemate is crystallised from an aqueous solution of *l*-malic acid, an observation which provided an example of the activation of an externally compensated compound on crystallisation from an optically active medium (T., 1915, 107, 440). This anomalous behaviour is not restricted to potassium hydrogen racemate, since *l*-malic acid was also found to cause optical activation with the racemates of sodium, rubidium, and caesium, respectively. But *l*-malic acid was exceptional. No fewer than fifteen other optically active acids were tested separately, and the crystals deposited by the action of each one of those active acids on an aqueous solution of potassium or sodium racemate were in every case inactive, consisting, as they did, of the acid racemate only (T., 1922, 121, 349).

It was obviously desirable that the above observations should be extended so as to embrace a study of the behaviour of *d*-malic acid.

As this acid was not readily attainable in a state of purity, a convenient method for its preparation was devised whereby it was obtained from *l*- γ -trichloro- β -hydroxybutyric acid (this vol., p. 1090). It is now shown that *d*-malic acid causes activation to about the same extent as when its *l*-isomeride was employed, but the optical activity acquired is in the opposite direction. Thus, when *d*-malic acid is added to a solution of potassium racemate, the crystals which separate consist of a mixture of potassium hydrogen racemate and potassium hydrogen *l*-tartrate. When

potassium hydrogen racemate is crystallised from an aqueous solution of *d*-malic acid, the crystals which separate are also *laevorotatory*, and consist of a mixture of the acid racemate and the acid *l*-tartrate.

When it was decided to apply *d*-malic acid for the activation of racemic acid, the first attempts made to obtain it were by the resolution of *r*-malic acid. Some observations on the latter acid were incidentally noted, and are perhaps worth recording.

The history of *r*-malic acid dates from the time of Pasteur's early work. The announcement by Dessaignes (*Compt. rend.*, 1850, 30, 324) that he had prepared aspartic acid from ammonium *l*-malate, and his claim in a subsequent paper (*Compt. rend.*, 1850, 31, 432) that the same acid can be obtained from ammonium maleate or from ammonium fumarate immediately attracted the attention of Pasteur. The maleate and the fumarate are devoid of optical activity, and consequently a polarimetric examination of the aspartic acid from those sources was called for, because if this amino-acid proved to be optically active it would have constituted the first example of the artificial formation of an optically active substance in an optically inactive environment. The inactivity of Dessaignes's acid derived from maleic or fumaric acid was then established by Pasteur himself, who at once converted it into malic acid by Piria's method, and thus isolated *r*-malic acid for the first time (*Compt. rend.*, 1851, 33, 217).

The conversion of maleic or fumaric acid into *r*-malic acid did not prove in the hands of Loydl, Jungfleisch, Pictet, H. J. van't Hoff, Tanatar, Anschütz, and Skraup to be a method suitable for obtaining the acid in quantity. Recently, however, Weiss and Downs (*J. Amer. Chem. Soc.*, 1922, 44, 1118; 1923, 45, 1603) have shown that when a mixture of maleic, fumaric, *r*-malic (or *l*-malic) acids is heated with water in a closed space, the maleic acid substantially disappears at higher temperatures, and an equilibrium is ultimately established between fumaric acid and *r*-malic acid; approximately the same end-point is reached irrespective of which one of the above acids is used as the starting material. The method of preparation of *r*-malic acid adopted by Weiss and Downs consisted in heating an aqueous solution of maleic acid in an autoclave and then separating the *r*-malic from the fumaric acid.

By the decomposition of *r*- γ -trichloro- β -hydroxybutyric acid by concentrated aqueous alkali, Thurnlackh (*Monatsh.*, 1891, 12, 556) obtained calcium *r*-malate in small yield. Based upon this observation, a practical method of obtaining *r*-malic acid is now described. We resolved the *r*-acid by quinine, but the method

already described (*loc. cit.*) is obviously much more convenient for the preparation of *d*-malic acid.

EXPERIMENTAL.

The *d*-malic acid used in the following experiments was obtained from *l*- γ -trichloro- β -hydroxybutyric acid (*loc. cit.*). It was free from fumaric acid, and melted at 99–99.5°, whereas *l*-malic acid melts at 100° according to Walden (*Ber.*, 1896, 29, 1699). 3.82 C.c. of potassium hydroxide (0.3251*N*) and 6.04 c.c. of a standard solution of uranium nitrate (32.936 grams of the hydrated salt made up to 1 litre with water) were added to 0.236 gram of the acid. The solution, when made up to 20 c.c. with water, gave $\alpha_D + 2.41^\circ$ ($l = 2$), whereas *l*-malic acid, obtained from Kahlbaum, gave $\alpha_D - 2.40^\circ$ under similar conditions.

Addition of d-Malic Acid to an Aqueous Solution of Potassium Racemate.—Four grams of *d*-malic acid (1 mol.) were dissolved in 250 c.c. of a warm aqueous solution of potassium racemate prepared from 5 grams of hydrated racemic acid (1 mol.). On cooling, crystals began to separate, and after seventeen hours at the ordinary temperature these were collected, washed with 10 c.c. of water, and dried at 100° for one hour. The yield was about 5.6 grams. 0.4702 required 28.95 c.c. of potassium hydroxide ($N/10 \times 0.8626$) for neutralisation, whereas $\text{CO}_2\text{H}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CO}_2\text{K}$ requires 28.97 c.c.

1.99 Grams of this product were neutralised with the calculated quantity of potassium hydroxide, and the solution was made up to 16 c.c., being the amount requisite to fill a 2-dcm. tube. The distinct levorotation of $\alpha_D - 0.30^\circ$ was observed. On dissolving 0.5 grams of boric acid in this solution, the values $\alpha_D - 1.07^\circ$ and $\alpha_{5461} - 1.27^\circ$ ($l = 2$) were observed.

2.38 Grams of the above crystals and 2.05 grams of antimony oxide were made into a paste with water, and heated on the water-bath for half an hour, water being added at intervals. The product was then boiled with water and filtered. After twenty-four hours the crystals of the antimony salt were separated, and the filtrate when examined in a 2-dcm. tube gave the strong levorotation of $\alpha_D - 4.39^\circ$ and $\alpha_{5461} - 5.16^\circ$.

Racemic acid may also be activated by adding it to a solution of potassium *d*-malate. A solution of 4 grams of anhydrous racemic acid in 25 c.c. of water was added to 250 c.c. of a solution of potassium *d*-malate (5 grams). The yield of crystals was about 5 grams. Three grams were neutralised by potassium hydroxide, and the solution in a 2-dcm. tube gave $\alpha_D - 0.32^\circ$. The addition of 2 grams of boric acid enhanced the rotatory power to $\alpha_D - 1.47^\circ$.

Crystallisation of Potassium Hydrogen Racemate from an Aqueous Solution of d-Malic Acid.—1.72 Grams of *d*-malic acid (1 mol.) were dissolved in 100 c.c. of water, and to the boiling solution 2.41 grams of potassium hydrogen racemate (1 mol.) were added. The salt dissolved rapidly, and the boiling was continued for five minutes. After forty-eight hours at the ordinary temperature, the crystals were collected, washed with 10 c.c. of water, and dried at 100° for one hour. Yield = 1.7 grams. 0.3889 required 24 c.c. of potassium hydroxide ($N/10 \times 0.8626$) for neutralisation, whereas $\text{CO}_2\text{H}\cdot\text{CH}(\text{OH})\cdot\text{CH}(\text{OH})\cdot\text{CO}_2\text{K}$ requires 23.96 c.c.

By the use of 3.2 grams of *d*-malic acid and 4.4 grams of potassium hydrogen racemate in a second experiment, the yield of crystals amounted to 2.3 grams.

2.15 Grams of the crystals were neutralised by the calculated quantity of potassium hydroxide, and the solution was evaporated to 16 c.c., being the bulk necessary to fill a 2-dcm. tube. The rotation was $\alpha_D -0.26^\circ$. The addition of 1.5 grams of boric acid enhanced this value to $\alpha_D -0.99^\circ$, $\alpha_{5491} -1.15^\circ$.

1.32 Grams of the crystals were acted on by 0.95 gram of antimony oxide. The filtrate after the removal of 0.78 gram of the antimony salt gave $\alpha_D -1.48^\circ$ ($l = 2$).

Contrast between d-Malic and l-γγγ-Trichloro-β-hydroxybutyric Acid.—2.071 Grams of *l*-γγγ-trichloro-β-hydroxybutyric acid (1 mol.) were added to a warm aqueous solution (100 c.c.) of potassium racemate prepared from 1.499 grams of anhydrous racemic acid (1 mol.). The crystals deposited amounted to 1.5 grams. When examined in the usual manner, they were found to be quite inactive and consisted of potassium hydrogen racemate only. Again, when 2.47 grams of potassium hydrogen racemate (1 mol.) were crystallised from 75 c.c. of an aqueous solution of 2.72 grams of the *l*-chloro-acid (1 mol.), the crystals which separated exhibited no optical activity when examined as usual, and consisted of the original acid racemate only.

The behaviour of *l*-γγγ-trichloro-β-hydroxybutyric acid is thus identical with that of the other optically active acids which had been previously tested (*loc. cit.*), and differs from that of *l*- and *d*-malic acids.

Preparation of r-Malic Acid.—Amongst the methods for the preparation of *r*-malic acid quoted in the literature, the following were examined.

(1) The action of silver oxide and water on *r*-monobromosuccinic acid (Duboux and Cuttat, *Helv. Chim. Acta*, 1921, **4**, 753; compare Kekulé, *Annalen*, 1860, **117**, 126; 1864, **130**, 24).

(2) The decomposition of *r*-monobromosuccinic acid in neutral

or feebly alkaline solution (Holmberg, *J. pr. Chem.*, 1913, [ii], 87, 456, 553).

(3) The action of mercuric acetate on maleic acid (Biilmann, *Ber.*, 1910, 43, 578).

We ultimately adopted the method suggested by Thurnlackh (*loc. cit.*), the following description being typical. Twenty grams of anhydrous *r*- $\gamma\gamma\gamma$ -trichloro- β -hydroxybutyric acid were added gradually within twenty minutes to a solution of 39.5 grams of potassium hydroxide in 150 c.c. of water, the solution being kept cold throughout. After the addition, the liquid was allowed to remain at the ordinary temperature for twenty-four hours, then heated on the water-bath for one hour, and finally neutralised with hydrochloric acid. Barium chloride was added in slight excess (26 grams), and the solution was concentrated at 100° until crusts of barium *r*-malate began to form. The salt was removed and washed until free from chloride. Yield = 20 grams (77 per cent. of the theoretical).

The method of direct decomposition of the chloro-acid by barium hydroxide is also quite convenient (Found: Ba = 51.2. Calc., Ba = 51.0 per cent.).

The free acid was obtained by decomposing the barium salt by either dilute sulphuric or oxalic acid. 40.5 Grams of crude *r*-malic acid (78 per cent. of the theoretical yield) were obtained from 104 grams of barium *r*-malate. The fumaric acid present in the crude acid was separated by the addition of acetone, in which it is very sparingly soluble, whilst the *r*-malic acid was precipitated from the acetone solution by the addition of an excess of xylene (Equivalent: Found: 67.3. Calc., 67).

The figures given in the literature for the melting point of *r*-malic acid are discordant. We found that the pure acid melts at 129—130° (on quick heating) in agreement with the value 128.5—129° quoted by Weiss and Downs (*loc. cit.*).

Resolution of r-Malic Acid.—Bremer (*Ber.*, 1880, 13, 382) prepared the *r*-acid by the reduction of racemic acid by hydriodic acid. By means of cinchonine, he obtained a small quantity of pure ammonium hydrogen *d*-malate.

Equimolecular proportions of *l*-malic acid and quinine were taken in ethyl-alcoholic solution and the salt which separated was crystallised twice from ethyl alcohol, in which it is very sparingly soluble at the ordinary temperature. It melted at 177—179° with decomposition (Found: C = 63.0; H = 6.3. $C_{20}H_{24}O_2N_2 \cdot C_4H_6O_5$ requires C = 62.9; H = 6.6 per cent.). When the acid and alkalioid were employed in the proportions of 1 mol. of acid to 2 mols. of quinine with ethyl alcohol as solvent, the resulting salt melted

2880 OPTICAL ACTIVATION OF RACEMIC ACID BY *d*-MALIC ACID.

at 186—187° [Found: C = 67·3; H = 7·0. $(C_{20}H_{24}O_2N_2)_2 \cdot C_4H_6O_5$ requires C = 67·5; H = 7·0 per cent.]. Also, when the acid (1 mol.) and quinine ($\frac{1}{2}$ mol.) were taken with water as solvent, the salt, after crystallisation, melted at 186—187° [Found: C = 67·5; H = 7·0. $(C_{20}H_{24}O_2N_2)_2 \cdot C_4H_6O_5$ requires C = 67·5; H = 7·0 per cent.]. In each of the above cases, the salts were dried in a desiccator over sulphuric acid.

12·1 Grams of quinine (1 mol.) were dissolved in a solution of 5 grams of *r*-malic acid (1 mol.) in 75 c.c. of ethyl alcohol. The resulting crystals were crystallised three times from ethyl alcohol and then amounted to 6·2 grams. The barium salt prepared from this was inactive. This negative result was probably due to the formation of a partially racemic quinine salt. A similar result was obtained when the proportions employed were 1 mol. of acid to 2 mols. of quinine. Under the following conditions a resolution was, however, effected. 3·63 Grams of quinine ($\frac{1}{2}$ mol.) were added to a boiling solution of 3 grams of *r*-malic acid (1 mol.) in 30 c.c. of water. The crystals which separated on cooling were crystallised from water. Yield = 2 grams. The salt was decomposed by the calculated amount of potassium hydroxide, and the precipitated quinine was removed. The filtrate was extracted three times with chloroform, then neutralised with hydrochloric acid, and acted on by the requisite amount of barium chloride. The salt precipitated was removed and washed free from chloride, the residue proving to be pure barium *d*-malate (0·4 gram), as was shown as follows: 0·2362 Gram was decomposed by 1·55 c.c. of dilute hydrochloric acid containing the calculated amount of acid. 3·85 C.c. of potassium hydroxide (0·3251*N*) were added, and then 6·04 c.c. of a standard solution of uranium nitrate (32·936 grams of the hydrated salt made up to 1 litre with water). The solution, when made up to 25 c.c. with water, gave $\alpha_D + 2·11^\circ$ ($l = 2$), whereas pure barium *l*-malate gave under similar conditions $\alpha_D - 2·12^\circ$.

We wish to express our thanks to the Department of Scientific and Industrial Research and to the Carnegie Trust for the assistance given by them.

CCCCXXVII.—*The Conversion of Paraformaldehyde into Glycollic Acid.*

By DALZIEL LLEWELLYN HAMMICK and ALFRED REGINALD BOEREE.

By heating paraformaldehyde with a small quantity of sulphuric acid, Dunlop (T., 1914, 105, 1155) obtained methyl formate, methyl alcohol and formic acid presumably being produced by a Cannizzaro transformation. He failed to obtain α -trioxymethylene as described by Pratesi (*Gazzetta*, 1885, 14, 139).

The present authors have shown that α -trioxymethylene can be produced by the action of sulphuric acid and water on paraformaldehyde (T., 1914, 121, 2738); they now find that the considerable 'tarry residue' obtained by Dunlop is mainly glycollic acid.

Paraformaldehyde (100 parts) and concentrated sulphuric acid (10 parts) were heated in an autoclave at 115° for four and a half hours. A considerable pressure was developed, owing to the formation of carbon monoxide, which from time to time was allowed to escape. In order to obtain a sample of the gas for analysis, an experiment was carried out using a glass tube fitted to enable the gas to be collected over water: 95.5 c.c. contained 93.0 c.c. of carbon monoxide, 0.5 c.c. of oxygen, and 2.0 c.c. of nitrogen. No hydrocarbons, carbon dioxide, sulphur dioxide, or hydrogen were found. The liquid remaining in the autoclave gave (compare Dunlop, *loc. cit.*) on distillation methyl formate, a liquid boiling at 90–100°, and left a viscous residue. The latter was treated with water, heated with excess of calcium carbonate on the water-bath, and filtered. The filtrate on evaporation and cooling gave crystals of calcium glycollate, which were dried at 120° [Found: C = 25.75; H = 3.37; Ca = 21.08. Calc. for $\text{Ca}(\text{C}_2\text{H}_3\text{O}_3)_2$, C = 25.2; H = 3.2; Ca = 21.05 per cent.].

A specimen of ethyl glycollate was prepared by passing hydrogen chloride into an alcoholic suspension of the calcium salt and boiling under reflux for some time (Found: C = 46.56; H = 7.85. Calc., C = 46.2; H = 7.7 per cent.).

The yield of glycollic acid, using paraformaldehyde and sulphuric acid* in the proportions mentioned above, is about 20–22 grams per 100 grams of paraformaldehyde.

The nature of the reaction whereby glycollic acid is produced from formaldehyde is not obvious. The possibility of the primary formation of glycollaldehyde by an aldol condensation between two

* Paraformaldehyde, heated under exactly the same conditions but without sulphuric acid, gave no glycollic acid.

molecules of formaldehyde, followed by an oxidation to glycollic acid, would seem to be excluded by the fact that the only obvious oxidising agent present, namely, sulphuric acid, is not reduced during the reaction. No glycollaldehyde could be detected in the reaction mixture immediately on opening the autoclave, and therefore the production of glycollic acid cannot be due to atmospheric oxidation. Formic acid, however, is produced during the reaction, as is shown by the fact that methyl formate is isolated at the end; formic acid, as its structure and reducing actions imply, is capable of reacting as an aldehyde. It is therefore suggested that an aldol condensation takes place between molecules of formaldehyde and formic acid, yielding glycollic acid:—

[Received, September 10th, 1923.]

CCCXXXVIII.— ω -Trichloro- and ω -Tribromo-quin- aldine and the Preparation of Quinaldinic Acid.

By DALZIEL LLEWELLYN HAMMICK.

ω -HALOGENATED derivatives of certain methylquinolines have been prepared by Howitz (*Ber.*, 1906, **39**, 2705; *Annalen*, 1912, **396**, 23), who obtained them by heating the dibromo-hydrobromides of the various bases. Attempts to prepare ω -tri- or di-bromoquinaldines by Howitz's method failed, although much hydrogen bromide was evolved on heating the perbromide. It seemed possible that the presence of hydrogen bromide interfered with the smooth course of the reaction, and the bromination was attempted in glacial acetic acid containing an excess of anhydrous sodium acetate, which would convert any hydrogen bromide formed into sodium bromide. The device proved completely successful, and quantitative yields of ω -tribromoquinaldine, $\text{C}_9\text{H}_6\text{N}\cdot\text{CBr}_3$, were readily obtained. The corresponding trichloro-derivative was obtained, although not in quantitative yield, by the same method. Hydrolysis of the above halogen compounds by boiling with dilute sulphuric acid gave quantitative yields of quinaldinic acid, thus proving that the halogenation of the quinaldine has occurred entirely in the side chain and providing a simple method for the production of the acid.

Attempts to graduate the bromination so as to obtain ω -mono- or di-bromoquinaldine have so far been unsuccessful, and further experiments are in progress. The method is also being applied to the other methylquinolines and to the picolines.

EXPERIMENTAL.

ω-Tribromoquinaldine.—To a mixture of 50 grams of dry powdered sodium acetate, 100 grams of glacial acetic acid and 14 grams of pure quinaldine (1 mol.) at 70°, 48 grams of bromine (3 mols.) in 100 grams of acetic acid were added in the course of ten minutes, the mixture being thoroughly shaken. The solution was boiled for a few minutes (until the separation of sodium bromide caused violent bumping), left for half an hour on the water-bath, cooled, and poured into water, and the faintly yellow, crystalline precipitate washed and dried (weight 36 grams = theoretical yield of *ω-tribromoquinaldine*). After recrystallisation from alcohol or glacial acetic acid, the crystals were colourless and had m. p. 128° (uncorr.).

When ordinary quinaldine is used (Kahlbaum's "refined") in the above preparation, the product obtained on pouring into water contains tarry matter difficult to remove. A good product is obtained, however, by allowing the acetic acid solution to cool and omitting the treatment with water. A mixture of sodium bromide and *ω-tribromoquinaldine* separates, which is filtered, washed with cold glacial acetic acid and finally with water (Found : Br = 63.5. $C_{10}H_8NBr_3$ requires Br = 63.2 per cent.).

ω-Trichloroquinaldine.—The procedure for the preparation of this compound was practically identical with the above. The quantity of chlorine absorbed was about 30 grams and the mixture was allowed to get hot during the introduction of the gas. The chlorinated product was heated as before and the dark-coloured oil obtained on dilution with water was washed with water and kept over-night, when it solidified. After recrystallisation from low-boiling ligroin, colourless crystals were obtained, m. p. 56° (Found : Cl = 43.5. $C_{10}H_8NCl_3$ requires Cl = 43.2 per cent.).

Hydrolysis of ω-Trichloro- and ω-Tribromo-quinaldine: Preparation of Quinaldinic Acid.—The hydrolysis was carried out by boiling under a reflux condenser with dilute (1 : 10) sulphuric acid until a test portion, on neutralisation, yielded no unchanged halogen compound. After the solution had been cooled and nearly neutralised, excess of copper sulphate solution was added, the insoluble, pale green copper salt that separated was washed, suspended in hot water, and subjected to prolonged treatment with hydrogen sulphide. After removal of the copper sulphide the clear solution was evaporated to dryness and the solid recrystallised from glacial acetic acid; m. p. 157° (compare Reissert, *Ber.*, 1905, **38**, 1606) (Found : N = 8.1. Calc., N = 8.1 per cent.).

The hydrolysis is quantitative; thus 7 grams of *ω-tribromoquin-*

dine gave 3.1 grams of quinaldinic acid; theory requires 3.2 grams.

Part of the expense of the above investigation was met by a grant from the Chemical Society's Research Fund.

CCCXXXIX.—*The Interaction of $\beta\beta'$ -Dichlorodiethyl Sulphide, Sulphoxide, and Sulphone with Glycine Ester and with Potassium Phthalimide.*

By ALBERT ERIC CASHMORE and HAMILTON MCCOMBLE.

It has been shown by Clarke (T., 1912, **101**, 1583) that derivatives of 1:4-thiazan are formed by the interaction of $\beta\beta'$ -dichlorodiethyl sulphide and primary aliphatic amines when warmed together in ethyl-alcoholic solution in presence of anhydrous sodium carbonate and anhydrous sodium acetate. The yield is usually some 40 per cent. of that demanded by theory. The parent substance, 1:4-thiazan, has been prepared by Davies (T., 1920, **117**, 297) by warming $\beta\beta'$ -dichlorodiethyl sulphide in a sealed tube at 60° with an excess of alcoholic ammonia. Helfrich and Reid (*J. Amer. Chem. Soc.*, 1920, **42**, 1208) have found that $\beta\beta'$ -dichlorodiethyl sulphide, sulphoxide, and sulphone may be caused to react with primary aromatic amines to form 4-aryl derivatives of 1:4-thiazan and its oxide and dioxide.

It is evident from the above examples that, under certain conditions, the removal of the halogen atoms from $\beta\beta'$ -dichlorodiethyl sulphide is accompanied by ring formation. Certain cases are known, however, in which the open-chain derivatives are formed; some of these will now be reviewed.

It has been shown in a previous communication (Cashmore, this vol., p. 1738) that $\beta\beta'$ -dichlorodiethyl sulphide reacts with aqueous alkali to form $\beta\beta'$ -dihydroxydiethyl sulphide, whilst the sulphoxide and the sulphone form the oxide and dioxide of 1:4-thioxan under similar conditions.

Another example of the formation of open-chain derivatives from $\beta\beta'$ -dichlorodiethyl sulphide has been supplied by Davies (*loc. cit.*), who examined the action of sodiomalonic ester and sodioacetacetic ester upon this compound. In the former case he obtained ethyl γ -thiodiethylmalonate, $S[CH_2 \cdot CH_2 \cdot CH(CO_2Et)_2]_2$, which was an unstable liquid and on hydrolysis yielded γ -thiodibutyric acid,

$S(CH_2 \cdot CH_2 \cdot CH_2 \cdot CO_2H)_2$. The product of the latter reaction was an open-chain derivative which on alkaline hydrolysis also yielded γ-thiodibutyric acid.

Davies also investigated the reaction between ββ'-dichlorodiethyl sulphide and potassium cyanide in ethyl alcohol; this reaction proceeded in an altogether unexpected manner, giving a compound of the formula $C_6H_{12}S_2(CN)_2$ which on hydrolysis yielded the corresponding dibasic acid. The only possible structural formula for the nitrile is $CN \cdot CH_2 \cdot CH_2 \cdot S \cdot CH_2 \cdot CH_2 \cdot S \cdot CH_2 \cdot CH_2 \cdot CN$.

It may be interesting at this point to compare the properties of ββ'-dichlorodiethyl sulphide with those of its oxygen analogue, ββ'-dichlorodiethyl ether, and also ββ'-di-iododiethyl ether.

Kamm and Waldo (*J. Amer. Chem. Soc.*, 1921, **42**, 2225) have shown that 4-phenylmorpholine is produced by the interaction of ββ'-dichlorodiethyl ether and aniline. The reaction between ββ'-di-iododiethyl ether and ammonia does not give morpholine (Sand, *Ber.*, 1901, **34**, 2906), but a tertiary base, the structural formula of which is probably

Clarke (*T.*, 1912, **101**, 1792) has shown that 1 : 4-thioxan is produced by the interaction of ββ'-di-iododiethyl ether and potassium sulphide. The corresponding reaction with ββ'-dichlorodiethyl sulphide results in the formation of diethylene disulphide. Finally, it has been shown by Kamm and Waldo (*loc. cit.*) that the product of the reaction between ββ'-dichlorodiethyl ether and sodiomalonic ester is a ring compound of the structural formula (I) :

The main portion of the present investigation deals with the reaction between glycine ester and ββ'-dichlorodiethyl sulphide, sulphoxide, and sulphone. This reaction was chosen for two reasons :

(1) The amino-group is attached to a rather bulky residue. This might be expected to hinder ring formation if the tendency towards ring formation is not very great. The product of the reaction between ββ'-dichlorodiethyl sulphide and glycine ester should therefore be an open-chain compound, whereas in the reaction between ββ'-dichlorodiethylsulphone and glycine ester a sulphonazan derivative might be formed.

(2) It has been suggested that the vesicant action of ββ'-dichlorodiethyl sulphide may be due to the product formed by the reaction

between this substance, or its oxidation products, and the amino-acids present in the skin. Obviously, glycine should have been tried first, but owing to the extremely low solubility of glycine in alcohol and in most other organic solvents, the reaction could not be carried out. As an alternative, the ester was employed. The products of the reaction have been purified and examined physiologically, but no important results have been obtained.

The research has yielded results which are interesting from the purely chemical point of view. The condensation of $\beta\beta'$ -dichlorodiethyl sulphide and glycine ester hydrochloride was carried out under conditions similar to those employed by Clarke, and the product isolated was a liquid ester, $S(CH_2CH_2NHCH_2CO_2Et)_2$, which boiled at $159-160^\circ/15$ mm., the yield being some 40 per cent. of that demanded by theory.

That this is the structure of the ester is evident from the fact that it forms a chloroplatinate, and on hydrolysis yields the free acid, which melts at 134° . This acid gives a blue, crystalline copper salt, which is rather readily hydrolysed; the *sulphilimine* of the acid has also been prepared.

The reaction between $\beta\beta'$ -dichlorodiethylsulphone and glycine ester was next examined and the sole product isolated was an ester which on analysis gave figures corresponding to those required for *ethyl 1:4-sulphonazan-4-acetate*. This ester was a solid (m. p. 66°) practically insoluble in ether and the yield was some 50 per cent. of that demanded by theory. It was characterised by the formation of a *picrate* and also by hydrolysis to the free acid (m. p. 177°), which gave a blue, crystalline copper salt.

The sulphoxide could not be caused to react with glycine ester under the conditions employed in the other two experiments.

The reaction between $\beta\beta'$ -dichlorodiethyl sulphide and potassium phthalimide has also been examined in the hope that on subsequent hydrolysis of the intermediate product, $\beta\beta'$ -diaminodiethyl sulphide might be formed. However, although the intermediate product has been isolated in a pure state, subsequent hydrolysis with acid or alkali yields 1:4-thiazan, which has been characterised by means of its chloroplatinate. $\beta\beta'$ -Diaminodiethyl sulphide apparently is not known, although Gabriel and Colman (*Ber.*, 1912, 45, 1644) have prepared β -chloro- β' -aminodiethyl sulphide by the interaction of aminoethyl mercaptan and ethylene chlorohydrin. This substance, when warmed with alkali, gives no trace of 1:4-thiazan, and the course of the reaction is by no means certain. It has also been shown that $\beta\beta'$ -dichlorodiethyl sulphoxide or sulphone does not react with potassium phthalimide under the conditions employed in the experiments with $\beta\beta'$ -dichlorodiethyl sulphide.

EXPERIMENTAL.

Reaction between $\beta\beta'$ -Dichlorodiethyl Sulphide and Glycine Ester.—Glycine ester hydrochloride (30 grams), suspended in 98 per cent. ethyl alcohol (80 c.c.), was neutralised with anhydrous sodium carbonate (10 grams), the mixture being warmed on the water-bath. Anhydrous sodium acetate (16 grams) and $\beta\beta'$ -dichlorodiethyl sulphide (16 grams) were then added and the mixture was warmed on the water-bath for four hours. It was noticed that some solid collected in the condenser and a peculiar amine-like smell was perceived. The cooled mixture was filtered, the precipitate consisting almost entirely of sodium chloride. This was washed well with alcohol, and the washings and filtrate, concentrated to 50 c.c., were poured into an excess of dilute hydrochloric acid. The oil that separated, consisting of unchanged $\beta\beta'$ -dichlorodiethyl sulphide, was removed with ether, and the aqueous residue neutralised with sodium carbonate and extracted six times with ether, the ethereal extract being washed with water and dried over anhydrous sodium sulphate. After removal of the ether there remained a brown oil (8 grams) which after two distillations gave a fraction which boiled at 159–160°/15 mm. and possessed a peculiar odour, not unlike that of 1:4-thiazan. Analysis showed that this oil is the ethyl ester of $\beta\beta'$ -diglycinodiethyl sulphide. It is soluble in the usual organic solvents but insoluble in water [Found: N = 9.45; S = 10.84. $S(CH_2 \cdot CH_2 \cdot NH \cdot CH_2 \cdot CO_2Et)_2$ requires N = 9.59; S = 10.96 per cent.].

The *chloroplatinate*, formed by the addition of a solution of platonic chloride in hydrochloric acid to a 30 per cent. alcoholic solution of the ester, is a yellow, amorphous solid, which is not very soluble in water or alcohol and may be crystallised from either solvent (Found: Pt = 34.90. $C_{12}H_{24}O_4N_2S$, $2H_2PtCl_6$ requires Pt = 35.07 per cent.).

The free *acid* was formed by hydrolysing the ester (6 grams) with 50 c.c. of boiling N-aqueous sodium hydroxide for four hours, when all the oil had disappeared. The clear solution was added to a slight excess of an aqueous solution of copper sulphate, the blue crystals that formed on keeping were washed with cold water and suspended in water at about 80°, the copper was removed with hydrogen sulphide, and the filtrate and washings were concentrated. A crop of pale brown crystals separated (2.5 grams) which, after crystallisation from ethyl alcohol, appeared as small plates melting at 132° after shrinking at 107°. These crystals are not very soluble in cold ethyl alcohol, but are very soluble in water (Found: C = 40.24; H = 7.3; N = 11.70; S = 13.83. $C_8H_{16}O_4N_2S$ requires C = 40.34; H = 6.7; N = 11.83; S = 13.55 per cent.).

The *sulphilimine* of the free acid, formed by the addition of a strong aqueous solution of chloramine-T to the aqueous solution of the free acid, was obtained in white, lustrous plates, nearly insoluble in cold water, but soluble in hot water, from which it was crystallised. It melts at 172° after charring slightly at 158° (Found : S = 17.10. $C_{15}H_{23}O_6N_3S_2$ requires S = 16.98 per cent.).

Reaction between $\beta\beta'$ -Dichlorodiethylsulphone and Glycine Ester.—Glycine ester hydrochloride (15 grams) was dissolved in 95 per cent. ethyl alcohol (200 c.c.) and neutralised with anhydrous sodium carbonate as before. Anhydrous sodium acetate (10 grams) and $\beta\beta'$ -dichlorodiethylsulphone were added and the mixture was warmed on the water-bath for four hours, filtered, most of the alcohol removed by distillation, and the residue poured into water (250 c.c.). As $\beta\beta'$ -dichlorodiethylsulphone is nearly insoluble in cold ether, it was thought that the product of the reaction might be separated by extraction with ether, but the ethereal extract, after the usual treatment, yielded only a trace of solid residue. The aqueous residue from the ethereal extraction was next concentrated by evaporation on the water-bath until the sodium salts separated out, ethyl alcohol (200 c.c.) was added, and the mixture warmed and filtered. The filtrate on concentration yielded a granular, crystalline, white solid (11 grams), which, after two crystallisations from ethyl alcohol, melted at 68.5° . *Ethyl 1:4-sulphonazan-4-acetate* is insoluble in ether, but soluble in water or methyl or ethyl alcohol (Found : N = 6.5; S = 14.5. $C_8H_{15}O_4NS$ requires N = 6.35; S = 14.5 per cent.).

The *picrate*, prepared in alcoholic solution, may be recrystallised from ethyl alcohol and forms small, yellow crystals melting at 178° (Found : N = 13.70. $C_{14}H_{21}O_{11}N_4S$ requires N = 13.63 per cent.).

The *free acid*, formed by hydrolysing the ester (5 grams) with 25 c.c. of boiling N-aqueous sodium hydroxide for half an hour, was isolated by means of the copper salt, preferably by the addition of a slight excess of copper carbonate in the presence of ammonium carbonate solution. The blue, crystalline copper salt separated together with excess copper carbonate; this was filtered and on cautious evaporation of the mother-liquors a further crop of crystals was obtained, but on prolonged warming hydrolysis took place. The copper salt was suspended in hot water and hydrogen sulphide passed through the hot liquor as before, the subsequent treatment being precisely that employed in the previous case. The free acid after recrystallisation from alcohol formed colourless plates melting at 177° (Found : N = 7.6; S = 16.40. $C_6H_{11}O_4NS$ requires N = 7.3; S = 16.57 per cent.).

The copper salt was best prepared by treating the aqueous solution of the acid with rather less than the required amount of copper carbonate. This dissolved to form a blue solution, from which, after filtration and slow evaporation of the filtrate, blue crystals separated. The salt is hydrolysed on boiling with water and is best crystallised from 5 per cent. aqueous ammonia or by dissolving it in warm water and allowing the solvent to evaporate at the ordinary temperature (Found : Cu = 14.40. $C_{12}H_{20}O_3N_2S_2Cu$ requires Cu = 14.30 per cent.).

Behaviour of $\beta\beta'$ -Dichlorodiethyl Sulphoxide with Glycine Ester.—Glycine ester hydrochloride (15 grams) was dissolved in 150 c.c. of 95 per cent. alcohol and neutralised with sodium carbonate. Anhydrous sodium acetate (15 grams) and $\beta\beta'$ -dichlorodiethyl sulphoxide (15 grams) were added and the mixture was warmed on the water-bath for four hours, filtered, and concentrated. The precipitate consisted almost entirely of sodium chloride. The filtrate was concentrated as before and extracted with ether after pouring into water, but from this the only product was a small amount of solid which contained chlorine and sulphur but no nitrogen and from its melting point (108°) was evidently $\beta\beta'$ -dichlorodiethyl sulphoxide.

The aqueous residue was concentrated as before and the solid mass extracted with boiling ethyl alcohol, but on evaporation of this extract no residue was obtained. The solid mass was redissolved in water and a small amount of copper oxide was added, the mixture warmed and filtered, and the filtrate left over-night, when blue crystals separated. The substance was found to contain no sulphur and was evidently the copper salt of glycine (Found : Cu = 27.1. Calc. for $C_4H_8O_4N_2Cu.H_2O$, Cu = 27.7 per cent.).

The reaction was carried out under various conditions, the time of heating being varied, and sodium carbonate or sodium acetate being employed alone. However, in each experiment, although the chlorine was removed as sodium chloride (presumably by the action of the alkali salts), no product containing both nitrogen and sulphur could be isolated.

Reaction between $\beta\beta'$ -Dichlorodiethyl Sulphide and Potassium Phthalimide.—A mixture of $\beta\beta'$ -dichlorodiethyl sulphide (14 grams) and potassium phthalimide (48 grams) was heated under an air condenser at 170° for six hours. The product was washed with hot water and dilute sodium hydroxide solution, and the dark, sticky residue purified by recrystallisation from ethyl alcohol containing a little animal charcoal. The substance was obtained as fine, pale cream needles melting at 125° . The yield was 20 grams (Found : C = 62.9; H = 4.2; N = 7.73; S = 8.47. $C_{20}H_{16}O_4N_2S$

requires C = 63.1; H = 4.2; N = 7.38; S = 8.42 per cent.). The substance is evidently the condensation product

On warming this substance with dilute alkali, a strong odour of ammonia was observed, but no amine could be isolated, although phthalic acid was precipitated and identified when the solution was acidified.

The substance was hydrolysed by heating 3 grams with 10 c.c. of concentrated hydrochloric acid in a sealed tube at 200° for two hours. Some tar was produced, and also long crystals of phthalic anhydride. These were filtered after the addition of water and the filtrate was concentrated. The hydrochloride of the base was deposited as brown crystals which were very hygroscopic. These were dissolved in ethyl alcohol and a small amount of animal charcoal was added. The mixture was warmed and filtered and an aqueous solution of chloroplatinic acid was added to the colourless filtrate; an amorphous, yellow precipitate slowly formed and after leaving the mixture over-night, this was filtered off and washed with alcohol. The chloroplatinate was a yellow, amorphous powder, insoluble in water and organic solvents and corresponded in properties to the chloroplatinate of 1:4-thiazan described by Davies (Found: Pt = 41.0. Calc., Pt = 41.1 per cent.).

The condensation product was found to be very resistant to the action of boiling dilute hydrochloric acid, most of it being recovered unchanged after the mixture had been boiled for three hours.

Reaction between $\beta\beta'$ -Dichlorodiethyl Sulphoxide (and Sulphone) and Potassium Phthalimide.—A mixture of $\beta\beta'$ -dichlorodiethyl sulphoxide (1 mol.) and potassium phthalimide (2 mols.) was heated at 160° for four hours. Much charring took place and on washing the product with hot water and dilute sodium hydroxide, no residue was left except a small amount of tar, which was not further examined. An experiment carried out at 130 – 140° yielded the same result.

$\beta\beta'$ -Dichlorodiethylsulphone behaved in the same manner when heated with potassium phthalimide.

CCCXL.—*The Interaction of Potassium Tetroxide with Ice and with Dilute Sulphuric Acid.*

By HERBERT HAWLEY and HENRY JULIUS SALOMON SAND.

THE question whether an oxide of hydrogen higher than that corresponding to the formula H_2O_2 can be prepared in a similar manner to the higher sulphides of hydrogen is one of considerable interest. Bach (*Ber.*, 1900, **33**, 1506, 3111) believed that such a higher peroxide should, on treatment with acid and permanganate, contribute more than one atom of oxygen to each atom of oxygen supplied by the permanganate. On testing the matter by measuring in the same experiment the permanganate employed and the oxygen evolved, using peroxide from various sources, he in many cases found an excess of the latter, corresponding, according to his views, to the presence of a small amount of a higher peroxide. This was particularly the case with the peroxide derived from potassium tetroxide. H. E. Armstrong (*P.*, 1900, **16**, 134) pointed to the possibility that Bach's results might be due to the formation of a persulphuric acid. Following up this idea, Ramsay (*T.*, 1901, **79**, 1324) showed that on the addition of hydrogen peroxide to a mixture of sulphuric acid and permanganate more oxygen may be obtained than if the permanganate is added to the same amount of hydrogen peroxide mixed with sulphuric acid; and similarly, that more permanganate is used in the former than in the latter case. This is due to the formation of a persulphuric acid in the second instance the action of which on permanganate is very slow. For the purpose of a criticism of Bach's experiments, Ramsay's results are, however, not valid, for the concentration of his sulphuric acid was different from that of Bach, and, as was shown later by Clover (*Amer. Chem. J.*, 1903, **29**, 463), no persulphuric acid is formed under the conditions of Bach's work; besides, some of Bach's results were obtained when acetic acid was employed in place of sulphuric acid. Secondly, even if persulphuric acid had been formed, this would not have affected the relative amounts of permanganate employed and oxygen evolved, as was pointed out later in Bach's reply. The correct explanation of Bach's results was doubtless supplied two years later by Clover (*loc. cit.*), who showed that the discrepancies observed were probably due to an insufficiency of acid, in which circumstances hydrated manganese dioxide is precipitated which catalytically decomposes more hydrogen peroxide than corresponds to its own available oxygen. It was thus proved that Bach's results furnish no evidence for the existence of hydrogen tetroxide. Nevertheless, the importance of the matter justifies the search for more

positive evidence of the absence of this substance when potassium tetroxide is treated with water or with acid.

The method pursued in the following experiments consisted in allowing potassium tetroxide to react with ice or with dilute sulphuric acid at or below 0° and measuring the oxygen evolved. If this were less than the amount which would leave hydrogen peroxide in the solution, the presence of a higher oxide of hydrogen would be proved. The experiments, however, showed that even when the greatest care was exercised in bringing the reactants together, slightly more oxygen was evolved than corresponded to the quantitative conversion of the tetroxide into a derivative of hydrogen peroxide. There was thus no evidence for the formation of a higher peroxide in solution. On the contrary, a small amount of the ordinary peroxide formed must have undergone decomposition under the conditions of the experiment. However, it was still possible that there remained a small amount of a higher peroxide as well as some ordinary peroxide. The most suitable method to test this question was considered to be the quantitative determination of a property of the solution. The rate of reaction with hydrogen iodide was therefore measured, and compared with that of a similar solution made up from Merck's hydrogen peroxide. As a result, it was found that the velocity coefficients under corresponding conditions were in every case the same for the test as for the standard solution.

EXPERIMENTAL.

Measurement of the Oxygen evolved when Potassium Tetroxide is treated with Ice or Dilute Sulphuric Acid.—Two preparations of potassium tetroxide were made from weighed amounts of potassium. Vernon Harcourt's instructions were followed (T., 1862, 14, 267), with the only alteration that the potassium for the second preparation was obtained in bright pellets by the method recommended by Bunbury and Martin (T., 1914, 105, 417). In the first case, 15.61 grams of the product were obtained from 9.46 grams of potassium, corresponding to a yield of 73 per cent. of potassium tetroxide and 27 per cent. of potassium peroxide. In the second case, the yield was 49.94 grams of the product from 20.71 grams of potassium, corresponding to 84.1 per cent. of tetroxide and 15.9 per cent. of the peroxide. The amount of potassium in each preparation was confirmed by dissolving a weighed amount in water and titrating the potassium hydroxide formed. From these numbers we calculate that in the case of the first preparation 64.4 grams correspond to 39 grams of potassium, and yield, on reduction to potassium peroxide, 6.55 litres of oxygen at *N.T.P.* and 12.15

litres on reduction to potassium monoxide. In the second preparation, 67.9 grams correspond to 39 grams of potassium and yield 9.0 litres of oxygen on reduction to the peroxide and 14.6 litres on reduction to the monoxide. The apparatus employed was a tube of the shape shown in the accompanying sketch; this was attached to a nitrometer by a length of thick-walled rubber tubing. The tetroxide was weighed into the opening *A*, the apparatus cooled in ice water, and dry ice introduced through *B*. All nitrometer readings were taken with the tube immersed in ice-water. The reactants were brought together gradually with great care by suitable manipulation after further cooling in a freezing mixture. In some of the experiments the tube was afterwards heated in a calcium chloride bath and the contents were allowed to boil for about half an hour, after which it was again cooled to 0° to allow the nitrometer to be read. The results are recorded in Table I. Nos. 1 to 8 refer to the experiments on sample 1 of the tetroxide, in which the latter was brought together with ice, No. 9 to an experiment in which about 10 c.c. of a mixture of ice and water, containing 3 c.c. of *N*-sulphuric acid, were allowed to act on sample 2 of the tetroxide.

FIG. 1.

TABLE I.

Litres of oxygen at *N.T.P.* per 39 grams of potassium calculated

No.	Gram of tetroxide taken.	from evolution	to yield	from evolution	to yield
		of gas in freezing mixture.	K_2O_2 .	of gas on boiling.	K_2O .
1	0.192	7.34	6.55		
2	0.186	7.27	"		
3	0.247	7.35	"		
4	0.268	7.27	"		
5	0.173	7.27	"

8	0.207	7.80	"	12.15	"
9	0.177	10.0	9.0	14.9	14.6

It will be seen that in every case slightly more oxygen is liberated than corresponds to the quantitative production of hydrogen peroxide, a certain amount of which must therefore have undergone decomposition. This is not surprising, for it is well known that hydrogen peroxide is very unstable in alkaline as compared with acid solutions. The total amount of oxygen liberated after boiling, however, agrees closely in every instance with the calculated amount. This is in accordance with a series of experiments in which

it was proved that hydrogen peroxide may be accurately estimated gasometrically by simply boiling its alkaline solution, provided that air-free water be employed and the boiling be continued for about half an hour.

Comparison of the Aqueous Solution obtained from Potassium Tetroxide with a similar one derived from Merck's Perhydrol as regards Velocity of Reaction with Hydrogen Iodide.—The velocity of the reaction between hydrogen peroxide and hydrogen iodide has been studied by Magnanini (*Gazzetta*, 1891, **21**, 476) and by Noyes (*Z. physikal. Chem.*, 1895, **18**, 131). There is some doubt whether the reaction is uni- or bi-molecular with reference to the hydrogen iodide, that is, whether it is bi- or ter-molecular as a whole. Since the object of the present experiments was only to compare solutions derived from potassium tetroxide with such known to contain only hydrogen peroxide, the conditions were chosen so as to make it possible to calculate either a bimolecular or a termolecular coefficient, that is, a large excess of hydrogen iodide was employed. This was obtained by adding to a solution of potassium iodide an exactly equivalent amount of dilute sulphuric acid. A considerable amount of potassium sulphate was thus present in all the experiments. The temperature chosen was 0°. In the experiments in which the peroxide was derived from potassium tetroxide, a quantity of the latter weighed by difference was brought together with ice and cautiously neutralised at 0° with the calculated amount of *N*/10-sulphuric acid. Fifty c.c. of this solution were placed in a conical flask in ice-water for each experiment. The strength of the solution in terms of available oxygen was determined by titration with permanganate. In other flasks at 0° were placed 200 c.c. of solutions derived from weighed quantities of potassium iodide and the equivalent volumes of *N*-sulphuric acid. At the beginning of a determination, the solutions containing the peroxide and the hydrogen iodide were mixed by pouring backwards and forwards from one flask to another. Three identical experiments were started for each series and the whole of the solution in each flask was rapidly titrated at 0° by means of standard thiosulphate after a suitable interval. The time taken to the completion of the titration was the value adopted.

Those experiments in which the peroxide was derived from Merck's perhydrol were carried out in an exactly similar manner. The solution was diluted to agree approximately with the corresponding one from potassium tetroxide. In one series of experiments (No. 5, Table II) a small amount of potassium sulphate was added to make the concentration of this salt the same as that in the companion series (No. 4). In some preliminary experiments, the

procedure followed in a well-known lecture experiment was adopted, of adding a known quantity of thiosulphate to the reacting mixture at the beginning of the experiment and noting the time required for the appearance of the blue colour. This method was, however, found to lead to complications, owing to the very considerable action which was proved by a special series of experiments to take place between thiosulphate and hydrogen peroxide. Table II gives the particulars of the experiments carried out. The concentration of the hydrogen iodide (a), hydrogen peroxide (b), iodine (x), and potassium sulphate are given in gram-equivalents per litre, the time *t* in minutes. Coefficients *k*₂ and *k*₃ for a second and a third order reaction, respectively, were calculated by means of the formulae

$$k_2 = \frac{2.3026}{(a-b)t} \log_{10} \frac{b(a-x)}{a(b-x)} \quad \text{and} \quad k_3 = \frac{k_2}{a-b} - \frac{x}{a(a-b)(a-x)t}.$$

It will be seen that under the conditions of the experiment good coefficients were calculated in each series for *k*₂ as well as for *k*₃, the latter being slightly better and also allowing a more consistent interpretation of the effect of the presence of potassium sulphate. Series 1 and 2 and particularly series 4 and 5 allow a direct comparison to be made of the reaction velocity in the case of the solutions derived from potassium tetroxide and from perhydrol respectively. Thus, in series 1, we have the average value *k*₂ = 2.23 for hydrogen peroxide from perhydrol and *k*₃ = 2.17 for hydrogen peroxide from the tetroxide. In series 4 and 5, the identical average value 2.92 is obtained for *k*₃. Similar good agreement is found on comparison of the *k*₂ values. There can thus be no doubt as to the identity of the product in the two cases.

Summary.

The amount of oxygen liberated on bringing together potassium tetroxide and ice or dilute sulphuric acid at 0° was found to be slightly greater than that which would have quantitatively left a derivative of hydrogen peroxide in solution. The solutions left were tested as regards their velocity of reaction with hydrogen iodide and found to agree accurately with corresponding ones made up from hydrogen peroxide. It is thus proved that only hydrogen peroxide results from the interaction of potassium tetroxide with ice or with dilute sulphuric acid.

CCCXLI.—*Note on Glasstone's Discussion of Over-voltage Measurement.*

By HENRY JULIUS SALOMON SAND and EDWARD JOSEPH WEEKS.

In a paper (this vol., p. 1745) on overvoltage measurement, Glasstone draws the conclusion that the difference between the results obtained by the direct and by the commutator method is due partly to the induced currents which may be generated when the latter method is employed with inductive circuits, and that the values yielded by the method are therefore dependent on the type of apparatus used. Having been engaged for some time in measuring overvoltages by the commutator method, we feel compelled to state in contradiction to these conclusions that the commutator method yields very definite results, which are reproducible in the case of some metals to about a centivolt, and that they are independent within ordinary limits of the self-induction of the circuit.

There are several errors in Glasstone's work. In order to arrive at his conclusions, he attempts to compare overvoltages measured during the passage of the current when first a continuous and then an intermittent current is employed. In the latter case, however, he uses no arrangement for disconnecting his potentiometer in the intervals during which the current is interrupted. It is therefore not surprising that the results should be intermediate between those which are in operation when the current is on and those which hold when it is off. Yet it is on these results that he bases all his conclusions. There is another pitfall that has been overlooked. To render the experiments with continuous and with intermittent

current comparable, it would have been desirable to have the current density during the actual passage of the current as nearly as possible the same in the two cases. Owing to the arrangement of his circuit, Glasstone's intermittent current rises comparatively slowly from zero to its maximum value, so that it would be difficult to assign a definite value to it. There is, however, a more serious error. In all his experiments Glasstone employs ammeters which act as coulombmeters. The average current density during the actual passage of the current for a given reading of the ammeter was thus approximately twice as great with the intermittent as with the continuous current. If, therefore, it had been possible to connect the cathode to the potentiometer during the intervals only in which the current was on, Glasstone should have obtained higher values for overvoltage with intermittent than with continuous current instead of the lower ones actually registered by him.

The following experiments are recorded to substantiate the statements just made.

Overvoltage with Intermittent Current, measured during the Passage of the Current.—A Whetham double commutator (*Phil. Trans.*, 1900, [A], 194, 321) was employed. One of the commutators was utilised to obtain the intermittent current, only two of the brushes being in use. The second commutator made and broke the connexion between the potentiometer and the cathode, so that the make occurred a little after and the break a little before the corresponding makes and breaks of the working current. The number of makes and breaks was about 3600 per minute. The cathode was a circular disk of platinum foil having an area of one square centimetre. This was let into a glass tube and was insulated at the back by melting upon it a mixture of paraffin and beeswax. A pinhole was pierced through it, and connexion was made to the auxiliary hydrogen electrode by means of the electrolyte in the interior of the tube. The electrolyte of the hydrogen electrode was the same as that undergoing electrolysis, so that potentiometer readings gave overvoltages direct. The ammeter was of the moving-coil type. When employed with intermittent current, this instrument acted with sufficient accuracy as a coulombmeter. As already explained, higher overvoltages were therefore to be expected for a given reading with intermittent than with continuous current. This expectation was fulfilled in every instance. Thus in one series of measurements in *N*-sulphuric acid, for a reading of 100 milliamps., an overvoltage of 0.60 was obtained with continuous, an overvoltage of 0.65 immediately afterwards with intermittent current. With a current reading of 150 milliamps., the corresponding numbers were 0.75 and 0.76. In *N*-sodium hydroxide, a current reading of

100 milliamps. corresponded to an overvoltage of 0.72 with continuous, to an overvoltage of 0.79 with intermittent current, the corresponding voltages for a current reading of 150 milliamps. being 0.75 and 0.84, respectively.

Attempts were also made to compare overvoltages on continuous current corresponding to a given current density, with those holding for intermittent current, the average density of which, during the intervals in which it was in operation, was the same as that of the continuous current. For this purpose, a special calibration curve of the ammeter was constructed, correlating readings on the intermittent current with the actual values of the latter during the intervals it was in operation. These values were determined in each case by balancing the potential difference between the ends of a resistance of known value through which the current was flowing against that of a potentiometer; the latter being in connexion through the commutator in the identical manner explained above only while the current was flowing. Passing up the ammeter scale, and leaving out the first quarter, it was thus found that the ratio of intermittent current strength measured by the potentiometer to that measured by the ammeter varied fairly continuously from 2.40 to 2.15, the average value of about 2.25 corresponding, as nearly as could be judged from an inspection of the commutator, to the ratio of total time to time during which the current was on.

TABLE.

		Overvoltages (during current).			
		In H_2SO_4 solution.		In NaOH solution.	
Ammeter readings.					
For continuous current.	For intermittent current.	For continuous current.	For intermittent current.	For continuous current.	For intermittent current.
0.137	0.060	0.68	0.52	0.74	0.70
0.161	0.070	0.73	0.55	0.75	0.72
0.183	0.080	0.75	0.58	0.78	0.75
0.201	0.090	0.77	0.60	0.78	0.77

The accompanying table gives a comparison of overvoltages measured with continuous and with intermittent current, the strength of the current while it was actually on being as nearly as possible the same in both cases. The values in the first column may be taken as current densities; a comparison of these with the values in the second illustrates the difference in ammeter readings to be taken with continuous and with intermittent current. The numbers given are the mean of results obtained in two series of experiments; in the first, the current was successively taken from low to higher values; in the second, it was similarly successively diminished. It will be seen that the continuous-current values are throughout somewhat higher than the corresponding intermittent ones. This

is not surprising when we remember that with intermittent current there is more opportunity than with continuous for some of the transfer-resistance to disperse. There is no justification for ascribing these differences to induced currents in the sense done by Glasstone.

Effect of Self-inductance of the Circuit.—The only rational method that is apparent to us for deciding whether the self-induction of intermittent currents has any influence on overvoltage measurements, is to determine whether identical results are obtained when circuits of widely differing self-inductance are employed. Some considerable time before the appearance of Glasstone's publications we satisfied ourselves on this point. For this purpose, we first connected the terminals of the battery employed to the end terminals of a sliding rheostat consisting of wire wound on an enamelled iron drum, and regulated the current by shunting it on part of this resistance. Later we obtained the same current by using the rheostat in series. No difference in overvoltage was observed. On the publication of Glasstone's recent paper we carried out further experiments in which first a circuit which was as nearly as possible non-inductive and later one with considerable self-inductance of known value was employed. The non-inductive circuit consisted simply of a battery, the commutator, the electrolytic cell, and the moving-coil ammeter, through the shunt of which most of the current passed. The return wires were tied close to the leading-out wires. The inductive circuit contained besides, a regulating resistance and an electromagnet the self-inductance of which for currents from 0 to 1 ampere was known to be 25 millihenrys. The two circuits were arranged so that by altering a single switch it was possible to pass from one circuit to the other. The maximum current strength over the whole electrode at any instant was one ampere. For the overvoltage during the intervals in which the current was off (ordinary commutator method) we found independently of the self-inductance of the circuit in *N*-sodium hydroxide solution, for platinum the value 0.080, and for lead the value 0.590; the current density being 180 millicoulombs per second and square centimetre.* In *N*-sulphuric acid solution at current densities of 100 and 200 millicoulombs per second and square centimetre,* for platinum the overvoltage 0.200 was found independently of the self-inductance of the circuit. Intermittent current overvoltages measured during

* In order to indicate that the magnitudes of intermittent currents are stated in terms of the average over the whole time as recorded by the ammeter, and not during the time only when the current is on, we propose to substitute for the term ampere which we have previously used in conformity with the practice of other writers, the term coulomb per second.

the passage of the current were also determined in the inductive and non-inductive circuits according to the method described above. These likewise were found to be independent of the self-inductance of the circuit.

Discussion.

In a previous paper (this vol., p. 457), the opinion to which we still adhere was expressed that overvoltage determined by the commutator method measures polarisation; and we propose where necessary to refer to it in future as polarisation-overvoltage. Our principal reason for attaching great importance to it is that very definite and reproducible values are obtainable, so that even if our interpretation were proved incorrect, the numbers would still retain experimental significance. In contrast to this, overvoltage values determined by the "direct" method are dependent on a great many factors, extremely difficult to control. We propose where necessary to refer to these values as total overvoltages. Whereas polarisation overvoltage measures an effect which is reversible in so far as it persists for a short time after the interruption of the current, total overvoltage undoubtedly comprises completely irreversible effects. We consider that the best method to express this is to ascribe the difference between total and polarisation overvoltage to transfer-resistance, a term we owe to Gore. In doing this, we by no means wish to commit ourselves to the view that transfer-resistance is in all cases due entirely, or even partly, to films of gas. On the contrary, we are quite alive to the possibility that its range may be partly of a molecular order, that part of it may be inherent to the transfer of current from the electrode to the electrolyte, and that the potential gradients due to it may be of importance to the chemical processes occurring at the electrode. The opinion is sometimes expressed that overvoltage measured by the direct method is due in part to a polarisation which persists for so short a time only that it is impossible to measure it by the commutator method. Such a view we cannot refute, but even if it were correct, it would have no bearing upon the fact that overvoltages measured by the commutator method correspond to an experimental reality which is independent, over considerable ranges, of the conditions of the experiment. These overvoltages are therefore of experimental, and as we hope to show in a future publication also of very considerable theoretical interest. The foregoing discussion is independent of the admitted fact that electric waves affect total overvoltage during the time they are in operation, and also of the possibility that the chemical results of intermittent current may differ from those of continuous.

Summary.

Owing to an error in the arrangement of Glasstone's experiments, these can give no information on the matter they were intended to elucidate, and all his conclusions are invalid. Contrary to these conclusions, we find that intermittent-current overvoltages are independent of the self-inductance of the circuit over a much wider range than is likely to come in question during ordinary experiments. The relation of polarisation to total overvoltage has been discussed.

We take this opportunity to express our indebtedness to Dr. D. Owen for the loan of the Whetham commutator and of the electromagnet employed, and for having the self-inductance of the latter determined for us.

[Received, October 2nd, 1923.]

CCCXLII.—*Preparation and Stability of Cuprous Nitrate and Other Cuprous Salts in presence of Nitriles.*

By HOWARD HOULSTON MORGAN.

If a decinormal solution of silver nitrate in acetonitrile be placed in contact with finely divided copper, precipitation of the silver will rapidly take place. The resulting solution is colourless and, after filtration, will remain so almost indefinitely if air be excluded. Even in contact with the air, it will remain colourless for several hours, but thereafter will become very slightly turbid and develop a faintly green tinge.

The copper in the solution is present in the cuprous condition, as is shown by the following typical experiment, in which the precipitated silver and the excess of copper were both estimated: 0.5588 gram of pure copper powder, added to 0.6938 gram of silver nitrate dissolved in 50 c.c. of acetonitrile, precipitated 0.4409 gram of silver (equivalent to 0.6940 gram of silver nitrate); the remaining copper was 0.2982 gram. This gives 63.78 grams of copper, equivalent to 107.9 grams of silver.

On distilling off the acetonitrile on a water-bath, a slightly greenish-blue, very viscous residue is obtained, from which, on the addition of two or three times its bulk of water, hydrated cuprous oxide is precipitated. The clear, almost colourless solution obtained

by filtering this contains cuprous nitrate and free nitric acid; the addition of concentrated hydrochloric acid yields a white precipitate of cuprous chloride, and dilution with water precipitates more cuprous hydroxide: $\text{CuNO}_3 + \text{H}_2\text{O} \rightleftharpoons \text{CuOH} + \text{HNO}_3$. This action is similar to that which takes place between water and other cuprous salts, with the exception of cuprous sulphate, which, according to Recoura (*Compt. rend.*, 1909, **148**, 1105), decomposes under similar conditions into cupric sulphate and metallic copper.

If during the last stages of distilling off the solvent from the acetonitrile solution of cuprous nitrate a slow current of inert gas be passed through the distilling flask and continued for some little time after acetonitrile ceases to drop from the condenser, the residue will become distinctly green and contain particles of metallic copper. If, however, the flow of gas be stopped as soon as distillation is complete, then the liquid residue will be quite free from colour and, on cooling to the ordinary temperature, will solidify to a mass of white crystals having the composition $\text{CuNO}_3 \cdot 4\text{CH}_3\text{CN}$. These crystals are colourless so long as they remain sealed up, but, on allowing air to enter, they immediately turn green. On passing an inert gas over them at the ordinary temperature, they change first to a pale yellow colour, then, very gradually, give rise to a dark green substance together with particles of metallic copper. It appears that, in an atmosphere saturated with acetonitrile, the crystals are stable, but, when the vapour pressure of the atmospheric acetonitrile falls below a certain value, the "acetonitrile of crystallisation" is given off and the remaining cuprous nitrate decomposes thus: $2\text{CuNO}_3 = \text{Cu}(\text{NO}_3)_2 + \text{Cu}$. Colourless crystals having the same composition as those mentioned above, namely, $\text{CuNO}_3 \cdot 4\text{CH}_3\text{CN}$, are more readily obtained in a pure state by distilling off the acetonitrile from the solution under reduced pressure at the ordinary temperature, and then passing a slow current of inert gas for about a quarter of an hour over the crystals that have been gradually deposited as the solvent evaporated (Found: in two specimens obtained in this way, Cu = 21.70, 22.06. $\text{CuNO}_3 \cdot 4\text{CH}_3\text{CN}$ requires Cu = 21.80 per cent.).

Although the experiments referred to above indicate that cuprous nitrate is not capable of existing alone, nevertheless a further experiment was carried out, in which the most rigorous precautions were taken to exclude air and moisture, and in which the decomposition temperature of the crystals was kept very low. The various parts of the apparatus were all sealed together with glass joints. The cuprous nitrate crystals were formed at 10° in an atmosphere of hydrogen at 2 mm. pressure. That part of the

apparatus containing the crystals was then immersed in ice and water at 0° , whilst the other part was cooled in liquid air. After six hours, the crystals had become green and particles of metallic copper were visible; acetonitrile had condensed in the colder bulb.

It would seem impossible, therefore, for cuprous nitrate to be isolated. In the molecule $\text{CuNO}_3 \cdot 4\text{CH}_3\cdot\text{CN}$ the four molecules of acetonitrile are apparently attached to the atom of copper in a tetrahedral arrangement, thereby protecting it from oxidation, or, in other words, preventing the transference of the second "normally active" electron of the copper atom from the latter to the acidic radicle. Or again, it might be expressed, according to Werner's theory, as a case where one of the principal valencies of copper is temporarily suppressed by the activity of four auxiliary valencies of that metal. The mere removal of these four molecules of acetonitrile, which, it would appear, are not held very tenaciously, causes the second principal valency of the copper atom to become active, entailing, in this case, a redistribution of the valency electrons amongst the copper atoms themselves, as there are no neutral acidic radicles present. Thus :

In the case, however, where oxygen is presented to the molecule $\text{CuNO}_3 \cdot 4\text{CH}_3\cdot\text{CN}$, the second principal valency of the copper atom is immediately called into play, the activity of four auxiliary valencies being insufficient to prevent the transference of an electron from the copper atom to the oxygen atom, or hydroxyl group. Thus :

The above suggestions would seem to account for the observations that the colourless crystals become green, but only slowly and with simultaneous formation of metallic copper, when the pressure of acetonitrile in the atmosphere above them is kept very low, whereas the presence of air produces a green compound immediately and yields no free copper.

The fact that dilute solutions ($N/10$ or weaker) of this salt in acetonitrile can be kept for many hours in free contact with the air, without showing signs of oxidation, may perhaps be partly due to the slight solubility of oxygen in acetonitrile. On the other hand, it may be ascribed to further solvation of the copper atom as the active mass of solvent is increased. In this connexion, it is noteworthy that strong solutions of this salt are less stable in contact with the air than those that are more dilute. Thus it was found

impossible to use, in the ordinary way, solutions of concentration $N/4$ or $N/5$ for the determination of some of their physical properties, which were determined for solutions of $N/10$ strength and downwards with comparative ease and accuracy. Further, the stronger solutions became blue within a quarter of an hour after filtering from excess of copper.

It is well known that the valency of an element, that is, its normal or principal valency, is dependent on physical conditions such as temperature and pressure, but that such valency may be dependent also on the solvent does not appear to have been remarked upon.*

There seems no doubt, however, that when acetonitrile is used as a solvent for salts of copper, the reaction $\overset{++}{\text{Cu}} + \text{Cu} = 2\overset{+}{\text{Cu}}$ takes place rapidly and proceeds to completion. In other words, copper behaves as a stable univalent element towards its salts in solution in acetonitrile. This is further illustrated by what follows.

Cuprous Chloride.—Anhydrous cupric chloride dissolves fairly readily in acetonitrile, giving, in solutions of about $N/10$ strength, a golden-yellow solution. A $N/10$ -solution, when shaken with excess of copper powder in an atmosphere of nitrogen, becomes colourless in about half an hour. This solution is not quite so stable in the air as the $N/10$ -solution of cuprous nitrate, but it can be filtered in the usual way, transferred from one vessel to another, and will remain bright and colourless for about an hour in a loosely covered flask.

Evaporation of the solvent from this solution, in absence of air, yields colourless crystals having a composition represented by the formula $\text{CuCl} \cdot \text{CH}_3 \cdot \text{CN}$.

This compound has been described previously by Naumann (*Ber.*, 1914, 47, 247) and by Rabaut (*Bull. Soc. chim.*, 1898, [iii], 49, 786). In both cases, however, the compound was prepared from cuprous chloride which had been made previously to bringing it in contact with acetonitrile. Naumann states that his solution developed a greenish-brown turbidity in one or two minutes. He is probably referring, however, to stronger solutions than $N/10$, or, alternatively, moisture must have been present.

Cuprous Bromide.—Anhydrous cupric bromide dissolves readily

* Werner (*Z. anorg. Chem.*, 1897, 15, 5) mentions that, when added to pyridine, mercurous chloride immediately decomposes into soluble mercuric chloride and metallic mercury, the latter being precipitated. The same author ("New Ideas on Inorganic Chemistry," p. 64) states that when iron is combined with 3 mols. of σ -phenanthroline or 3 mols. of α -dipyridyl, it passes with very great ease into the bivalent condition, and, under these conditions, tervalent iron can only be retained by very cautious work.

in acetonitrile, giving a dark greenish-brown solution. Shaken with copper powder in an atmosphere of nitrogen, this solution (of about $N/10$ strength) becomes colourless in about an hour. The stability of the filtered solution when in contact with the air is almost the same as that of cuprous chloride mentioned above. Evaporation of the solvent from this solution, in absence of air, yields glistening, white crystals having a composition represented by the formula $\text{CuBr}_2\text{CH}_3\cdot\text{CN}$.

That the number of molecules of acetonitrile combined with one atom of copper is much higher in the cuprous nitrate salt than in the cases of the chloride and bromide just described, is probably accounted for, in part at all events, by there being greater association of the cuprous chloride or bromide molecules than is the case with cuprous nitrate. Indication has been obtained, from electrical measurements, that in solutions of as high a dilution as $N/100$, or still higher, the cuprous chloride and bromide molecules are, for the most part, associated, whilst under similar conditions cuprous nitrate is dissociated. In such associated molecules the auxiliary valencies of the copper atom would be less free to combine with extra molecules of solvent.

Solutions of these cuprous salts in acetonitrile give ionic reactions comparable with those which take place in aqueous solutions of ordinary salts. For example, a $N/2$ -solution of silver nitrate was added to a $N/10$ -solution of cuprous bromide, the silver nitrate being in slight excess of that required to react completely with the cuprous bromide. A strictly quantitative precipitation of silver bromide was proved to have occurred.

Approximately $N/10$ -solutions of cuprous nitrate and of potassium iodide, respectively, were mixed. A white, finely granular precipitate was immediately thrown down, but the solution remained turbid until excess of potassium iodide was added, when, on shaking, the precipitate immediately coagulated and quickly settled to the bottom of the flask. The precipitate, after being washed with acetonitrile and dried, proved to be pure potassium nitrate, whilst the residue obtained by distilling off the solvent from the filtrate contained cuprous iodide and was free from nitrate :

A solution of anhydrous cadmium nitrate in acetonitrile was electrolysed, a copper anode and a platinum cathode being used. The current was allowed to pass until all the cadmium had been deposited. The solution remained colourless throughout, and, on distilling off the solvent, pure crystals of $\text{CuNO}_3\cdot 4\text{CH}_3\cdot\text{CN}$ were obtained.

Determination of the Electro-chemical Equivalent of Copper in the Acetonitrile Solution of Cuprous Nitrate.—The copper voltameter was arranged in a weighing bottle, 6 cm. high and 3 cm. in diameter; the copper was estimated by using a copper-plated platinum anode. The weight of copper coating on the platinum was obtained by placing a silver voltameter in the circuit containing the copper-plating bath. After the passage of the current through the acetonitrile solution of cuprous nitrate, the copper-plated platinum anode was washed and the remaining copper dissolved off in nitric acid and estimated by means of potassium iodide and sodium thio-sulphate, which had been standardised against pure copper. In this way errors due to oxidation of the copper were eliminated. The quantity of electricity passing was accurately measured by means of a small silver voltameter in which the silver was deposited as firmly adherent crystals. The following results are typical of those obtained in three separate experiments, using cuprous nitrate solutions of different strengths varying from $N/10$ to $N/50$:

(A) Electroplating platinum for use as anode: Silver deposited = 0.2326 gram, equivalent to 0.06850 gram of copper.

(B) Acetonitrile solution in circuit: Silver deposited = 0.0832 gram (approx. 0.007 amp. for $3\frac{1}{4}$ hours).

The weight of copper remaining on the anode was 0.01958 gram, and the copper dissolved from the anode was $0.06850 - 0.01958 = 0.04892$ gram.

Therefore ratio of silver to copper = $0.0832 : 0.04892$ or $107.9 : 63.46$.

Clearly, therefore, metallic copper, in the presence of acetonitrile, goes into solution in the form of univalent ions, and, so long as oxygen is not present, these ions exhibit no tendency to become bivalent.

Cuprous Nitrate and Succinonitrile.—That the above behaviour of acetonitrile is connected with the presence of the unsaturated CN radicle needs no emphasising, but it was thought worth while to try to prepare, in a similar manner, a compound containing cuprous nitrate and succinonitrile. As was expected, a colourless compound, $\text{CuNO}_3 \cdot 2\text{C}_2\text{H}_4(\text{CN})_2$, was obtained [Found: Cu = 21.53; N = 23.63. $\text{CuNO}_3 \cdot 2\text{C}_2\text{H}_4(\text{CN})_2$ requires Cu = 22.11; N = 24.47 per cent.].

The succinonitrile was prepared from ethylene dibromide and potassium cyanide by Fauconnier's method (*Bull. Soc. chim.*, 1888, [ii], 50, 214). After a second distillation under reduced pressure, the product distilled at $151^\circ/16$ mm. within 0.5° . Silver nitrate very readily dissolved in this substance at 60° and, on the addition of copper powder to the solution, a rapid deposition of black spongy silver took place, whilst the solution remained colourless. After standing for two hours, the mixture was filtered (at 60°), the residue washed with alcohol and ether, and the remaining mixture of copper

and silver estimated. The following results showed that the silver had been completely replaced by univalent copper : Initial weights of silver nitrate and copper = 0.328 and 0.2762 gram, respectively.

Final weights of copper and silver = 0.1550 and 0.2080 gram (equivalent to 0.327 gram of silver nitrate).

Ratio of silver to copper = 107.9 : 63.02.

The filtrate, which was colourless, was extracted several times with a mixture of ether and alcohol. This dissolved the succinonitrile which had acted as the solvent, leaving a comparatively small quantity of colourless liquid as a lower, heavier layer. The latter was warmed in the steam-oven for a few minutes until it ceased to smell of ether. On cooling, it solidified to a colourless, crystalline mass which had the composition given above, that is, $\text{CuNO}_3 \cdot 2\text{C}_2\text{H}_4(\text{CN})_2$.

This compound is practically stable in the air, and may be weighed on an open watch-glass. It may be kept in an ordinary stoppered bottle for many months without decomposing, and shows only the very slightest green coloration after several years' storage in the same way. It dissolves readily in water and the precipitation of yellow hydrated cuprous oxide from this solution takes place comparatively slowly.

The experiments described in this communication formed a part of a more extended investigation carried out several years ago at the Imperial College of Science and Technology. The author wishes to thank Professor J. C. Philip for the kind interest he took in the work and for placing the resources of his laboratory at the author's disposal.

REVELSTOKE, SLOUGH.

[Received, February 28th, 1923.]

CCCXLIII.—*Derivatives of Thionaphthacoumarin.*

By SAMUEL SMILES and LESLIE RALPH HART.

PREVIOUS experiments with the sulphuric acid solutions of 2-thiolbenzoic acid or of 2 : 2'-dithiobenzoic acid have shown that 3-oxy-(1)thionaphthen or its derivatives are formed from these in presence of substances containing the diketomethylene group. It has been further shown that the reactions may be interpreted as the condensation of the hypothetical sulphenic acid with the methylene group of the substances in question :

Reactions of this type have been observed with ethyl malonate, ethyl acetoacetate, acetylacetone, benzoylacetone, acetonedicarboxylic acid, and malonic semi-aldehyde and in none of these cases has the oxythionaphthen derivative (for example, I) containing the two carbonyl groups been isolated; one at least of these was always removed by hydrolysis at some stage of the process, whilst under more severe conditions 3-oxy(1)thionaphthen itself has been observed. It may be here mentioned that the product from dibenzoylmethane has been stated to be (T., 1915, 107, 1378) the 2:2-dibenzoyl-3-oxythionaphthen; but re-examination of the material has shown that this is incorrect, and the matter will be referred to in a subsequent communication. This type of reaction appears to be of a general nature and it seemed desirable to examine the behaviour of other substances containing a labile methylene group of different character.

In the experiments now described, the case of glutaconic acid and a few of its derivatives has been investigated. Since this reaction appears to be concerned with the methylene tautomerides of the substances quoted in illustration, the successful application to the glutaconic acids seemed doubtful, for Thorpe and his collaborators have shown that the methylenic forms of these substances are extremely labile, although substitution at the β -carbon atom of the system tends to confer stability on them. For this reason, the first substances to be examined were aconitic acid and β -chloro-glutaconic acid. These acids very readily undergo the condensation with 2-thiolbenzoic acid, giving the corresponding 4-carboxy- and 4-chloro-derivatives of the *thionaphthacoumarin* (II and III) in 65–70 per cent. of the amount required by theory. Glutaconic acid gave the parent *coumarin* (IV), but, as might be expected

from the greater instability of the methylene form of the unsubstituted acid, the yield was much smaller than in the foregoing cases.

The constitution (II) assigned to the product obtained from aconitic acid is inferred from the following considerations. The substance, like all the members of this group, yields "thioindigo" when treated with alkaline oxidising agents, a fact which indicates that condensation of the 2-thiobenzoyl group has taken place with

the terminal atom of the three-carbon system, leading at first to the arrangement (V). Direct titration of the product with sodium

hydroxide shows that two of the carboxyl groups of aconitic acid have been eliminated, one evidently being removed as carbonic acid from the 2-position, as commonly observed in all the syntheses of this type hitherto examined. The view that the γ -carboxyl group has become involved in forming the lactone group of a coumarin is supported by the fact that titration after treatment with excess of sodium hydroxide indicates the liberation of a second carboxyl group by this reagent. Moreover, the ease with which the thionaphthacoumarin arrangement is formed from a system of this type (VI) perhaps needs no comment, but it has been demonstrated in the case of the formation of the 4-hydroxy-derivative (IX) from acetonedicarboxylic acid and 2-thiolbenzoic acid (T., 1921, 119, 1810). Also the substance may be sublimed without loss of carbon dioxide, thus exhibiting the stability which is to be expected (von Pechmann and Kraft, *Ber.*, 1901, 34, 422; Stuart, T., 1886, 49, 367) of a coumarin-4-carboxylic acid. Final confirmation of the structure assigned to this substance (II) has been obtained by its synthesis from oxymaleic acid and 3-oxy(1)thionaphthen, an extension of the usual von Pechmann synthesis which has already been applied to α -naphthol (Bartsch, *Ber.*, 1903, 36, 1968), giving ethyl naphthacoumarin-4-carboxylate. The constitution of the 4-chloro-derivative (III), which is formed from β -chloroglutaconic acid and 2-thiolbenzoic acid, follows from its relations to 4-hydroxythionaphthacoumarin (IX), the structure of the latter having been independently proved (T., 1921, 119, 1813). The chloro-derivative is formed when the latter is treated with phosphorus halides. Moreover, when the 4-hydroxythionaphthacoumarin is heated with aniline the 4-anilino-derivative is formed and this (VII) is identical with the product obtained from the chloro-compound and aniline

under similar conditions. The product yielded by glutaconic and 2-thiolbenzoic acids is evidently the parent thionaphthacoumarin

(IV), for it may also be obtained by heating the silver salt of the 4-carboxy-derivative, the reaction being closely analogous to that observed by von Pechmann and Kraft (*loc. cit.*) in the formation of coumarin from coumarin-4-carboxylic acid. Thionaphthacoumarin is also readily formed by the mild reduction of 4-chlorothionaphthacoumarin. Thus the relations between these members of the group have been completely established. It may be mentioned that in the foregoing reactions close analogy between these substances and the corresponding derivatives of the benzocoumarin series appears to exist, for Anschutz (*Annalen*, 1909, **367**, 200) has shown that benzotetronic acid is converted by phosphorus halides into the 4-chlorocoumarin, which by reduction yields coumarin. Moreover, 4-anilincoumarin may be obtained from either the 4-chloro-derivative or from benzotetronic acid (Anschutz, *loc. cit.*).

For the preparation of the pure β -chloroglutaconic acid used in some of these experiments the excellent method of Ingold and Nickolls (T., 1922, **121**, 1642) was followed. Experiments with the product of von Pechmann's process (*Ber.*, 1887, **20**, 145) fully confirm the opinion of these authors concerning the impurity of the material obtained. When this was submitted to condensation with 2-thiolbenzoic acid, mixtures of chlorothionaphthacoumarins were always obtained which varied in composition according to slight changes in the conditions of preparation of the chloroglutaconic acid. In the majority of these experiments the 4-chlorothionaphthacoumarin was isolated together with a dichlorocoumarin (VII) which increased in amount if the conditions of reaction in preparing the chloroglutaconic acid had been intensified. With regard to the structure of the dichloro-derivative, it is evident that the halogen must be situated in the coumarin complex and either at carbon atoms 3 and 4 as indicated (VII), or as the arrangement $-\text{CCl}_2-\text{CH}_2-$. Since the action of aniline removes only one halogen atom, giving a chloroanilino-derivative, it is clear that the former alternative is to be preferred.

Finally it may be remarked that the reactions of glutaconic acid and its derivatives here recorded are not exhibited by either itaconic or citraconic acid, and it is interesting to notice that *m*-thiolbenzoic acid, whilst capable of union with the aromatic nucleus under these conditions (T., 1922, **121**, 2509) like the ortho-compound, does not condense with acids of the glutaconic series nor indeed does it show reaction with acetylacetone or other substances of that type.

EXPERIMENTAL.

Thionaphthacoumarin-4-carboxylic Acid (II).—(a) A mixture of 2-thiolbenzoic acid (5 grams), aconitic acid (8 grams), and concn-

trated sulphuric acid (50 c.c.) was kept at 25° for half an hour and continually shaken. The red solution was then poured over crushed ice, the solid material which separated being collected and thoroughly washed with water. The product (5.5 grams) was purified with the aid of charcoal and by crystallisation from acetic acid.

(b) Equivalent quantities of 3-oxy(1)thionaphthen and hydroxy-maleic acid were mixed and added to 73 per cent. sulphuric acid. The mixture was kept at 50--60° for half an hour and then added to crushed ice. The product which separated was isolated and purified as in the foregoing preparation. It was found to be identical with the substance obtained from aconitic and 2-thiolbenzoic acids.

Thionaphthacoumarin-4-carboxylic acid forms bright yellow needles which melt at 285° and sublime when heated in a vacuum. The substance is sparingly soluble in most cold organic media; these dilute solutions exhibit a green fluorescence, that of the ethereal solution being particularly intense. It is readily converted into "thioindigo" by a warm ammoniacal solution of silver nitrate or by a warm alkaline solution of ferricyanide (Found: C = 58.3; H = 2.6; S = 13.2. $C_{12}H_6O_4S$ requires C = 58.5; H = 2.5; S = 13.0 per cent.). The substance may be directly titrated in alcohol by N/10-alkali [Found: equivalent = 245. $C_{11}H_5O_3S \cdot CO_2H$ requires equivalent = 246. Found: after addition of excess of N/10-alkali hydroxide and estimation of the amount of this remaining uncombined, equivalent = 139. $C_{10}H_5S(OH)(CO_2H)_2$ requires equivalent = 132].

Thionaphthacoumarin (IV).—(a) A mixture of glutaconic acid (10 grams), 2-thiolbenzoic acid (11 grams), and concentrated sulphuric acid (100 c.c.) was kept at 40° for three-quarters of an hour and frequently shaken. When cold, the purple solution was treated with ice, the solid which separated was collected, washed, and treated with a solution of sodium carbonate, and the residue (4.5 grams; 30 per cent. of the theoretical yield), after treatment with charcoal, was recrystallised from alcohol or acetic acid. *Thionaphthacoumarin* was thus obtained in pale yellow needles which melted at 176° and sublimed when heated in a vacuum. The substance is moderately soluble in the usual organic media, the solutions exhibiting a violet fluorescence. It is readily converted into "thioindigo" by a warm alkaline solution of a ferricyanide (Found: C = 65.2; H = 3.1; S = 15.8. $C_{11}H_6O_2S$ requires C = 65.3; H = 3.0; S = 15.8 per cent.).

(b) A cold saturated solution of 4-chlorothionaphthacoumarin in alcohol was treated with zinc dust and a few drops of hydrochloric acid. The mixture was kept for twelve hours and then, after the

greater part of the solvent had been evaporated, the dissolved material was precipitated by the addition of water. This product was purified in the usual manner. It melted at 176° whether heated alone or with thionaphthacoumarin from other sources.

(c) A dried sample of the sparingly soluble silver salt of thionaphthacoumarin-4-carboxylic acid was heated in a vacuum. The sublimate of long, yellow needles was identified as thionaphthacoumarin by comparison with the products of the foregoing methods of preparation.

4-Chlorothionaphthacoumarin (III).—A mixture of 2-thiolbenzoic acid (10 grams), chloroglutaconic acid (11 grams; prepared by the method of Ingold and Nickolls, *loc. cit.*), and concentrated sulphuric acid (100 c.c.) was kept at 40° and frequently shaken for three-quarters of an hour. The solid product, which was isolated in the usual manner, was treated with aqueous sodium carbonate to remove any unchanged thiolbenzoic acid. From the crude product (10 grams; about 65 per cent. of the theoretical yield), after recrystallisation from hot alcohol or sublimation in a vacuum, *4-chlorothionaphthacoumarin* was obtained in pale yellow prisms which melted at 173° (Found: C = 55.6; H = 2.0; Cl = 14.9; S = 13.7. $C_{11}H_5O_2ClS$ requires C = 55.8; H = 2.1; Cl = 15.0; S = 13.5 per cent.). The dilute solution in chloroform exhibits a green fluorescence. "Thioindigo" may be obtained from the substance by the usual reagents. The same compound was isolated from the product obtained by condensing 2-thiolbenzoic acid with the impure chloroglutaconic acid prepared by the method of von Pechmann and Burton (*loc. cit.*). The experiment is described in a subsequent paragraph. It may also be obtained in small quantity by the regulated action of phosphorus halides with 4-hydroxythionaphthacoumarin. Thus an excess of phosphorus pentachloride was added to a solution of the 4-hydroxycoumarin in phosphoryl chloride at 75° . This temperature was maintained for half an hour. The solid that separated from the cooled mixture was treated with aqueous sodium carbonate and dried before being sublimed in a vacuum. The product, which was obtained in small yield, was identified with the substance prepared from chloroglutaconic acid.

4-Anilinothionaphthacoumarin (VII).—(a) The 4-chloro-derivative was treated with aniline (2 mols.) at 150° for an hour and a quarter. The cooled mixture was triturated with dilute hydrochloric acid, the insoluble residue being then collected and purified by crystallisation from hot alcohol, in which it was sparingly soluble. The anilino-derivative was thus obtained in small needles which melted at 281° (Found: N = 5.0. $C_{17}H_{11}O_2NS$ requires N = 4.8 per cent.).

(b) A mixture of 4-hydroxythionaphthacoumarin with aniline (2

mols.) was kept at 180° for one hour. After the excess of aniline and unchanged hydroxy-compound had been removed, the residue was purified as in the foregoing preparation. The product melted at 281° and was identified in the usual manner.

3 : 4-Dichlorothionaphthacoumarin (VIII).—In the first series of experiments made on the condensation of 2-thiolbenzoic acid with chloro-derivatives of glutaconic acid, the "chloroglutaconic acid" prepared by the method of von Pechmann and Burton was used as the latter component. Excellent yields of the coumarin product were obtained; but in many experiments this was found to be a mixture in which a dichloro-derivative very greatly preponderated, whilst in others, where the chloro-acid used had been prepared by prolonged or intensified action of the phosphorus halide with acetonedicarboxylic ester, the dichlorocoumarin appeared to be the sole product. From a chloro-acid of this character the dichlorocoumarin was obtained in the following manner. A mixture of 2-thiolbenzoic acid (10 grams), "chloroglutaconic acid" (19 grams), and concentrated sulphuric acid (100 c.c.) was kept at 30–35° for one hour and constantly shaken. After isolation in the usual manner and treatment with aqueous sodium carbonate, the product (17 grams; 96 per cent. of the theoretical yield) was purified by crystallisation from acetic acid, when the *dichloro*-coumarin was obtained in pale yellow needles which melted at 206° and readily sublimed when heated in a vacuum. Solutions of the substance in organic media exhibit a violet fluorescence (Found: C = 48.8; H = 1.5; Cl = 26.0; S = 12.0. $C_{11}H_4O_2Cl_2S$ requires C = 48.7; H = 1.5; Cl = 26.1; S = 11.8 per cent.).

In experiments where the chloro-acid had been prepared under less intense conditions, the product consisted of a mixture from which the foregoing dichlorocoumarin, being the least soluble material present, was easily isolated by fractional crystallisation. From the mother-liquors of these crystallisations small amounts of a monochloro-derivative were isolated; this was found to be identical with the 4-derivative prepared from the pure chloroglutaconic acid of Ingold and Nickolls. In all experiments where mixtures of chloro-derivatives were obtained the monochloro-compound was present only in quite small quantity.

3-Chloro-4-anilinothionaphthacoumarin was prepared from the dichlorocoumarin by the action of excess of aniline at 260° for one hour. The product after purification from alcohol formed feathery needles which melted at 229° (Found: Cl = 11.0; S = 10.1; N = 4.39. $C_{17}H_{10}O_2NCIS$ requires Cl = 10.8; S = 9.8; N = 4.28 per cent.).

CCCXLIV.—*The Melting-point (Solidus) Curve for Mixtures of Potassium Nitrate and Sodium Nitrate.*By WALTER MATTHEW MADGIN and HENRY VINCENT AIRD
BRISCOE.

DURING the determination of the freezing-point curve for mixtures of potassium nitrate and sodium nitrate previously reported (Briscoe and Madgin, this vol., p. 1608), it became apparent that the points on the *solidus* curve determined by Hissink (*Z. physikal. Chem.*, 1900, 32, 537) were open to some doubt.

It was therefore decided to apply the method then worked out to determine a sufficient number of points to permit a reasonably accurate location of the complete *solidus* or melting-point curve.

This determination seemed the more desirable in that it could afford important confirmation of our former conclusion that the freezing-point curve is continuous. We are indebted to Professor Bruni for directing our attention to a note published by Amadori (*Atti R. Istituto Veneto Sci.*, 1912, 72, 451), which apparently has not been abstracted in the English, American, or German journals, and thus escaped our notice.

This note reports the determination of the freezing points of seventeen mixtures of potassium nitrate and sodium nitrate with results essentially in agreement with those of Carveth (*J. Physical Chem.*, 1898, 2, 209) plotted in our previous paper (Briscoe and Madgin, *loc. cit.*, p. 1609). Amadori plots his data by means of a continuous curve but, as Carveth deduced a discontinuous curve from a very similar set of data, Amadori's evidence for the continuity of the curve can scarcely be regarded as conclusive, and is much strengthened by our numerous determinations of freezing points in the neighbourhood of the minimum, and by the determination of the *solidus* curve now reported.

EXPERIMENTAL.

In order to determine the composition of the various solid phases in equilibrium with the molten mixtures synthetically prepared, the apparatus already described and illustrated (Briscoe and Madgin, *loc. cit.*, p. 1614) was employed, with one slight modification. It was found that mixtures containing relatively large amounts of sodium nitrate gave crystalline deposits which were not adherent to smooth glass tubes. For such mixtures, therefore, the tube G (Fig. 3, *loc. cit.*) was provided with annular indentations in which the rings of crystals were deposited and retained on lifting the tube.

Separation and analysis of the solid and liquid phases were in all cases effected in the manner previously described.

TABLE I.

Composition of solid and liquid phases in equilibrium in mixtures of potassium and sodium nitrates.

	Potassium nitrate KNO_3 (per cent.).						
(Liquid phase	19.1	20.1	22.5	26.1	27.5	32.5	34.5
(Solid phase ...	15.0	17.3	18.4	22.3	23.2	29.5	31.0
(Liquid phase	38.5	40.6	44.4	46.8	(50.1)	54.9	(57.75)
(Solid phase ...	35.2	37.7	42.3 †	43.0	(48.5) *	55.2 minimum (59.25) *	
(Liquid phase	59.9	65.25	65.5	70.4	75.0	81.0	85.6 90.4
(Solid phase...	62.9	69.0	70.0 †	75.1	79.8	85.5	90.7 93.4

* Data previously reported (Briscoe and Madgin).

† Points approximating most closely to the mean location of Hissink's determinations of points on the *solidus* curve.

FIG. 1.

Fusion diagram for potassium and sodium nitrates.

The results for twenty new points and for two already determined are given in Table I and plotted in Fig. 1, together with the freezing-

point curve. The data indicate a smooth *solidus* curve passing continuously through the minimum of the *liquidus* curve, but lying at all points much closer to the latter than had been anticipated from the location of Hissink's points.

Thus the equilibrium diagram for potassium and sodium nitrates, at temperatures above the transition point of potassium nitrate, is of Roozeboom's type III (*Z. physikal. Chem.*, 1899, **30**, 385) and affords a good and easily attained example of that type.

During the experiments with the mixture of minimum freezing point it was observed that, in sharp contrast with all other mixtures examined, the crystals formed a transparent, glassy mass almost indistinguishable from the liquid. They retained this appearance on cooling to the ordinary temperature and, in a desiccator, remained unchanged for twenty-four hours.

On exposure to moist air for an hour or so or on standing for more than twenty-four hours in a desiccator, the crystals became white and opaque. Hissink (*loc. cit.*) and Amadori (*loc. cit.*) have observed a lowering of the transition temperature of potassium nitrate by admixture with sodium nitrate, but the behaviour of the mixture of minimum melting point suggests that the lowering may be greater than those observers have supposed. Further experiments are projected on this point.

A great part of the experimental work in connexion with this note has been carried out by Messrs. E. E. Aynsley and S. Peaf, whose assistance the authors now desire to acknowledge.

CCCXLV.—Piperitone. Part VI. The Reduction of Piperitone.

By REGINALD SLATER HUGHESDON, HENRY GEORGE SMITH,
and JOHN READ.

PRELIMINARY investigations dealing with the action of reducing agents on *dl*-piperitone have shown that in a moist ether-alcohol solution it is readily converted by sodium amalgam into a bimolecular ketone, $C_{20}H_{34}O_2$ (Baker and Smith, "A Research on the Eucalypts," 2nd ed., Sydney, 1920, p. 393), whilst by hydrogenation in the presence of finely divided nickel its conversion into menthone has been reported (Smith and Penfold, *J. Proc. Roy. Soc. N.S. Wales*,

1920, 54, 40). Since, in the latter instance, the hydrogenated product gave a semicarbazone melting at 156° and upon further reduction yielded a menthol melting at 34° , it was assumed to consist of menthone rather than of *isomenthone* (compare Pickard and Littlebury, T., 1912, 101, 109): this assumption, however, does not accord with the results of the present investigation.

Upon reducing *dl*-piperitone directly to menthol by means of sodium and alcohol, we have been able to isolate without difficulty a crystalline menthol melting at $39-41^{\circ}$, and thus consisting presumably of an *isomenthol*. The ketone obtained by oxidising either this crystalline *isomenthol* or the accompanying liquid product with chromic acid appeared to consist mainly, or perhaps wholly, of *isomenthone*: it yielded a mixture of semicarbazones, the most prominent of which was a sparingly soluble substance melting at $219-220^{\circ}$. *isoMenthone* from the catalytic reduction of thymol gave a semicarbazone melting at 217° (Pickard and Littlebury, *loc. cit.*), whilst the "*i*-menthone" obtained by Wallach (*Annalen*, 1913, 397, 217) by the hydrogenation of synthetic Δ^1 -*p*-menthen-3-one gave a semicarbazone melting at $210-212^{\circ}$. The three products evidently contained a common derivative, characteristic of *isomenthone*, which we now term *dl-isomenthone- α -semicarbazone*.

Owing to rapid racemisation of optically active piperitone in the initial operation, it was not possible to produce optically active menthols or menthones by the above method. In the course of further investigations, however, *dl*-piperitone was found to be capable of ready hydrogenation, under carefully defined conditions, in the presence of either colloidal palladium or finely divided nickel, at temperatures of about 25° and 180° , respectively. In both instances, the product, of which a more detailed stereochemical examination is in progress, appeared to consist essentially of *dl-isomenthone*. Very interesting results were then obtained by using the two optically active forms of piperitone in these hydrogenation processes. In the case of nickel at 180° , partial racemisation occurred during the process (compare this vol., p. 2269), but with palladium at the ordinary temperature optically active *isomenthones* of reversed and somewhat enhanced rotatory powers were produced. Thus, *l*-piperitone having $[\alpha]_D^{25} - 51.53^{\circ}$ gave *d-isomenthone* having $[\alpha]_D^{25} + 65.14^{\circ}$, whilst from *d*-piperitone a specimen of *l-isomenthone* having $[\alpha]_D^{25} - 63.64^{\circ}$ was prepared. The corresponding optically active *isomenthols*, obtained by further reduction, will be described in due course. With the exception of a preparation of *d-isomenthone* derived in an indirect way from *l*-menthoneoxime (Beckmann, *Ber.*, 1909, 42, 846), these specimens appear to possess the highest optical rotatory powers yet recorded for *isomenthone*, and the present

investigation probably affords the most definite correlation available between the optically active and inactive forms of this ketone. The physical data observed for the three forms derived from piperitone are summarised below :

	Boiling point.	d_4^{20} (vac.).	n_D^{20} .	$[R_L]_D$.	$[\alpha]_D^{20}$.
<i>dl</i> -isoMenthone (ex solid menthol)	89—90°/15 mm.	0.8982	1.4520	46.31	—
<i>dl</i> -isoMenthone (ex liquid menthol) ...	89—90°/15 mm.	0.8980	1.4522	46.34	—
<i>dl</i> -isoMenthone (Pd method)	88—90°/14 mm.	0.8995	1.4527	46.28	—
<i>d</i> -isoMenthone	93.5—95°/19 mm.	0.8955	1.4530	46.51	+ 65.14°
<i>l</i> -isoMenthone	95—100°/18 mm.	0.8995	1.4537	46.37	— 63.64

Catalytic hydrogenation of piperitone at pressures up to 20 atmospheres, both in the presence of finely divided nickel at 140° and of colloidal palladium at the ordinary temperature, led to results very similar to those recorded above. In no instance was menthol produced. Preliminary experiments dealing with the electrolytic reduction of piperitone, in an acid or alkaline electrolyte, resulted mainly in the formation of the bimolecular ketone. The direct conversion of piperitone into menthol by catalytic hydrogenation or by electrolytic reduction thus appears to be impracticable under the conditions so far investigated.

Further investigations are in progress concerning the reduction of piperitone; in addition, attention is being devoted to the chemical and stereochemical relationships of the above-mentioned derivatives of piperitone and related substances (compare *J. Proc. Roy. Soc. N.S. Wales*, 1922, **56**, 170).

EXPERIMENTAL.

The Reduction of Piperitone with Sodium and Alcohol.

Pure *dl*-piperitone (40 grams), prepared as described in earlier communications (*J. Soc. Chem. Ind.*, 1923, **42**, 339 T.; this vol., p. 2270), was dissolved in absolute alcohol (450 c.c.) and reduced with sodium (50 grams) on the water-bath, in the usual manner. After about 45 minutes the original deep red colour had disappeared, and the resulting pale yellow solution was cooled, diluted with ice-water, and carefully neutralised with hydrochloric acid. The mixture was extracted twice with ether, the combined extracts being then washed with water and dried over sodium sulphate. After the ether had been distilled off, the residual crude menthol was purified by fractional distillation under diminished pressure. The bulk of the product passed over at 102—108°/18 mm. (29 grams) and the fraction distilling at 105—108°/18 mm. (8 grams) crystallised spontaneously after keeping for three days, forming a mass of long needles.

In further preparations, the crude menthol obtained from 120 grams of *dl*-piperitone yielded the following fractions when submitted to three consecutive distillations under 17 mm. pressure: 90—100° (21 grams), 100—102° (28 grams), 102—103° (22 grams), 103—104° (3 grams), 104—106° (8 grams). The yellow colour of the original crude product was eliminated during this process. The last three fractions crystallised on cooling. From the fraction distilling at 104—106°/17 mm. the crystalline menthol was separated by pressing between sheets of absorbent paper, but with the other two fractions it was found preferable to drain the cooled material in a cold centrifuge or filter. After such treatment, the menthol formed colourless, opalescent flakes, melting at 34—36°. When kept on a porous plate in a sulphuric acid desiccator for fourteen days, it changed to a mass of fine, glistening needles, melting at 39—41°. It exhibited no appreciable optical activity when dissolved in ether. The total yield of crystalline menthol actually isolated from the reduction product of 350 grams of *dl*-piperitone was about 30 grams, and the liquid residues contained a further quantity of similar material.

When the liquid residues were refractionated, the largest fraction (40 per cent.) distilled at 100—102°/17 mm. The fraction was optically inactive, and had d_4^{20} (vac.) 0.9054 and n_D^{20} 1.4642, whence $[R_L]_D = 47.63$, the calculated value for menthol being 47.55. Both the solid and the liquid preparations possessed an odour indistinguishable from that of ordinary *l*-menthol.

Optically active specimens of piperitone, when reduced in the same way, gave identical results, except that in some instances the resulting menthol possessed a faint dextrorotation, whilst the first fraction of the liquid distillate was slightly laevorotatory, owing probably to traces of a laevorotatory impurity in the original *l*-piperitone, derived from the essential oil of *Eucalyptus dives* (this vol., p. 2270). A typical preparation of menthol of this kind, distilling at 104—108°/18 mm., was obtained from a laevorotatory specimen of piperitone in 58 per cent. yield. It crystallised to a large extent when cooled in ice, and had d_4^{20} (vac.) 0.9017, n_D^{20} 1.4645, $[R_L]_D$ 47.85, and $[\alpha]_D^{20} + 0.06^\circ$.

The liquid menthol described above, distilling at 100—102°/17 mm., when oxidised with chromic acid by the method of Beckmann (*Annalen*, 1889, 250, 325), gave, in 66 per cent. yield, a menthone distilling at 89—90°/15 mm. and having d_4^{20} (vac.) 0.8980, d_4^{20} (vac.) 0.8942, n_D^{20} 1.4522, n_D^{20} 1.4501, $[R_L]_D$ 46.34. The calculated value of $[R_L]_D$ for menthone is 46.22.

The crystalline menthol, melting at 39—41°, when oxidised similarly, gave, in 73 per cent. yield, a menthone distilling at

89—90°/15 mm. and having d_4^{20} (vac.) 0.8982, d_4^{25} (vac.) 0.8945, n_D^{20} 1.4520, n_D^{25} 1.4500, $[R_L]_D$ 46.31. The product in this instance was further characterised by treatment with semicarbazide. To a solution of sodium acetate crystals (8.4 grams) in a little water were added, first, the ketone (7.0 grams), and then semicarbazide hydrochloride (6.0 grams), also dissolved in a little water. Upon adding just sufficient alcohol to effect complete solution of the ketone at the ordinary temperature, a crystalline deposit of semicarbazone started to separate within thirty minutes. After keeping for two days, the mixture was rendered faintly alkaline with ammonia and diluted with water to about twice the original volume. When collected, washed well with cold water, and dried at 100° for one and a half hours, the resulting colourless crystalline product (9.15 grams) softened at 150° and first melted completely at 205°. Upon dissolving it in boiling methylated spirit (150 c.c.) and keeping the solution over-night, a deposit melting at 210—212° was obtained. One more recrystallisation from the same solvent sufficed to raise the melting point to the ultimate value observed, namely, 219—220° when heated slowly, or 225° with rapid heating. The substance (2.75 grams) crystallised in lustrous, warty aggregates and exhibited no depression of melting point when mixed with the α -semicarbazone of *dl*-isomenthone, obtained, as described below, by the catalytic hydrogenation of *dl*-piperitone in the presence of colloidal palladium or finely divided nickel (Found: C = 62.40; H = 9.91. Calc. for $C_{11}H_{21}ON_3$, C = 62.51; H = 10.02 per cent.). In the course of a prolonged systematic fractional crystallisation, several fractions (5.7 grams) were isolated from the mother-liquors which melted rather indefinitely between 140° and 150°, whilst other fractions did not melt completely until about 170°. By careful recrystallisation from alcoholic solutions to which ether had been added after cooling, fractions were obtained melting at 140—145° and showing no depression of melting point when mixed with the third semicarbazone described in the next section (Found: C = 62.61; H = 10.19 per cent.). It was not found possible, however, to isolate a fraction melting at 177—178°, corresponding with the second semicarbazone from the undermentioned specimens of menthone obtained by catalytic reduction in the presence of colloidal palladium.

The Catalytic Hydrogenation of Piperitone in presence of Colloidal Palladium.

1. The method described by Wallach (*Annalen*, 1913, 397, 217) for the catalytic hydrogenation of synthetic Δ^1 -*p*-menthen-3-one yielded unsatisfactory results when applied to *dl*-piperitone, the

reaction having proceeded only to the extent of 25 per cent. after the lapse of six hours, with hydrogen at a pressure of 0.25 atmosphere. Both methyl alcohol and ethyl alcohol, when used in this process, caused gradual coagulation of the gum arabic and precipitation of the palladium after about two hours. It was accordingly found advantageous to emulsify the piperitone in an aqueous solution of the catalyst by means of vigorous mechanical stirring, which proved to be preferable to shaking.

dl-Piperitone (35 grams), which had been purified by steam distillation after liberation from the bisulphite compound, was added to a solution of palladium chloride (obtained by boiling 0.3 gram with 50 c.c. of water and 3 drops of dilute hydrochloric acid) and gum arabic (0.5 gram) in water (200 c.c.). The mixture was stirred continuously and submitted for four hours at the ordinary temperature (25°) to the action of purified hydrogen, under a pressure of 0.25 atmosphere. The resulting menthone was isolated by extraction with ether and subsequent fractional distillation under diminished pressure, the united ether extracts being dried over anhydrous sodium sulphate prior to distillation. A distillate which represented 60 per cent. of the calculated yield of menthone was collected between 90° and 95°/16 mm., and appeared to consist of practically pure *dl*-isomenthone. By redistilling the combined product from three such preparations, a colourless specimen of an optically inactive isomenthone was obtained, having the following physical characteristics; b. p. 88–90°/14 mm., d_4^{20} (vac.) 0.8995, n_D^{20} 1.4527, $[\alpha]_D^{20}$ 46.28.

For the successful catalytic hydrogenation of *dl*-piperitone in the manner described, it is essential to purify the ketone carefully after liberating it from the bisulphite compound; this may be accomplished by distillation under diminished pressure, or, preferably, by steam distillation. Failing such purification, the catalyst is prone to lose its activity.

When allowed to react with semicarbazide under the conditions outlined above, *dl*-isomenthone (7.0 grams) prepared in this way yielded a mixture of semicarbazones (9.5 grams) very similar to the product already described. By repeated fractional crystallisation from boiling alcohol, a sparingly soluble α -semicarbazone (3.0 grams) and a second more soluble semicarbazone (3.0 grams) were separated; whilst the solid residues from the final mother-liquors, when treated carefully with alcohol and ether, yielded a third semicarbazone (0.8 gram), which on account of its pronounced solubility was only freed with great difficulty from the isomeric derivatives.

dl-iso-Menthone- α -semicarbazone forms small, lustrous needles, sometimes occurring in warty aggregates. When heated in the

ordinary way, it melts with decomposition at 219–220°, or, if heated rapidly, at 225°. It is sparingly soluble in most of the ordinary organic solvents, except acetic acid, and is best recrystallised from hot alcohol. It is insoluble in cold dilute acid or alkali, but is readily hydrolysed by cold concentrated hydrochloric acid, in which it at first dissolves (Found: C = 62.46; H = 9.78 per cent.).

The second isomeric *semicarbazone* crystallised from alcohol in minute needles, which melted without decomposition at 177–178°. It dissolved slowly but completely in ether upon continued warming (Found: C = 63.08, 63.04; H = 10.39, 10.69 per cent.). The third isomeric *semicarbazone* formed minute crystals melting somewhat indefinitely at 140–145°, without decomposition. It dissolved in warm ether and was most conveniently purified by deposition from ether containing a little alcohol. Like the isomeric substances, it was insoluble in cold dilute acid or alkali (Found: C = 62.78; H = 10.28 per cent.).

2. A specimen of *l*-piperitone, isolated from the crude oil of *Eucalyptus dives* by repeated fractional distillation under diminished pressure (this vol., p. 2269), and having $[\alpha]_D^{20} - 51.53^\circ$, was submitted to similar treatment at 20°. Hydrogenation proceeded steadily with a slight rise of temperature, and after four hours 87 per cent. of the calculated quantity of hydrogen had been absorbed. At 35°, under similar conditions, the whole of the calculated quantity of hydrogen was absorbed without difficulty, and in this instance the yield of menthone was higher than recorded in (1) above. By distilling the crude product under diminished pressure, the condensate collected between 93–100°/20 mm. corresponded with 75 per cent. of the calculated yield of menthone; when twice refractionated under diminished pressure, it furnished a specimen of *d*-isomenthone distilling at 93.5–95°/19 mm., and having the following additional characteristics: d_4^{20} (vac.) 0.8955, d_4^{20} (vac.) 0.8917, n_D^{20} 1.4530, $[R_L]_D$ 46.51, $\alpha_D^{20} + 58.33^\circ$, $[\alpha]_D^{20} + 65.14^\circ$.

Three other specimens of *l*-piperitone, having $\alpha_D^{20} - 12.32^\circ$, $- 26.64^\circ$, and $- 32.08^\circ$, when hydrogenated in a similar manner, yielded preparations of *isomenthone* having $\alpha_D^{20} + 15.39^\circ$, $+ 30.36^\circ$, and $+ 38.95^\circ$, respectively.* When these two sets of values are represented graphically in the usual way, the points lie very nearly on a straight line passing through the origin.

When mixed with semicarbazide under the conditions described above, *d*-isomenthone (7.0 grams, $\alpha_D^{20} + 58.33^\circ$) reacted more slowly than *dl*-isomenthone. The first three fractions of the

* All the readings of α_D in this paper are recorded for a 1-dm. tube.

crystalline separation, collected after intervals of twenty-four hours, consisted mainly of *dl*-isomenthone- α -semicarbazone, melting at 219–220°. The filtrate from the third fraction was diluted, rendered faintly alkaline with ammonia, and extracted with ether. After repeated treatment with ether and light petroleum, this material eventually yielded a small amount (2.0 grams) of a soft, crystalline mass, melting without decomposition at 143–145°. When this substance was mixed with the optically inactive semicarbazone, described above, melting at 140–145°, the melting point sank to 134–136° (compare Beckmann, *Ber.*, 1909, 42, 846). This derivative, *d*-isomenthonesemicarbazone, exhibited a small dextrorotation, which, like the melting point, was not altered by recrystallisation: 0.2502 gram, dissolved in ethyl alcohol and made up to 20.0 c.c. at 20°, gave $\alpha_D^{20} + 0.28^\circ$ in a 2-dm. tube, whence $[\alpha]_D^{20} + 11.2^\circ$. The substance was readily soluble in ether; it also dissolved with moderate ease in warm light petroleum, from which it separated as a gelatinous mass (Found: N = 20.0. Calc. for $C_{11}H_{21}ON_3$, N = 19.90 per cent.).

3. In the case of *d*-piperitone, the purest specimen of the corresponding *l*-isomenthone was obtained similarly, by the catalytic hydrogenation at 20° of a fraction of the ketone isolated from the essential oil of *Andropogon Juarancusa*, and having $\alpha_D^{20} + 47.03^\circ$ (this vol., p. 2269). The greater part of the product distilled at 95–100°/18 mm., and the following physical constants were observed: d_4^{20} (vac.) 0.8995, n_D^{20} 1.4537, $[R_L]_D$ 46.37, $\alpha_D^{20} - 57.24^\circ$, $[\alpha]_D^{20} - 63.64^\circ$.

The Catalytic Hydrogenation of Piperitone in presence of finely divided Nickel.

As a result of numerous preliminary experiments, the following conditions were elucidated for the successful catalytic hydrogenation of piperitone in the presence of a nickel catalyst:

(1) The oxide, prepared by calcining purified pumice previously steeped in a solution of pure nickel nitrate, is reduced at 340–350° for a period of not less than three hours.

(2) The piperitone is steam distilled at least once after being extracted from the crude essential oil by means of sodium sulphite or bisulphite.

(3) The pumice bearing the catalyst is coated with a thin film only of piperitone and is maintained at 180° in an atmosphere of hydrogen.

In experiments involving the reduction of more than about 5 c.c. of piperitone, the effective application of the last condition necessitated the use of a special form of apparatus. Very satisfactory results were obtained by applying the principle adopted

in the laboratory circulating pump described by Morgan (T., 1915, 107, 1710), electrolytic hydrogen being introduced at a pressure of about 100 mm. The process was controlled by measuring the incoming and escaping hydrogen and by observing the refractive index of the product at intervals.

In a typical experiment with 35 c.c. of purified *dl*-piperitone, conducted under the conditions stated, the reduction took place rapidly in the presence of about 25 c.c. of catalyst, 4 litres of hydrogen being absorbed in eighty minutes, after which the rate of absorption moderated. The values of n_D^{20} were as follows, the last value corresponding with a content of 90 per cent. of menthone: 1.4675 (one hour), 1.4535 (two hours), 1.4516 (three hours), 1.4510 (four hours). The crude menthone was collected, the pumice being extracted with ether; and on fractional distillation under diminished pressure the first fraction (19 grams) distilled at 106–110°/30 mm., and had n_D^{20} 1.4475, whilst the second fraction (6 grams) distilled at 110–120°/30 mm., and had n_D^{20} 1.4520. The first fraction, which represented a 60 per cent. yield of menthone, exhibited no diminution in volume when shaken with hot sodium sulphite solution.

In a similar experiment with 145 grams of *dl*-piperitone, which had been steam distilled twice after racemising, about 18 litres of hydrogen were absorbed in five hours in the presence of about 50 c.c. of catalyst. Upon distilling the product under diminished pressure, a fraction (100 grams) having n_D^{20} 1.4535 was collected between 96° and 100°/20 mm., corresponding with a 70 per cent. yield of menthone.

Catalysts which had been reduced at lower temperatures gave less satisfactory results: a preparation reduced at 320–340° gave only a 60 per cent. yield of menthone after twenty hours, whilst with another preparation reduced at 300–330° the absorption of hydrogen was very slow and incomplete.

A partly racemised preparation of *l*-piperitone, having α_D^{20} –21.96°, after twenty hours' hydrogenation in the presence of a catalyst reduced at 320–340°, yielded a specimen of an optically active *isomenthone* of reversed and diminished optical rotatory power; it distilled at 115–120°/31 mm., and had n_D^{20} 1.4592 and α_D^{20} +11.04°.

The above preparations of *dl*-*isomenthone*, when brought into reaction with semicarbazide in the manner already described, readily yielded *dl*-*isomenthone*- α -semicarbazone, melting at 219–220°. During the isolation of this substance, which formed the main product of the reaction, various fractions were obtained which melted rather indefinitely at lower temperatures, as in the foregoing preparations.

The Catalytic Hydrogenation of Piperitone at High Pressures.

When piperitone (140 grams) was hydrogenated for three hours in an iron autoclave at 140° , under a pressure of about 18 atmospheres, in contact with a nickel catalyst reduced at 360° , a 66 per cent. yield of isomenthone, distilling at $89-94^{\circ}/14$ mm., was obtained, but no menthol could be detected in the product. A similar result was achieved by using a colloidal palladium catalyst under a pressure of about 20 atmospheres at the ordinary temperature.

The Electrolytic Reduction of Piperitone.

1. Piperitone (20 grams) was mixed with alcohol (300 c.c.) and a solution of sodium acetate crystals (4 grams) in water (70 c.c.); the resulting cathode liquid was heated on the water-bath in a beaker which also contained a porous pot charged with the anode liquid, composed of saturated sodium carbonate solution. The cathode and anode consisted of cylindrical lead plates, and the current density at the former was about 1 ampere per 100 sq. cm. When the apparatus was allowed to cool, after supplying about 20 ampere-hours, long, glistening crystals (8 grams) separated; these melted, when purified, at $156-157^{\circ}$, and were identical with the bimolecular ketone described by Baker and Smith (*loc. cit.*). The cathode liquor also contained a small quantity of menthone, in addition to unchanged piperitone. No menthol appeared to be formed during the reduction.

2. The reduction was also effected at the same temperature in an acid electrolyte (20 grams of piperitone, 200 c.c. of 20 per cent. sulphuric acid, 150 c.c. of alcohol), the anode liquid being sulphuric acid of 20 per cent. strength. The current density was about 2 amperes per 100 sq. cm., and the product, after the passage of 7.1 ampere-hours, consisted mainly of the bimolecular ketone with a possible trace of menthol.

3. With an amalgamated zinc plate as cathode, at the ordinary temperature, the main product was again the bimolecular ketone. *iso*Menthone, made from piperitone as described above, when reduced in this way gave an appreciable quantity of a liquid menthol.

We are indebted to the McCaughey Research Fund of the University of Sydney for a grant in aid of these investigations, which are being continued.

CCCXLVI.—*Intermittent Current Electrolysis. Part II.*
Overvoltage Study of the Lead Electrode.

By SAMUEL GLASSTONE.

It has been suggested (this vol., p. 1745) that part of the difference in overvoltage as measured by the direct and the commutator method may be due to the induced currents resulting from the repeated make and break of the polarising circuit; the object of the present work was to investigate the behaviour of the lead electrode in some detail in order to determine the influence of this and other factors on overvoltage measured with intermittent polarising current. By means of a special commutator (described below) the polarised electrode could be connected with the potentiometer system at any portion of a complete cycle, so that the potential could be followed during the whole time that the current was on or off; by varying the speed of rotation of the commutator an estimate could be obtained of the rate of fall of potential after the polarising current was switched off. Further, by altering the resistance, self- and mutual-inductance, and capacity of the circuit, the influence of induced currents could be examined. By measuring the fall of potential across a known resistance placed in the polarising circuit, the value of the current flowing at any point in a complete cycle could be determined and compared with the potential of the electrode at the same position.

Before proceeding to the consideration of the results obtained, an important source of error in potential measurements made by the direct method must be considered. Haber (*Z. physikal. Chem.*, 1900, **32**, 208) and others have realised the importance of fixing the jet of the tube, connecting the test electrode with the standard electrode, close to the surface of the former, and thus eliminating the error due to the fall of potential across the electrolyte from the surface of the electrode to the jet of the connecting tube. An examination of the arrangement of the apparatus used in these experiments shows, however, that the error in the measured potential introduced is due, not only to this layer of electrolyte, but also to the resistance of the whole of that portion of the apparatus lying between the jet of the connecting tube and the point at which the test electrode is connected with the potentiometer system. In the measurement of overvoltage, when gas is being liberated at the test electrode, the portion mentioned will include a metal-gas system, which may have a considerable resistance, situated at the surface of the electrode. Further, as a result of rapid electrolysis the concentration of the layer of electrolyte close to the surface of

the electrode may be greatly diminished and consequently its specific resistance increased; thus even a very thin layer may have a considerable resistance. It thus appears that even if the Haber-Luggin capillary is pressed as tightly as is experimentally possible against the surface of the test electrode, there may still be an appreciable error introduced in the measurement of potentials by the direct method; in subsequent portions of this paper this error is referred to as that due to the resistance of a metal-gas-electrolyte system situated at the surface of the electrode, or, more briefly, to the "surface resistance." In the commutator method of measuring overvoltage, this error does not occur, since the direct current does not flow while potential measurements are being made. By arranging the apparatus so that the direct current is reduced to a very small amount when the potential is being measured, and at the same time almost eliminating the effects due to induced currents, it has been found possible to estimate the error due to "surface resistance." For lead electrodes in *N*-sodium hydroxide or *N*-sulphuric acid, this error has been found to be 0.12 to 0.18 volt at a current density of roughly 0.025 amp. per cm.²; the resistance of 1 sq. cm. of electrode surface would thus be about 5–7 ohms, an amount which does not appear to be unreasonable. Experiments at other current densities indicate that the resistance of the metal-gas-electrolyte system decreases as the current density increases.

EXPERIMENTAL.

Arrangement of Apparatus.—The commutator, which is shown in diagram in Fig. 1, consisted of a cylinder 3 inches long and $1\frac{1}{2}$ inches in diameter, divided into two similar parts, A and B, which could be fixed in different positions relatively to one another on the axis of revolution, CD. The unshaded portions represent insulated parts of the commutator, whilst the shaded parts were metallic; connexion was made from the polarising circuit and from the potentiometer to the movable contact makers, a and c, respectively, whilst b was connected to the test electrode. By moving a, the electrode could be connected with the polarising circuit for any desired portion of a complete cycle, whilst by moving B relative to A round the axis CD, and also moving c, the electrode

could be connected to the potentiometer at any section of a cycle for any desired interval of time. The commutator was connected directly with an electric motor capable of giving more than 5,000 revolutions, and hence 10,000 makes and breaks of the polarising current, per minute; a small Veedee revolution counter was attached permanently to the shaft of the motor in order to determine the speed of the latter. As the polarised electrode was in most cases connected with the potentiometer system only for extremely short intervals of time, the impulses obtained were very small and consequently a low resistance Granta potentiometer (Pye) and pointer galvanometer were used for the measurement of the potentials.

The arrangement of the apparatus was of two kinds; the first arrangement (method I) was similar to that used by Newbery (T.,

FIG. 2.

1914, 105, 2419), in which there is no complete circuit when the polarising current is broken. The second arrangement (method II) is shown in Fig. 2; *A* represents the polarising battery, connected across a resistance, *BC*, of about 1,000 ohms, *B* represents the commutator, and *D* the test electrode. In this arrangement there is always a complete circuit even when the polarising current is switched off. In order to measure the current passing through the circuit at any instant, as distinct from the mean current measured by an ammeter, a known resistance was placed between *B* and *D*, and the fall of potential from *B* to the end of the resistance measured by means of the potentiometer; from the value of the potential and of the resistance, the current value was calculated. A similar method was adopted in connexion with method I.

The electrolytic cell consisted of a small beaker holding about 25 c.c. of the electrolyte (*N*-sodium hydroxide or *N*-sulphuric acid); the lead electrode was 2.5 cm. long, 1 cm. wide, and 0.2 cm. thick; it was completely waxed over with the exception of an

area of 1 sq. cm., which was scraped clean and bright. The standard electrodes and connecting tubes were as described in a previous paper (*loc. cit.*).

Preliminary Measurements.—The object of these was to determine the general behaviour of the electrode with varying speed of rotation of the commutator and with various types of intermittent current. It was found that with speeds of 2,000 to 10,000 changes per minute, the potential of each electrode measured immediately the polarising current was off, was constant within 0.03 volt. The subsequent rate of fall of potential was often quite considerable, and since the ordinary commutator method of measuring overvoltage (Newbery, *loc. cit.*) gives the average potential over the whole period when the current is off, the results obtained by this method were often found to be 0.05 volt below the values obtained immediately after the polarising current was cut off. In the commutator method, therefore, the potentials to be considered for the determination of overvoltage are those obtained immediately after the current is switched off, with fairly high commutator speeds.

When the current is suddenly switched on again, as a result of the rotation of the commutator the potential of the electrode, in general, rapidly reaches its maximum value for a given current density; hence the fact that the polarising current is off for half of a cycle has very little influence on the potential reached. The attainment of overvoltage equilibrium in the cases examined is thus a comparatively rapid process. When writing the previous paper in this series (*loc. cit.*), the author believed that a sort of dynamic equilibrium would exist over an appreciable interval of time, that a condition would be reached at which the rate of formation of gas at the electrodes would be equal to its rate of diffusion, and that the potential measured by the direct method with intermittent current would give an indication of the difference between this equilibrium and that obtained with direct current alone. This idea * is evidently incorrect, since the maximum potential is reached almost instantaneously when the current is started, and falls immediately the current is stopped, hence the potential measured with intermittent current would be the mean potential over the whole cycle.

It has also been found that a moving-coil ammeter indicates the arithmetic mean of the current passing over the whole cycle,

* The same idea has been tacitly, although probably erroneously, assumed by previous workers on alternating current effects; for example, Grube and Dulk (*Z. Elektrochem.*, 1918, **24**, 237), Goodwin and Knobel (*Trans. Amer. Electrochem. Soc.*, 1920, **37**, 617), and others.

and hence with an apparent current density of, say, 0.03 amp. per sq. cm. indicated, the actual current density, when the current is on for half of the total time, is at least 0.06, and may be more. It has thus been observed that a lead cathode in sodium hydroxide solution gives a slightly higher overvoltage by the commutator method than it does by the direct method at the same apparent low current density, 0.003 amp. per cm.². As a consequence of these facts it is clear that when the polarising current is on for four-fifths of a cycle, the potential measured may be lower than when the current is on for only half the time at the same current density, as indicated on the ammeter. In the following experiments the polarising current was passing through the circuit for roughly half of each cycle.

Final Measurements.—Four series of experiments were carried out: A. Lead anode in *N*-sodium hydroxide; B. Lead cathode in *N*-sodium hydroxide; C. Lead anode in *N*-sulphuric acid; D. Lead cathode in *N*-sulphuric acid. In each series measurements were made by methods I and II described above, under three different conditions in each case: (a) with an ordinary circuit containing no special inductance, (b) with a high self-inductance in the circuit, and (c) with self- and mutual-inductance. The self-inductance used was the primary coil of a transformer of 60 ohms resistance, which had been employed for transforming 100-volt 60-period alternating current to 6-volt; when the secondary coil was short-circuited, mutual inductance was also set up in the main circuit. A few experiments were also made with a condenser placed between the contact makers *a* and *b* (see Fig. 2).

The general procedure on setting up an electrode was to pass the polarising current for at least fifteen minutes until the potential had become fairly steady; then with each arrangement of the apparatus potential readings were taken when the polarising current was just off, in the middle of the off period, and just before the current was started again, and then also when the current was just on, midway in the on period and just before it was switched off again; the results below are given in this order and indicate the change in measured potential over the whole of a cycle. The three arrangements (a), (b), and (c) were made as rapidly as possible so that the electrode did not change appreciably during the period of measurement. A fresh electrode was used for each different method (I and II).

Although experiments were carried out at a number of different current densities and at varying commutator speeds, yet the results obtained were all very similar and only those for an average current density of 0.015 amp./cm.² and with a commutator speed of about

PART II. OVERTVOLTAGE STUDY OF THE LEAD ELECTRODE. 2931

4,000 changes per minute are given in detail below. All experiments were carried out at room temperature (about 20°).

The columns headed *P.D.* contain the overvoltages in volts, whilst those headed *C.D.* give the corresponding current densities in amps./cm.²; the currents are marked with a negative sign when they and the polarising current travel in opposite directions.

Additional Observations.—In the course of these experiments it was found that on some occasions the results obtained during the period the polarising current was off were very much lower than usual; this discrepancy was found to correspond with considerable sparking at the commutator. When the contact brushes were adjusted so that the sparking was reduced, the potentials obtained were 0.1 to 0.2 volt higher. If a condenser was placed across the spark gap, then in method I (a) alone the potential was increased by 0.05 to 0.07 volt in series A, B, and D. Further, if in method II a resistance coil of 28 ohms was used instead of the usual 1000-ohm coil, considerable induced currents were produced and the potentials measured were often 0.3 volt lower than those recorded above; the introduction of another resistance coil caused the induced currents to decrease and the potential to rise.

Discussion.

It is clear from the results given above that induced currents must have some influence on the potential measured by the commutator method when the polarising current is off: the actual extent of this influence will depend on the resistance and general arrangement of the apparatus, and also on the amount of sparking at the commutator contacts.

In method I, it is seen that, in general, in arrangements (a) and (c), similar potentials are obtained, whilst those obtained in (b) are higher when the current is off and lower when it is on. This behaviour is rather unexpected, since in case (b) the induced currents must be greater than in (a), where the inductance is small, or in (c), where self- and mutual-inductances compensate one another to a great extent. The only explanation that can be offered is that the current in case I (b) rises to a maximum very slowly owing to the opposition of induced currents, and at the instant of switching off a very high value must be reached in order that the average

current may be 0.015 amp.; the result is that the potential measured immediately the current is stopped corresponds to a much higher current density than that actually indicated.

In method II (a), when the main current is switched off a reverse current always flows through the circuit; this may be due to the discharge of the electrolytic cell, but is equivalent to an alternating current superimposed upon the direct polarising current. The introduction of a large self-inductance, as in (b), alters the form of the current, so that positive current is in the circuit the whole time and naturally higher potentials are obtained when the polarising current is supposed to be off. The introduction of a mutual inductance compensates the self-inductance, and the form of the current becomes such that only very small positive currents flow in the intervals; since the error in the potential measurements caused by these small currents is negligible, it is believed that the values obtained under these conditions approximate most closely to the true overvoltage. The difference between the potentials obtained at the end of the on-period of the current and the beginning of the off-period, in method II (c), will then be due to the error caused by the resistance of the metal-gas-electrolyte system at the surface of the test electrode, whilst the corresponding difference of potential in method I (a) will include both this error and also that due to induced currents. The results may be summarised as follows:

Series.	Difference between direct and commutator potentials due to:	
	Induced currents.	Surface resistance.*
	Volt.	Volt.
A	0.09	0.13
B	0.13	0.15
C	0.03	0.12
D	0.12	0.18

* These values include any fall of potential that may occur during the first five-hundredth part of a second that elapses after the current is switched off.

At higher current densities, the relative effect of induced currents decreases slightly, whilst that due to the resistance effect increases fairly rapidly, but not nearly in proportion to the current.

In a separate series of experiments it has been found that if small alternating currents are superimposed upon direct current there will be a considerable lowering of potential in the case of electrodes A, B, and D, but with a lead anode in sulphuric acid (electrode C) alternating current will have very little effect: this is exactly in agreement with the results obtained above. Further, in the same experiments it was found that alternating currents had no effect on the potential of an electrode of electrolytically deposited

lead dioxide if sodium hydroxide or sulphuric acid was the electrolyte, and experiments with such electrodes on the lines described in this paper showed that methods I (a) and II (c) gave almost identical results, indicating that the induced currents also had no effect on the potentials of these electrodes.

Conclusion.

It appears that electrode potentials measured by the direct method are too high owing to the fact that the resistance of the metal-gas-electrolyte system at the surface of the test electrode causes a potential, in addition to that of the test and standard electrodes alone, to be applied to the potentiometer system. On the other hand, potentials measured by the commutator method may be too low on account of the fall of potential that occurs when the current is off, and also on account of induction effects in the circuit. Sparking at the commutator contacts appears to cause a diminution in the measured potential. As far as can be seen at present, the best determinations of overvoltage appear to be those made by the method II (c) described in this paper, provided the potential measurements are made as soon as possible after the main current is switched off. Experiments with other electrodes may give more information on this point.

The author wishes to express his thanks to the Chemical Society for a grant from its Research Fund which enabled him to purchase the rotary commutator used in this work.

[Received, July 30th, 1923.]

CCCXLVII.—*Succinylfluorescein and its Derivatives.*

By SIDNEY BIGGS and FRANK GEO. POPE.

NENCKI and SIEBER (*J. pr. Chem.*, 1881, [ii], 23, 154), in the course of an extended investigation on the condensation of phenols with aliphatic acids, first described succinylfluorescein and prepared one or two of its derivatives. A more extended examination of this substance has now been made and the results are embodied in the present communication.

The fluorescein is analogous in nearly all respects with ordinary fluorescein, one great point of difference, however, being its behaviour with phosphorus pentachloride. Using this reagent, Baeyer (*Annalen*, 1876, 183, 18) found that fluorescein gave a chloride, $C_{20}H_{10}O_3Cl_2$, in the form of a colourless, crystalline powder. All attempts to prepare a similar chloro-derivative from succinyl-

fluorescein have so far failed. A green mass, soluble in sodium hydroxide, and containing both chlorine and phosphorus, has invariably been the product of the reaction, whatever conditions have been employed. All attempts to purify this and to isolate the pure chloride have as yet been ineffectual. Using thionyl chloride in place of phosphorus pentachloride, a brown product containing sulphur was always obtained.

EXPERIMENTAL.

Succinylfluorescein, $C_{16}H_{12}O_5$, was prepared by Nencki and Sieber by heating its components with concentrated sulphuric acid at 190° . On account of the amount of by-product formed, the yield amounted only to 60–70 per cent. of the theoretical. We have found that a yield of about 90 per cent. can be obtained by working under the following conditions.

A mixture of 11 grams of succinic anhydride, 25 grams of resorcinol, and 53 c.c. of 73 per cent. sulphuric acid is boiled under reflux for six hours. After cooling, the product is poured into a litre of water and carefully neutralised by sodium hydroxide. The precipitated fluorescein is collected, well washed, and crystallised from 5 per cent. hydrochloric acid. For analysis, it is further twice crystallised from hydrochloric acid, dissolved in warm sodium carbonate solution, precipitated by acetic acid, collected, washed, and dried. This method of treatment appears to be necessary, since the product crystallised from hydrochloric acid retains a small amount of chlorine. It was also found necessary to dry the fluorescein to constant weight at 160° owing to the obstinate retention of a small quantity of water (Found: C = 67.33; H = 4.42. Calc. for $C_{16}H_{12}O_5$, C = 67.60; H = 4.22 per cent.). Succinylfluorescein crystallises from hydrochloric acid in dark crimson needles showing a blue reflex. It is sparingly soluble in alcohol or acetic acid, giving yellow solutions showing a green fluorescence. It is very soluble in solutions of the alkali hydroxides, carbonates, and bicarbonates, in the latter cases with evolution of carbon dioxide. It melts at 234° (decomp.). Reducing agents such as zinc dust and alkali, sulphurous acid, or sodium hyposulphite convert it into succinylfluorescin, which is thrown down as a colourless solid, but almost immediately reverts to the coloured fluorescein owing to oxidation on exposure.

The sodium salt, $C_{16}H_{11}O_5Na$, was obtained by boiling the fluorescein with a quantity of sodium carbonate insufficient to dissolve the whole. The solution was filtered from unchanged fluorescein, and concentrated until crystallisation commenced. The salt separated as a reddish-brown, crystalline powder, which

was rather hygroscopic (Found : Na = 7.67. Calc. for $C_{16}H_{11}O_5Na$, Na = 7.52 per cent.). Solutions of various metallic salts were mixed with solutions of the sodium salt with the following results. Lead salts—orange needles; stannous salts—yellow crystals; cobalt salts—yellowish-brown needles; cadmium salts—brown needles; mercury (ous, ic), antimony, calcium, strontium, and barium salts give yellow, amorphous precipitates; copper, aluminium, nickel, and manganous salts give buff-coloured, amorphous precipitates.

Succinylfluorescein diacetate, $C_{20}H_{16}O_7$, was obtained by heating the fluorescein with four times its weight of acetic anhydride for a quarter of an hour. The cooled solution was poured into alcohol and kept until the excess of acetic anhydride was destroyed. Water was added, and the precipitate was collected, washed, and recrystallised from boiling dilute alcohol (with the addition of animal charcoal). It separated as a practically colourless, crystalline powder, melting at 157° (Found : C = 65.41; H = 4.51. Calc. for $C_{20}H_{16}O_7$, C = 65.22; H = 4.35 per cent.). It is easily soluble in acetic acid, alcohol, chloroform, tetrachloroethane, or ethyl acetate, sparingly soluble in benzene or xylene, and practically insoluble in ether.

Succinylfluorescein Dibenzoate, $C_{30}H_{20}O_7$.—Two grams of the fluorescein were heated with 6 grams of benzoyl chloride for four hours. The resulting dark-coloured mass was repeatedly boiled with water until the excess of benzoyl chloride and benzoic acid were removed. It was then extracted with hot alcohol, from which the benzoate separated on cooling. On recrystallisation from alcohol, it separated as an almost colourless, crystalline powder melting at 250° (decomp.) (Found : C = 72.78; H = 3.61. Calc. for $C_{30}H_{20}O_7$, C = 73.17; H = 4.06 per cent.). It is readily soluble in benzene, xylene, or chloroform, and sparingly soluble in alcohol or acetic acid.

Succinylfluoresceinamide, $C_{22}H_{17}O_4N$.—Fischer and Hepp's method of preparing fluoresceinamide (*Ber.*, 1893, 26, 2236) was slightly modified in the following manner.

Five grams of the fluorescein were heated with 20 grams of freshly distilled aniline and 10 grams of aniline hydrochloride on the water-bath for a day. The mixture was made alkaline with sodium hydroxide, and the excess of aniline removed in a current of steam. The alkaline solution was then filtered into an excess of dilute hydrochloric acid, whereby a considerable amount of tarry matter was precipitated. This was removed and the solution exactly neutralised by sodium hydroxide solution, when a cream-coloured solid was precipitated. The precipitate was collected, washed, and crystallised from dilute alcohol, separating as a colourless, crystalline powder melting at 260° (decomp.) (Found : N = 3.87. Calc. for

($C_{22}H_{17}O_4N$, $N = 3.90$ per cent.). The anilide is soluble in alcohol, acetic acid, or acetone, and insoluble in benzene or chloroform.

Diethyl Ethers.—Two possibilities arise in the case of these ethers, namely, the coloured quinonoid form, and the colourless lactone form.

Quinonoid form. Coloured.

and

Lactone form. Colourless.

Twenty-eight grams of succinylfluorescein and 12 grams of potassium hydroxide were dissolved in 250 c.c. of 96 per cent. alcohol, 32 grams of ethyl iodide were added, and the whole was heated under reflux for eight hours. A further gram of potassium hydroxide and 3 grams of ethyl iodide were then added, and the heating was continued for another eight hours. The product was poured into 2 litres of water and the resulting precipitate collected and washed with water. It was then further washed several times with dilute alkali in order to remove any unchanged fluorescein, and fluorescein monoethyl ether. After drying, it was recrystallised from a mixture of chloroform and light petroleum (Found: $C = 70.64$; $H = 5.85$. Calc. for $C_{20}H_{20}O_5$, $C = 70.58$; $H = 5.88$ per cent.). It separates from the solvent as a yellowish-brown, crystalline powder and is readily soluble in alcohol, acetic acid, chloroform, or benzene. It is insoluble in cold dilute solutions of the caustic alkalis. It melts at 170° .

Lactone Form.—The crude diethyl ether prepared as above was dissolved in hot xylene, and a brown solid separated on cooling. This was collected, washed, dried, and recrystallised from alcohol (with the addition of animal charcoal). After three recrystallisations from alcohol it was obtained in colourless, hair-like needles which melted at $196\text{--}197^\circ$ (Found: $C = 70.65$; $H = 6.18$. Calc. for $C_{20}H_{20}O_5$, $C = 70.58$; $H = 5.88$ per cent.). It is very soluble in acetic acid, alcohol, or chloroform, but sparingly soluble in benzene or light petroleum. It is insoluble and unaffected by boiling dilute alkali, whereas the coloured form dissolves and is hydrolysed.

Monoethyl Ester (coloured carboxylic form),

—Twenty grams of succinylfluorescein and a mixture of 40 grams

of 96 per cent. alcohol and 30 grams of sulphuric acid were heated under reflux for eight hours. The mixture was poured into a litre of water and sodium hydroxide added until the precipitate just dissolved. A stream of carbon dioxide was passed through the liquid and the ester was thus precipitated as an orange-red powder. This was collected, washed, and crystallised from alcohol, from which it separated as a brown powder melting at $186-187^{\circ}$ (Found: C = 68.87; H = 5.30. Calc. for $C_{18}H_{16}O_5$, C = 69.23; H = 5.13 per cent.). It is readily soluble in alcohol, chloroform, ethyl acetate, or benzene, and sparingly soluble in acetic acid. It dissolves unchanged in cold dilute sodium hydroxide solution, but is hydrolysed, yielding the fluorescein, when this solution is heated.

Alkali Fusion of Succinylfluorescein.—Twenty grams of succinylfluorescein were heated under reflux for two hours with 80 grams of potassium hydroxide and 50 c.c. of water. At the end of this time the fluorescence was completely destroyed. The solution was then made up to 500 c.c. with water and carefully neutralised with acid. The solid which separated was collected, and the mother-liquor extracted several times with ether. The ether solution was distilled and the residual solid added to the original precipitate. The total solid was dissolved in water, boiled with animal charcoal, and allowed to crystallise. By two further recrystallisations from water, the decomposition product was obtained in colourless needles which melted at 205° . The acid thus obtained appears to be β -2 : 4-dihydroxybenzoylpropionic acid.

(Found: C = 56.59; H = 4.89. Calc. for $C_{10}H_{10}O_5$, C = 57.14; H = 4.76 per cent.). It is very soluble in hot water and in ether, and sparingly soluble in alcohol, acetic acid, or benzene. It gives a reddish-violet coloration with ferric chloride.

The silver salt of the acid was obtained by dissolving 2 grams of the acid in 150 c.c. of water and neutralising the solution with ammonia. Any excess of ammonia was removed by boiling the solution and the silver salt was then precipitated by the addition of a slight excess of silver nitrate. The precipitate was collected, washed, and recrystallised from hot water, separating in colourless needles (Found: Ag = 33.77. Calc. for $C_{10}H_9O_5Ag$, Ag = 34.07 per cent.). This result gives the value 213 as the molecular weight of the acid, the calculated value for $C_{10}H_{10}O_5$ being 210.

Succinyleosin, $C_{16}H_8O_5Br_4$, was first obtained by Nencki and Sieber (*loc. cit.*) by the addition of a slight excess of bromine to a solution of the fluorescein in 5 per cent. hydrochloric acid. A better method of preparation consists in dissolving the fluorescein in a slight excess of sodium hydroxide solution, and the theoretical amount of bromine in a separate quantity of sodium hydroxide. The two solutions were filtered, mixed, stirred rapidly, and the whole was then poured into a slight excess of dilute hydrochloric acid. The brick-red precipitate was collected, washed, dissolved in sodium hydroxide, and reprecipitated by acid. After washing and drying, it was dissolved in ethyl benzoate and the warm solution filtered into cold benzene, from which it separated as a brick-red, crystalline precipitate (Found: C = 32.52; H = 1.46; Br = 53.35. Calc. for $C_{16}H_8O_5Br_4$, C = 32.00; H = 1.33; Br = 53.33 per cent.). It is very soluble in ethyl benzoate and in phenol, moderately soluble in nitrobenzene, but almost insoluble in the common organic solvents. When heated, it blackens at 250° and decomposes. It is readily soluble in solutions of the alkali hydroxides, carbonates, and bicarbonates, in the latter cases with evolution of carbon dioxide.

The solution of the eosin in sodium hydroxide gives crimson precipitates on the addition of solutions of most metallic salts. With cadmium, magnesium, and nickel salts these appear to be crystalline, whilst lead, chromium, zinc, manganese, calcium, strontium, and barium salts yield amorphous precipitates. Iron and copper salts give brownish-red precipitates.

Succinyleosin diacetate, $C_{16}H_8O_5Br_4(CO \cdot CH_3)_2$, was obtained by dissolving 2 grams of the eosin in 10 grams of acetic anhydride, and adding a few drops of concentrated sulphuric acid, when the mixture became warm. After twelve hours, 50 c.c. of alcohol were added, the whole was warmed on the water-bath for an hour, and the solution poured into water, the precipitate collected, washed, and recrystallised from alcohol. It separated in small, colourless leaflets which on heating turned red at 185° and melted at 189° with decomposition (Found: Br = 46.26. Calc. for $C_{20}H_{12}O_7Br_4$, Br = 46.78 per cent.). It is soluble in acetic acid, alcohol, or chloroform, and moderately soluble in benzene.

Succinyleosin dibenzoate, $C_{16}H_8O_5Br_4(CO \cdot C_6H_5)_2$, was prepared by heating 5 grams of the eosin with an excess of benzoyl chloride for two hours at 150°. The cooled mixture was poured into 100 c.c. of alcohol, warmed on the water-bath for an hour, and diluted with 200 c.c. of water. The precipitate was collected, washed, dried, and extracted several times with hot amyl alcohol, from which it separated on cooling as an almost colourless solid. It was further

dissolved in epichlorhydrin and precipitated by alcohol as a colourless powder (Found : Br = 39.92. Calc. for $C_{30}H_{16}O_7Br_4$, Br = 39.60 per cent.). When heated, it softens at 220° , and melts at 275° (decomp.). It is very soluble in epichlorhydrin, ethyl benzoate, or tetrachloroethane, sparingly soluble in amyl alcohol, and almost insoluble in ethyl alcohol.

Succinyleosin Diethyl Ether (coloured quinonoid form),

—Seven grams of the eosin silver salt were heated with 50 c.c. of alcohol and 3 grams of ethyl iodide, in a pressure bottle, for eight hours at 100° . After cooling, the liquid was filtered from the precipitated silver iodide and concentrated until crystallisation commenced. The crystals were collected, washed, and recrystallised from dilute acetic acid, separating in red needles which melted at 210° (decomp.) (Found : C = 36.36; H = 1.91; Br = 47.80. Calc. for $C_{20}H_{16}O_5Br_4$, C = 36.58; H = 2.44; Br = 48.8 per cent.). The ether is very soluble in acetic acid, alcohol, or ether, and sparingly soluble in benzene.

Succinyleosincarboxylic ester,

was prepared by heating 20 grams of the eosin with 30 grams of sulphuric acid and 40 grams of 96 per cent. alcohol under reflux for eight hours. The mixture was then poured into an excess of a dilute solution of sodium hydrogen carbonate, the precipitate obtained being collected, washed, and dried. It was purified by crystallisation from tetrachloroethane, separating as a crimson, crystalline powder (Found : Br = 51.02. Calc. for $C_{18}H_{12}O_5Br_4$, Br = 50.96 per cent.). It is very soluble in acetone, alcohol, or epichlorhydrin, moderately soluble in ethyl acetate, ethyl benzoate, or tetrachloroethane, and almost insoluble in acetic acid, benzene, or xylene.

Dibromosuccinylfluorescein, $C_{16}H_{10}O_5Br_2$, was prepared in a manner similar to that used for the eosin, half the corresponding amount of bromine being used. The precipitate was collected, washed, dissolved in warm sodium carbonate solution, and reprecipitated by the addition of acid. It was again collected, washed,

dried, dissolved in phenol, and the solution poured into benzene. The precipitate was collected and washed with benzene until it was free from phenol. The dull red powder obtained melted and decomposed at 237° . It is soluble in phenol, ethyl benzoate, or nitrobenzene (Found: Br = 36.6. Calc. for $C_{16}H_{10}O_5Br_2$, Br = 36.2 per cent.).

Dinitrosuccinylfluorescein hydrate, $C_{16}H_{12}O_{10}N_2$, was obtained by dissolving 5 grams of the fluorescein in 100 grams of concentrated nitric acid which had previously been cooled to 0° to -10° , and then adding quickly with constant stirring 10 grams of fuming nitric acid. The mixture was immediately poured into water, the precipitate collected, well washed, and dissolved in 10 per cent. sodium hydroxide solution. The solution was then just acidified with dilute acetic acid and kept over-night. Any slight precipitate of succinylfluorescein was removed by filtration and the dinitrohydrate precipitated by the addition of dilute hydrochloric acid. It separated in very small, pale yellow prisms and was purified by recrystallisation from a large volume of hot water (Found: N = 6.99. Calc. for $C_{16}H_{12}O_{10}N_2$, N = 7.14 per cent.). The hydrate, which probably arises from the fission of the pyrone ring, is very soluble in alcohol or acetic acid, moderately soluble in hot water, and insoluble in benzene or chloroform. It decomposes suddenly with great violence at temperatures above 300° .

Dinitrosuccinylfluorescein diacetate, $C_{20}H_{14}O_{11}N_2$, was prepared by heating 0.8 gram of dinitrosuccinylfluorescein hydrate with 1 gram of fused sodium acetate and 4 grams of acetic anhydride for six hours on the water-bath. The mixture was poured into 50 c.c. of alcohol, warmed on the water-bath for half an hour, and kept over-night. It was then gently warmed and water added until a faint turbidity was produced; the brown, crystalline powder that slowly separated was collected, washed, and recrystallised from dilute alcohol. It is readily soluble in alcohol, acetone, or acetic acid, and practically insoluble in benzene or chloroform. It decomposes with explosive violence at about 200° (Found: N = 6.32. Calc. for $C_{20}H_{14}O_{11}N_2$, N = 6.11 per cent.).

Tetranitrosuccinylfluorescein, $C_{16}H_8O_{13}N_4$, was obtained by heating 5 grams of succinylfluorescein with 40 c.c. of fuming nitric acid for half an hour on the water-bath. The product was poured into 100 c.c. of water and the orange-yellow precipitate collected and washed. The solid was then dissolved in 10 per cent. sodium hydroxide solution and the sodium salt thrown down in the form of a yellow, crystalline precipitate by the addition of saturated brine solution. The salt was collected, decomposed by dilute hydrochloric acid, the resulting crude tetranitro-compound washed

with a small quantity of cold water and finally recrystallised from dilute alcohol, from which it separated in lemon-yellow rosettes of crystals. It melts at 203° and explodes violently at higher temperatures. It is very soluble in ethyl alcohol, moderately soluble in hot water, acetic acid, or chloroform, and slightly soluble in benzene. It decomposes the alkali carbonates, with evolution of carbon dioxide (Found: N = 12.25. Calc. for $C_{16}H_8O_{13}N_4$, N = 12.07 per cent.).

The sodium salt of the tetranitro-compound, $C_{16}H_8O_{13}N_4Na_2$, may be prepared by direct salting out from the tetranitro-compound by the addition of brine, but so prepared it contains a large proportion of sodium chloride, from which it cannot be freed. It was finally obtained by dissolving the tetranitro-compound in alcohol and adding a slight excess of sodium hydroxide, also dissolved in alcohol. The lemon-yellow, flocculent precipitate, which became crystalline on standing, was collected and washed with alcohol until free from alkali. It is very soluble in water. Owing to the violent explosive decomposition of the substance on heating, the sodium content could not be estimated by ignition with sulphuric acid, but was determined indirectly by evaporation of a weighed quantity of the salt with excess of hydrobromic acid on the water-bath. The residue was dissolved in water and the evaporation repeated, the amount of sodium bromide formed being then determined by precipitation with silver nitrate in the usual manner (Found: Na = 9.14. Calc. for $C_{16}H_8O_{13}N_4Na_2$, Na = 9.05 per cent.).

The diacetyl derivative, $C_{20}H_{12}O_{15}N_4$, was obtained by heating 0.8 gram of the tetranitro-compound with 1 gram of fused sodium acetate and 5 grams of acetic anhydride on the water-bath for three hours and then finally boiling the mixture for half an hour. The product was poured into 50 c.c. of alcohol, heated on the water-bath for half an hour, and then kept for several hours until the excess of acetic anhydride was destroyed. The precipitate was collected and washed, first with alcohol and then with hot water. It was then dissolved in hot acetone and precipitated by pouring the solution into benzene. It does not melt, but explodes with violence when heated above 350° . It is fairly soluble in hot acetone, slightly soluble in alcohol, glacial acetic acid, or ethyl acetate, and insoluble in benzene, chloroform, ether, or xylene. It is very soluble in boiling pyridine, but is there hydrolysed to the tetranitro-compound (Found: N = 10.13. Calc. for $C_{20}H_{12}O_{15}N_4$, N = 10.22 per cent.).

One of us (S. B.) desires to thank the Advisory Council of the

Department of Scientific and Industrial Research for a grant which has helped to defray the cost of this investigation.

[Received, October 2nd, 1923.]

CCCXLVIII.—A New Type of Reduction-Oxidation System. Part I. Cysteine and Glutathione.

By MALCOLM DIXON and JUDA HIRSCH QUASTEL.

THE discovery of glutathione as a normal constituent of all living tissues (Hopkins, *Biochem. J.*, 1921, **15**, 286), the peculiar relationships existing between it and the tissues, and its importance in the rôle of cell respiration have made the study of the dynamics of the oxidation of glutathione one of considerable interest. Glutathione, $\text{SH}\cdot\text{CH}_2\cdot\text{CH}(\text{CO}_2\text{H})\cdot\text{NH}\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{CO}_2\text{H}$, is a dipeptide of cysteine, $\text{SH}\cdot\text{CH}_2\cdot\text{CH}(\text{NH}_2)\cdot\text{CO}_2\text{H}$, and glutamic acid, and, as might be expected, its behaviour in the tissues seems to be closely paralleled by that of cysteine. It has many features in common with cysteine, and the differences are such as not to indicate any essential dissimilarity between the chemical behaviour of the two compounds. Of considerable practical importance, however, is the difference between the solubilities of their oxidised forms (I and II).

Oxidised glutathione is quite soluble in neutral, acid, or alkaline aqueous solutions, whilst cystine is soluble only in distinctly acid or alkaline solutions.

The $\text{RSH} \rightarrow \text{R}\cdot\text{S}\cdot\text{S}\cdot\text{R}$ system has hitherto been studied only from the point of view of reaction velocities. Electrometric evidence, which is necessary if the system is to be classed with the usual type of reversible reduction-oxidation process, is lacking. This lack of electrometric information appears to be due to the extraordinary difficulties experienced when potentials due to compounds of the type RSH are being measured. Continuous and extensive drifts of the potential appear to form the main feature of the system, if the ordinary platinum-calomel cell be adopted.

We have made an inquiry into the nature of these drifts, and although it is, as yet, difficult to state finally their actual causes, we have been successful in eliminating them to some extent in a modification of the platinum-calomel cell and in obtaining another cell which proves to be practically free from them. In no case, however, have we been able to attain the extremely high accuracy of measurement which obtains in the platinum-calomel cell containing such oxidation-reduction systems as the quinol-quinone or the ferrous-ion-ferri-ion. Nevertheless, the accuracy which has been attained is such that complete reliance may be placed on the potentials actually obtained—within the limits of error specified.

Our first inquiries turned, naturally, to the elucidation of those factors governing the drift of potential in the platinum-calomel cell. It is well known that extensive drifts in potential will occur when platinum is used as an electrode, but never when the cell contains an oxidation-reduction system of the usual type. This system immediately stabilises the potential, so that readings to a fraction of a millivolt are easily obtained and may be repeatedly reproduced. With cysteine-cystine mixtures, however, no such steady potential could be obtained. The readings in this case rose gradually to a maximum and then slowly fell. Our problem, then, was to determine how far the cysteine or cystine was responsible for the drift. With this point in view, we were able to trace three distinct factors governing the drift in buffer solutions containing neither cysteine nor cystine. These were:

- (1) The nature and previous history of the electrode.
- (2) The rate of stirring of the solution in which the platinum electrode was immersed.
- (3) The hydrogen- or hydroxyl-ion concentration of the solution.

The facts that platinum will act as a very efficient hydrogen electrode and that under the conditions of our experiments it possessed a hydrogen pressure which was being continually varied by diffusion, etc., seem to be a plausible explanation of the normal drift. In the presence of cysteine the same factors operate in a similar manner, but superimposed upon the normal drift is the rate at which the electrode attains equilibrium with the cysteine. The latter, however, is generally fairly quick, so that the potential due to the cysteine is fairly rapidly reached, and this then slowly falls in the usual manner of non-cysteine solutions. With cystine, the normal drift alone appears to occur. The fact that the whole of the drift in cysteine solutions can be attributed to changes in the metal electrode itself is easily demonstrated by the following experiment. If the electrode, the drift of which has become small and regular, and has acquired a certain potential, be transferred to

a fresh cysteine solution (of the same composition as that from which the electrode has been transferred), the drift is resumed from this potential at the same small and regular rate. The temperature, of course, must remain the same throughout the work. We can safely exclude, therefore, the possibility of cysteine itself undergoing changes in solution which bring about a drift in the reduction potential.

The next step in the inquiry was to investigate the possibility of modifying the cell so that relatively steady potentials could be rapidly attained. Replacing our electrode (which was a short stout piece of platinum wire) by a platinum foil coated with platinum-black only resulted in the slowing of the drift. Since the foil could not by any means be obtained in a condition which eliminated the drift, it was finally abandoned. Numerous attempts were then made to control the drift, and of these the following scheme proved to be the most efficient.

Two platinum electrodes cut from the same wire and of the same length were used in conjunction with the calomel electrode. The cysteine solution was placed in the cell and a very small polarising current (of 10^{-5} amp.) passed between the metal electrodes. The polarisation was continued until the potential difference between either of the metal electrodes and the calomel had attained an approximately steady value. The polarising current was then discontinued and the rate at which the metal electrodes returned to an equilibrium point observed. The equilibrium point was attained far more rapidly in alkaline than in acid solutions. Both electrodes then gave steady values which were not affected by stirring or bubbling with nitrogen. The values, too, seemed to be independent of the initial states of the electrodes—for example, the values were the same whether the electrodes had been previously ignited or not. In alkaline solutions ($p_H > 7.0$), the system proved to be very satisfactory, both metal electrodes quickly assuming identical steady potentials. In acid solutions, however, the system was by no means so satisfactory, the electrodes only slowly attaining a steady value and then giving considerably different readings. A certain amount of work was done with this system on cysteine in alkaline solutions, but since it was subsequently found that at a p_H greater than 9.5 the behaviour of cysteine diverged considerably from the laws which were found to govern it below this p_H , the utility of the system was considerably limited. It was evident that, on the whole, platinum was an unsatisfactory electrode for this particular type of oxidation-reduction system.

We therefore investigated other metal electrodes and of these pure gold proved to be the only one satisfactory.

The electrode actually adopted consisted of a pure gold plate (2.5 cm. by 1 cm. and 0.5 mm. thick). This gave very steady readings, independent of the rate of stirring, equally good in acid or alkaline solution, which returned to their initial values after slight anodic or cathodic polarisation. There was the objection, however, that the potential given by a definite concentration of cysteine or glutathione could not always be reproduced with great accuracy. Small deviations occurred which were probably connected with the conditions of the electrode system previous to the addition of the cysteine, but these were in no case sufficiently large to affect appreciably the magnitude of the potential. Whenever possible, in determining the effect of p_H or of the concentration of the sulphhydryl compound on the reduction potentials, the same initial conditions were obtained.

The cell consisted of a closed vessel through which a stream of pure nitrogen was passed by means of a tube dipping in the solution. The bubbling was continued while observations were taken, this being quite an efficient method of stirring. The calomel cell (containing saturated potassium chloride solution) was connected by means of a salt bridge to the solution in the vessel. In taking readings, the procedure, briefly, was to pipette a definite volume of a buffer solution into the vessel, to bubble nitrogen through vigorously, and to wait until the gold-calomel potential had reached a steady value. The gold electrode had been previously well washed with water, no other treatment being necessary. The steady value was usually attained in two or three minutes and gave us an indication of the initial state of the system. If, on repeating the work, this particular value was not obtained, the contents of the vessel were rejected and the gold was rewashed and fresh buffer solution used. Generally, we were able to reproduce the initial value with considerable accuracy. A known volume of the solution of the substance under investigation was then introduced into the vessel and the potential of the solution, when steady, determined in the usual way by the potentiometer. The temperature was maintained throughout at 22°.

Since the substances under investigation were of such a nature that they were easily susceptible to oxidation by the air, solutions of them, when made up to the correct p_H , were placed in tubes which were then thoroughly evacuated. Practically all the air was in this way removed from the solutions, which were not re-exposed for any period greater than the extremely short time necessary for the introduction of a quantity of the solution into the electrode vessel.

The Reduction Potentials of Cysteine-Cystine Mixtures.

The most characteristic feature of oxidation-reduction systems of the usual type is the assumption of a stable potential difference which is determined by the ratio of the concentrations of the reduced to the oxidised form. The curve expressing the variation of the potential differences with the ratio of the concentrations of reduced and oxidised forms is always *f*-shaped, the point of inflection lying at the point of equal concentrations of both forms. This follows theoretically from the conception of electronic transfer in reversible oxidation-reduction processes.

With cysteine-cystine mixtures we found no such *f*-shaped curve. Fig. 1 illustrates the variation of potential differences

with different relative concentrations of cysteine and cystine at a constant p_H (8.0). These results were obtained with the platinum system referred to above, and have been checked with considerably greater accuracy with the gold electrode. The observed potential differences can be converted to normal hydrogen electrode reference by the addition of 0.2475 volt.

The unusual form of this curve led us to believe that cystine was not exerting an oxidation potential. The effect of adding cystine to cysteine solutions was therefore investigated, and it was found that the addition was entirely without effect on the reduction potential. Cystine, too, did not affect the steady potential attained in a buffer solution containing no cysteine. Hence Fig. 1 exhibits the relation existing between various concentrations of cysteine and their potential differences (at the same p_H), and is quite independent of the quantity of cystine present. It does not express an oxidation-reduction curve of the usual type—the

reduction potential depends apparently solely on the concentration of the reduced form.

In determining accurately the form of this curve under various conditions, cysteine alone was subsequently used—this procedure being quite justified by the absence of any effect due to cystine. In the following work, only the gold-calomel system was used. The cysteine was prepared by the reduction of cystine, which was itself prepared from the products of hydrolysis of hair. The cysteine was separated and recrystallised a number of times as the hydrochloride (m.p. 172° uncorr.). Analysis gave the theoretical quantities of nitrogen and chlorine.

*Variation with p_H of the Potentials due to a Constant
Concentration of Cysteine.*

Two methods are available for this determination. The first consists in making up buffer solutions of different hydrogen-ion concentrations and adding a volume of a standard solution of cysteine to known volumes of each buffer so that the concentration of cysteine in the buffer is always kept the same. The potential difference of each solution is then determined. The second method consists in adding a quantity of the standard solution to a known volume of the buffer solution and titrating the latter with alkali (or acid) to definite concentrations of hydrogen-ion. The second method proves to be the more accurate of the two, for the same initial conditions of the system obtain at each reading. Corrections are made for the alterations in concentration of cysteine by the addition of the titrating solution, but if a suitably high concentration of cysteine be initially used the changes of potential due to the concentration variations are of the order of a small fraction of a millivolt. The limit of error in all the following observations is 0.002 volt.

Table I gives the results obtained with cysteine when the first method was adopted. The symbols π , π_0 , and τ_H are defined by equations to be given later.

Table IV gives those obtained with glutathione when the second method was adopted.

In the first series of results (Table I), the concentration of the cysteine was $N/665$, 4 c.c. of a $N/50$ -solution of cysteine being added to 50 c.c. of a buffer solution of known p_H . Experiment showed that the addition of the cysteine solution had no perceptible effect on the p_H of the buffer solution.

Fig. 2, in which the results given in Table I are plotted, demonstrates the linear relationship existing between the concentration

of hydrogen-ions and the potential differences of a constant concentration of cysteine.

Variation of Potential Difference with Concentration of Cysteine at a Constant Hydrogen-ion Concentration.

The method adopted here was to introduce known quantities of a standard cysteine solution of a known p_H into 50 c.c. of a buffer solution of the same p_H . The quantities of cysteine, which were generally small, were added consecutively to the same solution, and the strength of the solution was calculated after every addition. In the experiment the results of which are tabulated in Table II, five quantities of 1 c.c. of *N*/50-cysteine at p_H 6.0 were added consecutively to 50 c.c. of a buffer solution at p_H 6.0. In another experiment where the initial conditions of the system appeared to be somewhat different from those in the previous experiments,

the magnitude of the potentials for equivalent concentrations also differed.

Glutathione.

Glutathione was investigated in a precisely similar manner to cysteine. It was found that the oxidised form behaved in a similar manner to cysteine. It had no perceptible oxidation potential. Its action, however, was somewhat peculiar, in that its addition to a reduced glutathione solution invariably caused the potential to drift slowly a few millivolts in the direction of higher reduction potential. Reduced glutathione behaved similarly to cysteine.

Tables IV and V summarise the results.

In both the cases of cysteine and glutathione, the potential difference at a p_H higher than 9.5 had an anomalous value. Probably the divergence from the linear relationship existing between p_H and the potential difference for a constant concentration of cysteine and glutathione commences at a lower p_H , but it does not become marked until this high value is reached. In this phenomenon, cysteine and glutathione both resemble the quinol-quinone system. The relationship between the logarithm of the concentration of cysteine or of glutathione (at a constant p_H) and the potential difference is also linear and this linearity appears to be independent of the concentration of hydrogen-ions.

The experimental results may be summarised briefly in the two equations:

E (observed potential difference for constant concentration of RSH) = $k \cdot p_H + k'$.

E (observed potential difference for constant p_H) = $k'' \log c + k'''$, where k , k' , k'' , and k''' are constants and c = concentration of RSH.

Discussion.

Assuming the oxidation of cysteine to cystine to take place according to the scheme

we have for the affinity equation

$$\Delta = \frac{RT}{F} \log K - \frac{RT}{F} \log \frac{[\text{RSH}]^2}{[\text{R}\cdot\text{S}\cdot\text{S}\cdot\text{R}][\text{H}^+]^2} \quad (1)$$

5 F* 2

where K is the equilibrium constant of the equation given above and the square brackets denote concentrations.

$$\begin{aligned} E(E.M.F.) &= A/2 \text{ (since } E = \text{affinity per gram-equivalent)} \\ &= \frac{RT}{2F} \log K - \frac{RT}{2F} \log \frac{[\text{RSH}]^2}{[\text{R}\cdot\text{S}\cdot\text{S}\cdot\text{R}][\text{H}^+]^2} \\ &= \frac{RT}{2F} \log K - \frac{RT}{F} \cdot p_{\text{H}} - \frac{RT}{F} \log \frac{[\text{RSH}]}{\sqrt{[\text{R}\cdot\text{S}\cdot\text{S}\cdot\text{R}]}} \end{aligned}$$

It is evident that this equation must yield a curve of the usual λ -shaped type, and, moreover, the potential will be dependent on the concentration of cystine. A comparison of the actual results with the equation shows that the latter will apply rigorously if the term $[\text{R}\cdot\text{S}\cdot\text{S}\cdot\text{R}]$ be regarded as a constant.

All the calculated results in the tables given above have been derived from the equation

$$\pi = \pi_0 + \frac{RT}{F} \log [\text{H}^+] - \frac{RT}{F} \log [\text{CSH}] \quad . \quad . \quad (2)$$

where π = observed $E.M.F.$ given with reference to the normal hydrogen electrode, π_0 = "normal reduction potential" referred to the normal hydrogen electrode, and $[\text{CSH}]$ = concentration of cysteine or glutathione expressed in gram-equivalents per litre. The constancy of π_0 is shown in Tables I and IV and the agreement between observed and calculated values is sufficient to place the accuracy of the equation (2)—below a p_{H} of 9.0—beyond doubt. In Tables I and II, the values of r_{H} [(using the notation of Clark, *vide* Clark, "Determination of Hydrogen-ions," 2nd edit., p. 260) where $r_{\text{H}} = -\log p$, and p = (hypothetical) hydrogen pressure at the electrode in equilibrium with the solution, and the

relation of π to r_{H} is given by $\pi = -\frac{RT}{F} \log \frac{\sqrt{p}}{[\text{H}^+]}$ or $r_{\text{H}} = 2\left(\frac{\pi F}{RT} + p_{\text{H}}\right)$

have been given. It will be seen that these are constant at the concentration specified. Above p_{H} 9.5 there is considerable divergence from the constancy of r_{H} or of π_0 . This is probably due to ionisation of or to some change in the condition of the $-\text{SH}$ group at high concentrations of hydroxyl-ions.

If the $[\text{R}\cdot\text{S}\cdot\text{S}\cdot\text{R}]$ term is to be regarded as a constant, it is obvious that this cannot represent the concentration of cystine. It seems almost necessary, therefore, to postulate the possible presence of an intermediate compound which would be the "true" oxidised form of cysteine and is transformed irreversibly into cystine. In such a case the concentration of this intermediate oxidised substance would appear to be maintained at a constant value—as

though the solution in presence of cysteine (or glutathione) must be "saturated" with respect to this particular compound. Concerning the existence or nature of the hypothetical substance, however, it would be unwise to make any further speculation until we know more of the dynamics of irreversible oxidations and reductions.

Summary.

1. The reduction potentials of cysteine-cystine and glutathione-oxidised glutathione mixtures have been investigated.

2. The platinum-calomel cell usually employed for the determination of the reduction potentials of systems of the type quinol-quinone is not suitable for work on the RSH — R·S·S·R type. A modification of this cell, which is only useful within a restricted range of p_H , is described.

3. A gold-calomel cell has been substituted for the platinum-calomel with satisfactory results.

4. The reduction potentials of cysteine and of glutathione are independent of the presence or absence of their oxidised forms.

5. The variation of reduction potential with concentration of RSH and with p_H is given by the relation

$$\pi = \pi_0 + \frac{RT}{F} \log [H^+] - \frac{RT}{F} \log c,$$

where π = observed potential, π_0 = normal reduction potential and c = concentration of RSH.

6. The significance of this equation in relation to that of the usual type of reduction-oxidation system is discussed.

We are indebted to Prof. F. G. Hopkins for his interest and encouragement in this work, and to the Department of Scientific and Industrial Research for grants.

CCCXLIX.—*The Accurate Determination of Elevation of Boiling Point.*

By KAZIMIERZ JABŁCZYŃSKI and STANISŁAW KON.

IN order to improve the ebullioscopic method of determining molecular weights and bring it to the high degree of accuracy necessary for our investigations we devised a new model of the apparatus, based on the use of a thermostat and the vigorous

stirring of the boiling liquid.* As a result of the stirring, a whirl is produced which sucks the vapour of the solvent into the liquid in the shape of small bubbles; these form ebullition centres which together with the motion of the liquid render it thermally homogeneous and produce regular and quiet boiling. When a thermostat is employed, it is possible to control the heating of the liquid and to avoid almost completely the danger of superheating, because a difference of only a few degrees

between the boiling point of the solvent and the temperature of the thermostat is sufficient to cause regular boiling.

The apparatus, as illustrated, consists of a test-tube (A) blown out on one side at the bottom to allow the stirrer to revolve freely. The stem of the stirrer (C) passes through a glass tube forming a hydraulic seal and is prevented from vibrating when in motion by an india-rubber ring (B). A few centimetres above the driving pulley a revolution counter is fixed. The height of the tube is 215 mm., the general width 35 mm., and the bulbous portion 55 mm. in diameter. The ebullioscopic vessel has the usual two side-tubes, pointing upwards at an angle of 45°. One of the tubes is connected with the condenser and the second one is used for introducing the pellets. The sides and bottom of the

thermostat are covered with asbestos; it contains 4 litres of glycerol. A gas-pressure regulator and a mercury thermo-regulator maintain the temperature within limits of $\pm 0.1^\circ$.

The Beckmann thermometer used in the determinations was very carefully calibrated, all the usual corrections being introduced. These corrections, amounting sometimes to 25 per cent., are neglected by the majority of workers; the inaccuracy of the ebullioscopic method is partly attributable to this cause.

* A thermostat and a stirrer were employed by Beckmann (*Z. anorg. Chem.*, 1914, **89**, 171) in determinations made with mercury as solvent, as in that case the ordinary Beckmann method failed completely.

As the result of a number of experiments the average value of 1.519° on the Beckmann thermometer was found to correspond with 100° .

Effect of Stirring.—Seventy-five c.c. of freshly distilled water were introduced into the ebullioscopic vessel, the temperature of the thermostat was maintained constant, and the number of revolutions per minute of the stirrer was gradually increased from 0 to the maximum (2300). At each speed, ten observations were made every fifteen seconds. In Table I, the results are given for the thermostat temperature 107° and barometric pressure 751.2 mm. (corr.).

TABLE I.

Revs. per min. ...	0	400	600	900	1900
Readings.....	3.650 to 3.950	3.500 to 4.080	1.854 to 1.969	1.794 to 1.801	1.716 to 1.719
Average	3.848	3.765	1.873	1.797	1.718

The interpretation of these results is simple. At rates exceeding 900 r.p.m. the stirring is sufficiently rapid to form a whirl which sucks vapour into the liquid and prevents superheating; regular boiling is thus obtained. A further increase of the speed gives but a slow decrease of the superheating, which at the same time becomes more and more constant for the same number of revolutions; thus, for 900 revs. the variations amount to 0.007° , for 1900 only to 0.002° . Such a degree of accuracy has not previously been attained in ebullioscopic measurements.

It is obvious that there is a limit to the decrease in superheating caused by the increase in the number of revolutions. This limit is the true boiling point of water, which would be attained with an infinitely great rate of stirring. This temperature was calculated by means of the extrapolation equation

$$t = t_0 + \frac{B}{n^{0.5}} \text{ or } \frac{t_1 - t_0}{t_2 - t_0} = \left(\frac{n_2}{n_1}\right)^{0.5} = Q; \quad t_0 = \frac{t_1 - Qt_2}{1 - Q},$$

where t is the temperature corresponding to n revolutions per minute, and t_0 is the true boiling point. If our supposition were correct, we should obtain the same value for t_0 by direct measurement (above). A series of measurements was carried out for various thermostat temperatures and various barometric pressures, the rates of stirring varying from 1000 to 2200. The results obtained for the thermostat temperature 108° and corrected barometric pressure 769.7 mm. are given in Table II.

TABLE II.

n .	t .	t_0 .	n .	t .	t_0 .
1180	2.011°	1.718°	2050	1.960°	1.703°
1410	1.987	1.889	2200	1.951	
1600	1.981	1.827		Mean	1.784
1800	1.972	1.782	Corrected and reduced to 760 mm.		
					1.519

In Table III, the data obtained for t_0 are given.

TABLE III.

Thermostat temperature.	107°	108°	109°	111°	114°	115°	121°
t_0 .	1.521°	1.519°	1.494°	1.558°	1.538°	1.563°	1.595°
	1.495°		1.521°	1.535°			

The average value of t_0 is 1.529° at a barometric pressure of 760 mm. and for $n = \infty$. Direct measurement gave 1.519°. The agreement, although not so good for the higher thermostat temperatures, is satisfactory between 107° and 109°.

Influence of the Thermostat Temperature.—The influence of the temperature of the bath was found to be unexpectedly great; this temperature must be at least 104° to give regular boiling, the stirrer working at full speed; 107° appears to be the best. An increase of 1° in the thermostat temperature causes (for the same rate of stirring) a rise of 0.01° on the Beckmann thermometer, and for this reason it is necessary, during a series of determinations, to maintain a constant speed of stirring and a constant thermostat temperature.

Superheating.—It is obvious from what has been said that it is impossible to avoid superheating completely. We are, however, only concerned with the determination of differences in boiling point, and these can be accurately determined, the essential condition being that the degree of superheating must remain constant during the experiment. This condition is not fulfilled in the ordinary apparatus of the Beckmann type, and is the chief cause of the untrustworthiness of the ebullioscopic method (compare Beckmann, *Z. physikal. Chem.*, 1908, 63, 182).

In the present apparatus, the degree of superheating is always strictly constant, because the conditions under which the liquid boils do not vary. This is proved by placing a control Beckmann thermometer in the vapour of the boiling solvent, when it is found that the differences in the readings of the two thermometers observed under widely differing atmospheric conditions do not vary by more than 0.002°. These differences do not, of course, represent the degree of superheating owing to the difference in the setting of the 100° point on the two thermometers.

The real degree of superheating for different rates of stirring can be calculated by subtracting the true boiling point of water (1.519°) from the average temperatures given in Table I, corrected to normal barometric pressure (760 mm.).

TABLE IV.

n	0	400	640	900	1100	1300	1600	1900	2200
Superheating	2.370°	2.283°	0.305°	0.225°	0.202°	0.181°	0.163°	0.145°	0.133°

Method of Making Determinations.—The following optimum working conditions for the ebullioscopic apparatus were adopted: (a) Temperature of the thermostat 107°. (b) Number of revolutions per minute 1850. For controlling the barometric variations a control Beckmann thermometer, placed in the vapour, was used. The thermometer was tapped with an electric knocker to prevent the mercury remaining in the capillary tube. Observations of the temperature were made with the ebullioscopic thermometer every fifteen seconds, the average being taken. The variations never exceeded $\pm 0.002^\circ$.

The amount of water introduced into the ebullioscopic vessel was 74.93 grams (75 c.c. at 15.2°). The amount of water condensed in the form of vapour was estimated as follows: to the usual quantity of water about 4 grams (carefully weighed) of pure sodium chloride were added and the stirrer was set in motion. When thermal equilibrium was established, the solution was siphoned off without interrupting the stirring, cooled, an aliquot portion (about 25 c.c.) evaporated to dryness and ignited, and the residual sodium chloride weighed. From these data it was calculated that 1.32 grams of the original 74.93 grams of water were condensed against the walls or present in the form of vapour; the remaining 73.61 grams were contained in the solution. In subsequent determinations the weight of water in the solution was assumed to be 73.61 grams.

Boric Acid.—The commercial substance was recrystallised three times from water and dried at 50°. In Table V and subsequent tables the following symbols are used: h = corrected barometric pressure, g = number of grams of the substance in 73.61 grams of water, N_0 = number of gram-molecules of the substance in 1000 grams of water, Δt = elevation of the boiling point, $\Delta t/N_0$ = molecular elevation of the boiling point, and M = molecular weight as calculated from the equation

$$M = \frac{0.52 \times 1000}{73.61} \times \frac{g}{\Delta t}.$$

TABLE V.

Boric acid, H_3BO_3 . Mol. wt. 62.02. $h = 737.3$ mm.

g .	N_0 .	Δt .	$\Delta t/N_0$.	M .
1.8700	0.4096	0.214°	0.5225	61.73
3.6664	0.8030	0.421	* 0.5242	61.52
5.4318	1.1897	0.625	0.5253	61.40
7.3042	1.5998	0.838	0.5238	61.57
9.2681	2.0300	1.061	0.5227	61.71
11.0338	2.4167	1.265	0.5234	61.62
12.8661	2.8180	1.472	0.5223	61.75
14.5030	3.1766	1.656	0.5213	61.86
		Mean	0.5232	61.64

It will be seen from this table that the maximum deviation between two determinations does not exceed 0.8 per cent. and the average calculated molecular weight differs from the theoretical only by 0.6 per cent.; such a degree of accuracy has not been attained hitherto. It can also be seen that there is no difference between the first determination and those following: the change of surface tension has no influence on the boiling point; this is not the case when an apparatus of the Beckmann type is used. It is also another proof that the degree of superheating in our apparatus is constant.

Electrolytes.—One of the chief aims of the present work was to obtain exact ebullioscopic data for strong electrolytes in order to verify the Jabłczyński and Wiśniewski dilution law * $n_1^2/n_0 = K$, where n is the concentration of one of the ions and n_0 the concentration of the non-ionised molecules. In order to calculate n from ebullioscopic data the equation used was

$$n = \frac{\Delta t}{0.52} - N_0 \quad . \quad . \quad . \quad (1)$$

If solvation occurs, this equation becomes

$$n_1 = \frac{\Delta t/0.52 - N_0}{1 + 0.018A\Delta t/0.52} \quad . \quad . \quad . \quad (2)$$

where A is the number of water molecules combined with one cation and one anion.

As electrolytes, sodium, potassium, and ammonium chlorides, bromides, and iodides, and hydrochloric acid were used.

Sodium Chloride.—The Kahlbaum preparation "zur Analyse" was dissolved in water, precipitated with hydrogen chloride gas, washed, dried, and ignited in a platinum vessel.

* Jabłczyński and Wiśniewski, *Spraw. Tow. Nauk. Warsz.*, 1918, **11**, 351; *Roczniki Chemji*, 1921, **1**, 116; *A.*, 1922, **ii**, 190. The mathematical deduction of the law is given in the first-mentioned paper.

TABLE VI.

Sodium chloride. $h = 757.0$ mm.

N_o .	Δt .	K .	K_1 ($6.5H_2O$).	N_o .	Δt .	K .	K_1 ($6.5H_2O$).
[0.2085	0.191°	1.73	1.38]	1.5045	1.493°	10.99	2.14
0.4924	0.469	3.67	2.18	1.7672	1.780	17.61	2.14
0.9208	0.888	5.46	2.15	1.9824	2.022	30.99	2.13
1.2250	1.200	7.81	2.17	2.2639	2.347	205.03	2.12
							Mean 2.15

For $h = 751.2$ mm., the mean value of $K_1(6.5H_2O)$ is 2.07.

In the third column of each series is the equilibrium constant, K , calculated from equation (1); it increases rapidly with the concentration. If it is assumed that the ions are hydrated and that sodium- and chlorine-ions are both combined with 6.5 molecules of water (Jablczyński and Wiśniewski, *loc. cit.*), and K_1 is calculated by means of equation (2), a remarkably constant value is obtained (column four). The cause of the abnormal value of the first measurement (and, in general, of measurements below a concentration of 0.5N) is being investigated. In the present paper, the values for concentrations below 0.5N are omitted.

K was also calculated from the equation of Washburn and Read (*J. Amer. Chem. Soc.*, 1919, **41**, 729), a constant value being obtained; taking $A = 7H_2O$, the constant thus calculated, $K_1 = 2.54$, was slightly higher than that given above.

Potassium Chloride.—The Merck preparation "zur Analyse" contained small quantities of bromide. In order to eliminate this, a saturated aqueous solution of the salt was saturated with hydrogen chloride, boiled, evaporated, and the potassium chloride twice recrystallised from water and finally precipitated from its aqueous solution with hydrochloric acid, washed, dried, and ignited in a platinum vessel. The yield from 1 kilogram was 200 grams.

TABLE VII.

Potassium chloride. $h = 740.5$ mm.

N_o .	Δt .	K .	K_1 ($4H_2O$).	N_o .	Δt .	K .	K_1 ($4H_2O$).
[0.3853	0.358°	2.48	1.97]	0.0740	1.006°	3.83	2.16
0.5343	0.496	2.95	2.03	1.2678	1.192	4.24	2.17
0.7133	0.661	2.95	2.02	1.4533	1.371	4.62	2.14
0.8842	0.824	3.39	2.10				Mean 2.10

For $h = 748.1$ mm., the mean value of $K_1(4H_2O)$ is 1.99. The average of the two series is $K = 2.05$ for $4H_2O$ combined with the ions. The constancy is good. It must be remembered that a variation of 0.001° in Δt has a marked effect on the value of K_1 .

Ammonium Chloride.—Merck's preparation "zur Analyse" was twice recrystallised from water and dried at 100°. The results of

a series of determinations are given in Table VIII. The constancy of K_1 is remarkable; the hydration of the ammonium chloride is nearly the same as that of potassium chloride, which is to be expected, as these salts are chemically very similar.

TABLE VIII.

Ammonium chloride. $h = 765.1$ mm.

N_0 .	Δt .	K .	K_1 ($4H_2O$).	N_0 .	Δt .	K .	K_1 ($4H_2O$).
[0.3818	0.357°	2.66	2.22]	1.2309	1.128°	3.14	2.03
0.6281	0.578	2.62	2.04	1.4590	1.338	3.35	2.02
0.8255	0.757	2.77	2.03	1.6731	1.535	3.52	2.00
1.0288	0.942	2.93	2.02	1.8970	1.749	3.87	2.03
						Mean	2.02

For $h = 755.0$ mm., the mean value of $K_1(4H_2O)$ is 1.99. The average value of $K_1(4H_2O)$ for both series is 2.01. The equilibrium constant was also calculated from the vapour pressure data of Tammann (Landolt-Börnstein tables, 3rd ed., p. 414), the number of ions, n_1 , being calculated from the van't Hoff equation, assuming hydration, $\log p/p_1 = (N_0 + n_1)/(1000/18 - An_1)$; the average value of K_1 was found to be 1.94.

Sodium Bromide.—The preparation was twice recrystallised from water and dried at 150° to constant weight.

TABLE IX.

Sodium bromide. $h = 746.8$ mm.

N_0 .	Δt .	K .	K_1 ($9H_2O$).	N_0 .	Δt .	K .	K_1 ($9H_2O$).
[0.3643	0.340°	2.67	1.63]	1.5319	1.603°	— 95.42	2.10
0.7444	0.730	6.75	2.11	1.7501	1.866	— 25.16	2.10
1.1082	1.118	15.89	2.11	1.9970	2.169	— 15.90	2.02
1.3324	1.372	54.07	2.13	2.2320	2.472	— 11.84	1.99
						Mean	2.08

For $h = 752.4$ mm., the mean value of $K_1(9H_2O)$ is 2.05, the average value for both series being 2.06. The higher hydration of sodium bromide in comparison with sodium chloride agrees with the greater solubility of the bromide in water and with its hygroscopic nature. The sodium bromide solutions used by us were stable; after half an hour's boiling, the reaction was neutral and they were colourless. Jahn therefore was in error when he attributed the discrepancy between the cryoscopic measurements obtained with sodium bromide and the values calculated from his equation to the oxidising action of atmospheric oxygen (*Z. physikal. Chem.*, 1904, 50, 166), and his equation was founded on false premises.

Potassium Bromide.—The Kahlbaum preparation was twice recrystallised from water and dried at 150° to constant weight.

TABLE X.
Potassium bromide. $h = 746.6$ mm.

N_0 .	Δt .	K .	K_1 ($6H_2O$).	N_0 .	Δt .	K .	K_1 ($6H_2O$).
[0.3504	0.326°	2.44	1.81]	1.0406	0.995°	4.98	2.05
0.5239	0.492	3.37	1.98	1.1987	1.152	5.60	2.03
0.6990	0.659	3.60	1.99	1.3749	1.331	6.59	2.03
0.8708	0.827	4.26	2.03			Mean	2.02

For $h = 753.0$ mm., $K_1(6H_2O)$ is 1.98 (mean value), and the average value for both series is 2.00. The greater degree of hydration of potassium bromide in comparison with potassium chloride is doubtless connected with the fact that potassium bromide is more soluble in water and more hygroscopic than potassium chloride.

Ammonium Bromide.—The Kahlbaum preparation was twice recrystallised from water and dried at 90–100°.

TABLE XI.
Ammonium bromide. $h = 751.0$ mm.

N_0 .	Δt .	K .	K_1 ($4.5H_2O$).	N_0 .	Δt .	K .	K_1 ($4.5H_2O$).
[0.4471	0.414°	2.51	1.90]	1.3857	1.308°	4.60	2.06
0.6768	0.632	3.17	2.07	1.6406	1.556	5.17	2.03
0.9175	0.854	3.38	1.98	1.9874	1.899	6.11	1.99
1.1568	1.085	3.99	2.04			Mean	2.03

The ammonium bromide decomposed in the boiling solution, for the odour of ammonia was detected. The hydrolysis* had only a very small effect on the boiling point, as a corresponding quantity of hydrogen bromide was produced.

Potassium Iodide.—The preparation was twice recrystallised from water and once from absolute ethyl alcohol. The salt was then dried at 130–140° and kept in a desiccator in a dark bottle. The yield from 1 kilo. was 60 grams. After being made, the pellets were dried for four hours at 130–140°.

TABLE XII.
Potassium iodide. $h = 746.8$ mm.

N_0 .	Δt .	K .	K_1 ($8H_2O$).	N_0 .	Δt .	K .	K_1 ($8H_2O$).
[0.4191	0.390°	2.60	1.80]	1.0056	0.983°	7.03	1.99
0.5782	0.549	3.71	1.90	1.1432	1.130	9.18	2.02
0.7114	0.682	4.55	1.95	1.2778	1.273	11.47	2.00
0.8709	0.846	6.00	2.01			Mean	1.98

For $h = 749.4$ mm., $K_1(8H_2O) = 2.00$ (mean); the average value for both series is 1.99. The greater degree of hydration in

* Naumann and Rücker give the degree of hydrolysis of ammonium bromide in N -solution as equal to 0.03 per cent. at the boiling point.

comparison with potassium bromide is in keeping with the greater solubility in water of potassium iodide.

Ammonium Iodide.—The crude product showed signs of decomposition. In order to free it from iodine it was repeatedly washed with ether. The slightly coloured salt was then dissolved in pure ethyl alcohol and precipitated with chloroform, and the crystalline powder washed with chloroform and kept in a dark desiccator. It was dried directly before use; the product thus obtained was snow white. The pellets were once more dried before being weighed.

TABLE XIII.

Ammonium iodide. $h = 758.0$ mm.

N_0 .	Δt .	K .	K_1 ($5.5H_2O$).	N_0 .	Δt .	K .	K_1 ($5.5H_2O$).
[0.4652	0.439°	3.18	2.14]	1.2248	1.168°	5.06	2.02
0.6280	0.589	3.26	2.00	1.5280	1.474	6.46	2.02
0.8990	0.847	3.88	1.99				
1.0552	1.004	4.66	2.07			Mean	2.02

For $h = 759.0$ mm., $K_1(5.5H_2O) = 1.94$ (mean); the average value for both series is 1.97. The constancy of K_1 is good, although the variations are greater than in the case of the other salts. Ammonium iodide also decomposes slightly when its solution is boiled.

Sodium Iodide.—A solution in ethyl alcohol of the iodide, coloured brown by iodine, was filtered, the alcohol evaporated, and the salt twice recrystallised from water and dried in a vacuum at 90–100° and finally at 130–140°. The resulting crystalline powder was snow white and absolutely dry. The pellets were dried again for four hours at 130–140°.

TABLE XIV.

Sodium iodide. $h = 755.7$ mm.

N_0 .	Δt .	K .	K_1 ($12.5H_2O$).	N_0 .	Δt .	K .	K_1 ($12.5H_2O$).
0.3432	0.334°	4.54	2.04	1.3889	1.509°	— 13.89	1.88
0.6927	0.702	16.10	2.13	1.5819	1.752	— 10.55	1.81
1.0038	1.051	— 293.17	2.04	1.7691	1.997	— 8.74	1.75
1.2057	1.286	— 22.02	1.94	1.9644	2.260	— 7.62	1.69

Sodium iodide differs entirely from the other salts. The equilibrium constant calculated for the anhydrous salt increases very rapidly and for a normal solution gives negative values, showing the high degree of hydration of the sodium and iodine ions. The hydration of these ions must be greater than in the case of potassium iodide, just as sodium chloride and sodium bromide are more highly hydrated than potassium chloride and

bromide. Furthermore, the equilibrium constant with hydration for sodium iodide must be nearly the same as for the above-mentioned salts, as they are all electrolytes of the same strength. Taking these considerations into account, K was calculated for $12.5\text{H}_2\text{O}$. The constant, unfortunately, decreases distinctly for higher concentrations. This phenomenon is doubtless caused by the association of the sodium iodide molecules; it is to be expected that lithium iodide will show the same peculiarity to an even greater extent. Unfortunately, this salt was not available for experiment.

Hydrochloric Acid.—The acid used was quite pure. Seven solutions of different concentrations were prepared and a separate observation was carried out with each. The barometric pressures were nearly identical.

TABLE XV.
Hydrochloric acid.

N_0	Δt	K	K_1 ($8.5\text{H}_2\text{O}$)	N_0	Δt	K	K_1 ($8.5\text{H}_2\text{O}$)
0.2892	0.278°	3.51	2.22	1.5107	1.627°	17.67	2.71
0.5870	0.583	8.21	2.68	1.8453	2.046	10.94	2.63
0.8926	0.908	20.76	2.70	2.1612	2.466	8.73	2.57
1.2269	1.287	63.98	2.72			Mean	2.67

Comparison of the Results.—The equilibrium constants and the hydration of the ions are given in Table XVI.

TABLE XVI.

	Chloride.		Bromide.		Iodide.	
	K_1	Hydrtn.	K_1	Hydrtn.	K_1	Hydrtn.
Hydrogen	2.67	8.5	—	—	—	—
Sodium	2.11	6.5	2.06	9.0	—	—
Potassium	2.06	4.0	2.00	6.0	1.99	8.0
Ammonium	2.01	3.0	2.03	4.5	1.97	5.5

The equilibrium constant is nearly identical for all the salts; they must therefore be equally ionised. A higher value is observed only for hydrochloric acid; the acid is thus a stronger electrolyte than its salts. The hydration depends on the anion and the kation, and the following rule can be deduced: in the case of the alkali halides, the hydration increases with the weight of the anion and decreases with an increase in the weight of the kation.

From the data obtained by us it is impossible to calculate the hydration of each separate ion; this must be done by other means.

CCCL.—*Experiments on the Synthesis of the Polyacetic Acids of Methane. Part VIII. An Improved Synthesis of Methanetriacetic Acid.*

By MARCEL HENRY DREIFUSS and CHRISTOPHER KELK INGOLD.

THE synthesis of methanetriacetic acid starting with commercial citric acid (Ingold, T., 1921, 119, 341) suffers from the disadvantage that the preparation of acetonedicarboxylic acid and its reduction to β -hydroxyglutaric acid are laborious operations when conducted on a large scale. An alternative method of synthesis (Ingold and Perren, T., 1922, 121, 1414), which starts with commercial ethyl malonate and is based on a series of balanced reactions, is slow, because the balanced reactions catalysed by piperidine require about a month to reach equilibrium; moreover, the yields are considerably smaller than in the first synthesis.

β -Hydroxyglutaric ester has now been prepared by a method suitable to large-scale working. The commercial starting point is α -dichlorohydrin, and the reactions are those represented by the following formulæ:

The formation of the nitrile and its conversion, without purification, into the ester both take place smoothly, the yield of β -hydroxyglutaric ester being 75 per cent. calculated on the chlorohydrin originally employed.

Morgenstern and Zerner (*Monatsh.*, 1910, 31, 777), who first obtained dicyanohydrin as an amorphous substance which could not be purified, did not succeed in hydrolysing it to β -hydroxyglutaric acid, but obtained glutaconic acid from it by treatment with alkalis; a result which is readily explicable in the light of Fichter and Dreyfus's experiments (*Ber.*, 1900, 33, 1453) on the dehydration of β -hydroxy-acids in the presence of alkalis.

In order that ethyl acetoacetate or ethyl malonate may be employed in place of the less available ethyl cyanoacetate for the introduction of the third acetic acid group, ethyl β -hydroxyglutarate, which does not appear to condense to any considerable extent with either of the former substances, is converted by phosphorus pentachloride into ethyl β -chlorogluutarate (87 per cent. yield); this substance reacts with ethyl malonate or ethyl acetoacetate to give ultimately methanetriacetic acid or its ester in even better yield than that obtained in the original process (*loc. cit.*).

EXPERIMENTAL.

Preparation of Ethyl β-Hydroxyglutarate from α-Dichlorohydrin.—A solution of pure dichlorohydrin (64 grams) in 100 c.c. of methyl alcohol was boiled under reflux for half an hour while a solution of 65 grams of potassium cyanide in 60 c.c. of water was gradually added. The mixture was left on the steam-bath for one hour, cooled, the potassium chloride removed, the filtrate evaporated under reduced pressure, and the residue mixed with a small quantity of absolute ethyl alcohol. This solution was filtered, and evaporated under reduced pressure at 40–50°. The brown, amorphous residue (53 grams) consisted essentially of α-dicyanohydrin.

The crude product was mixed with 100 grams of ethyl alcohol and 40 grams of concentrated sulphuric acid (or the same quantity of ethyl alcohol saturated with hydrogen chloride), and the solution boiled for eight hours, cooled, and poured on to crushed ice. The oil was extracted with ether, and the extract washed with aqueous sodium carbonate and dried with sodium sulphate. The residue obtained on evaporation of the ether yielded on distillation a fraction, b. p. 154–157°/11 mm., weighing 76 grams, and consisting of pure ethyl β-hydroxyglutarate, the yield amounting to 75 per cent. of the theoretical calculated on the dichlorohydrin employed* (Found: C = 52.8; H = 7.9. Calc., C = 52.9; H = 7.8 per cent.). A fraction, b. p. 135–148°/11 mm., weighing 5 grams, and consisting essentially of ethyl glutaconate, was also collected.

α-Dibromohydrin may be used in place of α-dichlorohydrin in the above preparation. The ultimate yield is the same.

* Lepiran has recently (*Bull. Soc. chim.*, 1923, [iv], 33, 725) described the conversion of α-dicyanohydrin into ethyl β-hydroxyglutarate, but he obtained only a 50 per cent. yield even after complete purification of the nitrile.

Synthesis of Methanetriacetic Acid using Malonic Ester.

Ethyl β -Chloroglutarate.—Ethyl β -hydroxyglutarate (50 grams) was dissolved in 250 grams of dry ether and treated with 50 grams of phosphorus pentachloride. The product of the reaction was poured into water, and the ethereal solution washed with aqueous sodium carbonate, dried with sodium sulphate, and evaporated. The yield of ethyl β -chloroglutarate, 48 grams, was 87 per cent. of the theoretical. (The ester cannot be distilled.)

Ethyl ω -Carboxymethanetriacetate.—Ethyl malonate (32 grams) and ethyl β -chloroglutarate (44 grams) were successively added to a solution of sodium ethoxide prepared by dissolving 4.6 grams of sodium in 60 grams of alcohol. The mixture became neutral after heating for half an hour on the steam-bath, and was then poured into water. The solution was evaporated sufficiently to remove the bulk of the alcohol, acidified with hydrochloric acid, and extracted with ether. The extract was washed with aqueous sodium carbonate, dried with sodium sulphate, and evaporated, and the residue distilled. A fraction, b. p. 200–205°/12 mm., was obtained, weighing 58 grams, and consisting of pure *ethyl ω -carboxymethanetriacetate*, the yield amounting to 85 per cent. of the theoretical (Found: C = 55.4; H = 7.75. $C_{16}H_{26}O_8$ requires C = 55.5; H = 7.5 per cent.).

Unlike the condensation product with ethyl acetoacetate, the above ester must be carefully purified by distillation, as otherwise the methanetriacetic acid obtained from it does not solidify completely and has to be purified through its ester.

Methanetriacetic Acid.—The pure ester (1 part) was mixed with cold concentrated sulphuric acid (1 vol.), after which water (1 vol.) was added, and the whole heated until carbon dioxide ceased to be evolved (about forty minutes). The mixture was cooled, a further quantity (2 vols.) of water added, and the whole boiled for three hours under a reflux condenser short enough to permit the escape of alcohol vapour. Finally, the solution was cooled, saturated with ammonium sulphate, and the methanetriacetic acid extracted with ether. The yield of nearly pure acid, m. p. 110–115°, was 90 per cent. of the theoretical.

Ethyl Methanetriacetate.—The syrupy methanetriacetic acid which is obtained if the tetraethyl ester is not distilled before hydrolysis may be purified by way of its ester. A mixture of non-crystallisable syrup (9 grams), 25 grams of ethyl alcohol, and 1 gram of concentrated sulphuric acid was boiled for eight hours, a current of ethyl alcohol vapour being passed through the solution in order to carry away the water formed during the reaction. The product

was poured into water and extracted with ether, and the extract washed with aqueous sodium carbonate and dried with sodium sulphate. After evaporation of the ether the residue distilled at 200—205°/19 mm. The yield was 12 grams, that is, 94 per cent. of the theoretical (Found: C = 56·7; H = 8·2. $C_{13}H_{22}O_6$ requires C = 56·9; H = 8·1 per cent.). The distilled ester gave pure methanetriacetic acid on hydrolysis with hydrochloric acid.

Synthesis of Methanetriacetic Acid using Acetoacetic Ester.

Ethyl ω -Acetylmethanetriacetate.—An alcoholic suspension of ethyl sodioacetoacetate, prepared from 26 grams of ethyl acetoacetate, 4·6 grams of sodium, and 60 grams of alcohol, was mixed with 44 grams of ethyl β -chloroglutarate, and the mixture warmed for three-quarters of an hour, when it became neutral. The ester, isolated by pouring the solution into dilute hydrochloric acid, extracting it with ether, and washing, drying, and evaporating the extract as usual (the yield of crude ester was 50 grams, that is, 80 per cent. of the theoretical), was purified for analysis by distillation, and was isolated as a colourless liquid, b. p. 198—203°/11 mm. (Found: C = 57·1; H = 7·7. $C_{15}H_{24}O_7$ requires C = 57·0; H = 7·6 per cent.). For the preparation of methanetriacetic acid it is unnecessary and even undesirable to distil the crude ester, because the chief impurity is the alcoholysis product, ethyl methanetriacetate, from which ethyl acetylmethanetriacetate is separated only with difficulty and loss of material.

Ethyl Methanetriacetate.—The preceding crude ester (32 grams) was boiled for two hours with a solution of sodium ethoxide prepared from 2·3 grams of sodium and 30 grams of ethyl alcohol, and the product was poured into dilute hydrochloric acid and extracted with ether. The extract, after the usual treatment, yielded a residue which on distillation gave 24 grams of pure ethyl methanetriacetate, that is, 90 per cent. of the theoretical.

Methanetriacetic Acid.—The ester was boiled for three hours with 30 per cent. sulphuric acid (4 vols.), a condenser being used sufficiently short to permit the escape of alcohol vapour. The cooled solution was saturated with ammonium sulphate and extracted with ether, from which a quantitative yield of nearly pure methanetriacetic acid, m. p. 114—119°, was obtained. A single crystallisation from dry ether yielded the acid in a state of purity, m. p. 126° (Found: C = 44·4; H = 5·2. Calc., C = 44·2; H = 5·3 per cent.).

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY.

SOUTH KENSINGTON.

[Received, September 25th, 1923.]

CCCLI.—*Chloro-o-xyenols. Part I. 5-Chloro-o-3-xyleneol, 6-Chloro-o-3-xyleneol, and 5-Chloro-o-4-xyleneol.*

By LEONARD ERIC HINKEL, WILLIAM THOMAS COLLINS, and ERNEST EDWARD AYLING.

THE object of this series of investigations is the synthesis of the chloro-*o*-xylenols, since they are not described in the literature. In a previous communication (T., 1922, 121, 2498) it was shown that phosphorus pentachloride reacts with chlorodimethyldihydroresorcinol, CMe_2CHCl (I), in a complicated manner, several simultaneous reactions taking place with the formation of hydroaromatic and aromatic compounds. From the latter, a monochloroxylenol melting at 80–81° was isolated, but beyond the fact that on treatment with chlorine it yielded a trichloroxylenol melting at 181°, no evidence of its constitution could be obtained.

It has been shown (Crossley and Renouf, T., 1914, 105, 168) that the action of heat on 4:5-dibromo-1:1-dimethyl- Δ^4 -cyclohexen-3-one results in the formation of a mixture of 5-bromo-*o*-3-xyleneol and 6-bromo-*o*-4-xyleneol. The corresponding dichlorodimethylcyclohexenone is more stable than the dibromo-compound and does not yield a chloroxylenol on heating; moreover, it is the chlorine atom in position 5 which is the more easily removed, since monochlorodimethyldihydroresorcinol (I) can be readily regenerated from it (compare Crossley and Renouf, *loc. cit.*).

It would therefore appear that the monochloroxylenol melting at 80–81° is produced, not directly from the dichlorodimethylcyclohexenone, but at some earlier stage of the reaction between phosphorus pentachloride and chlorodimethyldihydroresorcinol. The first stage in this reaction results in the formation of a very unstable trichloro-derivative (II) which readily loses hydrogen chloride (T., 1922, 121, 2499). This loss may occur in two ways, either at the carbon atoms 4 and 5 or 5 and 6. It is probable that both decompositions take place, resulting in the formation, in the former case, of the stable dichlorodimethylcyclohexenone (III) and, in the latter case, of an unstable compound (IV) which should readily transform into an aromatic compound, since much less

rearrangement would be necessary than that occurring in some of the cases previously recorded (compare Crossley and Hills, T., 1906, 89, 876; Crossley and Renouf, *loc. cit.*). Moreover, only one monochloroxylenol, namely, 5-chloro-*o*-3-xylene (V), should be derived from it. This constitution of the resulting chloroxylenol melting at 80–81° has been proved by the synthesis of the compound from 5-nitro-*o*-3-xylidine :

Two processes suitable for the preparation of 6-chloro-*o*-3-xyleneol start with *o*-3-xyleneol and 3:6-dinitro-*o*-xylene respectively. The amount of each of these substances available was very small, and in order to obtain a sufficient quantity of the required chloroxylenol it was necessary to adopt both methods of synthesis.

In the first case, *o*-3-xyleneol in alkaline solution was coupled with benzenediazonium chloride. The constitution of the *benzeneazo-o*-3-xyleneol (VI) formed was proved by the identity of the chloro-

xyleneol derived from it with that prepared from 3:6-dinitro-*o*-xylene. The azo-compound was reduced to 6-amino-*o*-3-xyleneol (VII) by means of sodium hyposulphite in the way described by Diepolder (*Ber.*, 1911, 44, 2498), and the amino-group was then replaced by chlorine by means of the diazo-reaction, 6-chloro-*o*-3-xyleneol (VIII) being produced.

In the second case, 3:6-dinitro-*o*-xylene (IX) (Crossley and Renouf, T., 1909, 95, 210) was reduced to 3-nitro-6-amino-*o*-xylene (X) by alcoholic stannous chloride (compare Crossley and Wren, T., 1911, 99, 2342), the amino-group was replaced by chlorine, and the resulting 6-chloro-3-nitro-*o*-xylene (XI) reduced to 6-chloro-3-amino-*o*-xylene (XII), from which 6-chloro-*o*-3-xyleneol (XIV) was obtained by replacing the amino-group by hydroxyl :

It was subsequently discovered that this chloroxylenol could be prepared much more readily from aceto-*o*-3-xylylide (XIII) by direct chlorination to 6-chloroaceto-*o*-3-xylylide (XIV) and the following series of reactions:

The synthesis of 5-chloro-*o*-4-xyleneol was accomplished by means of *o*-4-xyleneol. Diepolder has shown (*Ber.*, 1909, **42**, 2918; 1911, **44**, 2498) that when benzenediazonium chloride is coupled with *o*-4-xyleneol in alkaline solution, a mixture of 83 per cent. of 1:2-dimethyl-4:5-benzoquinone-5-phenylhydrazone (XV) with 17 per cent. of 1:2-dimethyl-3:4-benzoquinone-3-phenylhydrazone (XVI) is formed.

These compounds can readily be separated by crystallisation from alcohol. 1:2-Dimethyl-4:5-benzoquinone-5-phenylhydrazone was reduced by sodium hyposulphite, and the resulting 5-amino-*o*-4-xyleneol (XVII) converted into 5-chloro-*o*-4-xyleneol (XVIII) in the usual way.

EXPERIMENTAL.

5-Chloro-*o*-3-xyleneol.

5-Nitro-*o*-3-xylydine (Crossley and Morrell, *T.*, 1911, **99**, 2351) was converted into 5-nitro-*o*-3-xyleneol by Crossley's method (*T.*, 1913, **103**, 2180), a modification in the purification of the nitro-xyleneol being adopted in which the crude material was dissolved in boiling water, from which on cooling it crystallised in fine, pale yellow needles melting at 120–121°.

The nitro-compound was reduced to 5-amino-*o*-3-xyleneol, 2.8 grams of which were diazotised in the usual way, the solution was added to 2.5 grams of cuprous chloride in 30 c.c. of concentrated hydrochloric acid and after one hour distilled with steam; the product extracted from the distillate with ether was purified by crystallisation from light petroleum (b. p. 60–80°) (Found: Cl = 22.61. Calc., Cl = 22.68 per cent.).

5-Chloro-*o*-3-xyleneol is very soluble in the cold in most of the common organic solvents, but is sparingly soluble in cold light petroleum (b. p. 60–80°). It dissolves readily in this solvent

when hot and crystallises therefrom in fine, glistening needles, m. p. 81—82°.

The *benzoyl* derivative, prepared in the usual manner, crystallised from alcohol in transparent prisms, m. p. 88° (Found : Cl = 13.70. Calc., Cl = 13.62 per cent.).

Trichloro-o-3-xyleneol, prepared by passing chlorine into a solution of 0.5 gram of 5-chloro-*o*-3-xyleneol in 10 c.c. of light petroleum (b. p. 40—60°) until the liquid became yellow, and removing the solvent, crystallised from dilute alcohol and finally from light petroleum (b. p. 60—80°) in fine, silky needles, m. p. 180—181° (Found : Cl = 46.96. Calc., Cl = 47.23 per cent.).

The *benzoyl* derivative, prepared in the usual manner, crystallised from alcohol in transparent, glistening plates, m. p. 128—129° (Found : Cl = 32.41. Calc., Cl = 32.32 per cent.).

6-Chloro-*o*-3-xyleneol.

*Preparation and Reduction of 6-Benzeneazo-*o*-3-xyleneol*.—The requisite amount of benzenediazonium chloride solution was coupled with 7 grams of *o*-3-xyleneol in slightly alkaline solution. The orange-red precipitate was purified by dissolution in boiling water; on cooling, it crystallised in bright yellow, flocculent masses of fine needles, m. p. 132°.

To a hot alcoholic solution of the azo-compound (4 grams) a saturated solution of sodium hyposulphite was gradually added until the colour was discharged (compare Diepolder, *Ber.*, 1911, 44, 2498), the solution was made alkaline with ammonia, and the alcohol removed by evaporation, when the aminoxyleneol separated in white crystals. These crystallised from ethyl acetate in colourless needles, m. p. 175°, which rapidly oxidised on exposure to air (Found : N = 10.45. Calc., N = 10.22 per cent.). 6-Amino-*o*-3-xyleneol is readily soluble in alcohol or warm water.

6-Chloro-*o*-3-xyleneol.—6-Amino-*o*-3-xyleneol (0.5 gram) was diazotised and the solution treated with cuprous chloride in the usual way. The product isolated by distillation with steam crystallised from well-cooled light petroleum (b. p. 60—80°) in long, silky needles, m. p. 84.5° (Found : Cl = 22.71. Calc., Cl = 22.68 per cent.).

The chloroxyleneol is readily soluble in the cold in most of the usual organic solvents, with the exception of light petroleum. It does not yield a trichloroxyleneol on treatment with chlorine in light petroleum solution, but a vigorous action occurs resulting in complete destruction of the xyleneol.

The *benzoyl* derivative, prepared in the usual manner, crystallised from absolute alcohol in transparent plates and from aqueous

alcohol in fine needles melting at 102° (Found: Cl = 13.46. Calc., Cl = 13.62 per cent.).

Preparation of 6-Chloro-o-3-xyleneol from 3:6-Dinitro-o-xylene.—6-Amino-3-nitro-o-xylene, prepared from 3:6-dinitro-o-xylene (Crossley and Wren, *loc. cit.*), in quantities of 1 gram, was suspended in 20 c.c. of water and 10 c.c. of concentrated hydrochloric acid and diazotised at 60° with 20 per cent. aqueous sodium nitrite. The resulting solution was poured into 1.2 grams of cuprous chloride in 12 c.c. of concentrated hydrochloric acid and after remaining for one hour the whole was steam-distilled, when 6-chloro-3-nitro-o-xylene passed over as a white solid. The compound is sparingly soluble in light petroleum (b. p. $40-60^{\circ}$) and crystallises from alcohol in felt-like, glistening, silky, faintly yellow needles, m. p. 62° , which form a waxy mass when pressed (Found: Cl = 19.14. Calc., Cl = 19.13 per cent.).

Two grams of the chloronitroxylene, dissolved in 20 c.c. of alcohol, were slowly treated with 9 grams of stannous chloride in 15 c.c. of concentrated hydrochloric acid, the mixture was heated for several hours on the water-bath, and the colourless oil obtained by distilling the basified liquid with steam was extracted with ether. After evaporation of the ether, a liquid remained which solidified when cooled in a freezing mixture. It crystallised from well-cooled light petroleum (b. p. $60-80^{\circ}$) in transparent, colourless rosettes, m. p. $30-31^{\circ}$ (Found: Cl = 23.04. Calc., Cl = 22.83 per cent.). 6-Chloro-o-3-xylidine is very soluble in the cold in all the common organic solvents except light petroleum (b. p. $60-80^{\circ}$).

Two grams of 6-chloro-o-3-xylidine were added to 40 c.c. of 40 per cent. sulphuric acid, with which it formed a sparingly soluble sulphate, and diazotised at 50° . The mixture was gently heated with 100 c.c. of 40 per cent. sulphuric acid until the evolution of nitrogen ceased, and distilled with steam, when 1.4 grams of 6-chloro-o-3-xyleneol, identical with the chloroxylenol described on p. 2971, were obtained.

Chlorination of Aceto-o-3-xylidide.—Dry chlorine was passed into a solution of aceto-o-3-xylidide (3 grams) in glacial acetic acid (30 c.c.) at 0° until the gain in weight corresponded with the substitution of one chlorine atom for hydrogen; towards the end of the reaction a white solid separated.

The mixture was poured into 400 c.c. of water and the 6-chloro-aceto-o-3-xylidide filtered, washed with water, and crystallised from aqueous alcohol, from which it separated in spherical masses of needles, m. p. 150° (Found: Cl = 18.27. Calc., Cl = 18.00 per cent.). The substance is almost insoluble in light petroleum, but is soluble in hot benzene.

The chloroacetoxyldide (4 grams) was hydrolysed by heating it with a mixture of 40 c.c. of sulphuric acid and 50 c.c. of water for two hours. The addition of an equal volume of concentrated hydrochloric acid to the cooled mixture precipitated the insoluble hydrochloride of the base; the base, obtained by distillation with steam in presence of excess of caustic soda, was purified in the way described on p. 2972.

5-Chloro-o-4-xyleneol.

Two grams of 1:2-dimethyl-4:5-benzoquinone-5-phenylhydrazone (XV), prepared and isolated by Diepolder's method (*loc. cit.*), were reduced in hot alcoholic solution (100 c.c.) with a saturated solution of sodium hyposulphite (compare Grandmougin, *Ber.*, 1906, 39, 2494). On evaporation of the alcohol and cooling, 5-amino-o-4-xyleneol separated in fine, glistening crystals. These were purified by crystallisation from alcohol (compare Crossley and Bartlett, *T.*, 1913, 103, 1299).

The aminoxyleneol (2.8 grams) was diazotised and then treated with cuprous chloride (1.5 grams) in the usual way. The product isolated by distillation with steam and extraction with ether was crystallised from light petroleum (b. p. 40–60°), 5-chloro-o-4-xyleneol being obtained in colourless needles, m. p. 71.5–72.5° (Found: Cl = 22.24. Calc., Cl = 22.68 per cent.). It does not yield a trichloroxyleneol on treatment with chlorine.

The *benzoyl* derivative, prepared in the usual manner, is very soluble in all the common organic solvents and crystallises from well-cooled alcohol in transparent, rhombic crystals, m. p. 43° (Found: Cl = 13.64. Calc., Cl = 13.62 per cent.).

One of the authors (L. E. H.) desires to express his thanks and great indebtedness to Dr. A. W. Crossley for a generous gift of many organic preparations which has rendered this investigation possible.

CCCLII.—*Inorganic Complex Salts. Part III. Racemisation and the Stability of Complex Ions.*

By WILLIAM THOMAS and RONALD FRASER.

It has been suggested (Thomas, *T.*, 1921, 119, 1140) that the racemisation of inorganic complex salts may be due to secondary ionisation. Evidence in support of this idea was obtained during an investigation on the autoracemisation of potassium chromi-

oxalate (Rideal and Thomas, T., 1922, 121, 196). If it is correct, the mechanism of the racemisation is very simple and can be represented as follows:

In this $[M(C_2O_4)_2]^-$ ion the two oxalato-groups are in the same plane (compare the configuration of complex salts with co-ordination number four); when the reverse process takes place, evidently there will be an equal chance of the formation of the *d*- and of the *l*-form.

The present investigation was carried out in order to test the above suggestion. The salts chosen for this purpose were potassium cobalti-oxalate, potassium chromi-oxalate, and potassium ferri-oxalate, as these racemise at very different rates; the active cobalt complex is fairly stable (Jaeger and Thomas, *K. Akad. Wetensch. Amsterdam*, 1918, 21), the chromi-complex loses its activity in one and a half hours (Werner, *Ber.*, 1912, 45, 3061), and the ferri-complex becomes inactive in less than one hour (Thomas, T., 1921, 119, 1140). These complexes produce oxalate-ions on secondary ionisation. It was decided to determine the concentration of these in solutions of various concentrations, in the hope that a connexion between secondary ionisation and autoracemisation might thereby be traced.

Determinations of *E.M.F.* were considered the most suitable method of measurement. Silver is known to have no tendency to form complex oxalates (Abegg and Schäfer, *Z. anorg. Chem.*, 1905, 45, 293), hence the solubility of silver oxalate will be less in solutions containing oxalate-ions than in water; the effect of solutions of these complex salts on the solubility of silver oxalate will therefore give a measure of the extent of their secondary ionisation.

The solubility product of silver oxalate was first determined by the *E.M.F.* of the following concentration cell.

The *E.M.F.* was found to be 0.223 volt, and therefore the concentration of silver-ion equals 1.41×10^{-5} . Sodium oxalate is ionised to the extent of 75 per cent. at this concentration, and therefore the concentration of oxalate-ion equals $0.0375 (C_2O_4^{2-})$

readiness with which the ferri- is reduced to the ferro-complex, as suggested by one of us (T., 1921, 119, 1140).

It is proposed to determine the concentration of the metallic ions in solutions of these salts, and therefrom to calculate their instability constants.

Great difficulty was experienced in obtaining consistent results when the *E.M.F.*'s of solutions of the chromi- and ferri-complexes were being measured, and this was attributed to the readiness with which these salts are reduced to the cobalto- and ferro-forms and free alkali oxalate :

This view was tested by preparing a solution of the cobalti-salt, exposing a part of it to diffused light for half an hour (light accelerates the reduction), and measuring the *E.M.F.*'s of the exposed and unexposed solutions. An increase of 10 per cent. in the former value indicated an increased concentration of oxalate-ions. The amount of the salt reduced under those conditions must have been very small, but it sufficed to produce a large increase in the *E.M.F.*, and therefore the explanation of the irregularities alluded to above may be correct.

The authors desire to thank Professor Findlay for facilities to carry out the above work and for his valuable advice and criticism.

CCCLIII.—*Sodium 6-Chloro-5-nitro-m-toluenesulphonate—A New Reagent for Potassium.*

By HERBERT DAVIES and WILLIAM DAVIES.

A BRIEF account (Davies, T., 1922, 121, 786) has already been given of the interesting difference in solubility of sodium and potassium 6-chloro-5-nitro-*m*-toluenesulphonates, and the present investigation is a more detailed examination of the value of the sodium salt as a qualitative and quantitative reagent for potassium.

The solubilities (grams in 100 grams of water) of the potassium salt at 0° and 20° are 0.235 and about 0.40, respectively, which compare favourably with the solubilities of potassium perchlorate (0.705 and 1.67) and the usually accepted values of potassium chloroplatinate (0.74 and 1.12) at the same temperatures. The new reagent is a good electrolyte, being formed from a strong base and a strong acid, and can be used in cold strongly alkaline or in

dilute mineral acid solution, and is thus of wider application than the chloroplatinate (which is really a test for potassium chloride and not the potassium-ion), tartaric acid, cobaltinitrite, and picrate methods. Moreover, the ratio of the solubilities of the sodium and the magnesium to that of the potassium sulphonate (about 40 and above 170, respectively, at the ordinary temperature) is large, and potassium can accordingly be detected in solutions containing large quantities of sodium and magnesium. As is the case with the usual reagents for potassium, ammonium must be removed before the reagent is added. The reagent will detect 1 part of potassium in about 2,500 parts of water.

With regard to the quantitative side, the percentage of potassium in potassium chloride, Rochelle salt, and potassium alum has been determined by this method, and results agreeing to within 0.5 per cent. of theory are obtained. After the addition of the reagent, the aqueous solution is not evaporated almost to dryness and then treated with alcohol as in the chloroplatinate and perchlorate methods, but the reaction is carried out in aqueous solutions dilute enough to enable the potassium salt to dissolve completely at the boiling point, and the precipitate formed on cooling and standing is washed with a little water and weighed. A considerable excess of the reagent is taken, so that owing to the influence of the common ion, the solubility of the potassium salt is still more depressed. The volume of the solution is purposely taken so small that the amount of the unprecipitated salt is almost negligible.

The quantitative side, however, is capable of further development along the lines suggested on page 2981. The presence of sulphate is without prejudice to the method, the contrary being the case with chloroplatinic acid (W. A. Davis, *J. Agri. Sci.*, 1912, **5**, 56), and even with perchloric acid (Davis, T., 1915, **107**, 1679). The presence of moderate amounts of aluminium, sodium, and presumably of magnesium is not detrimental, but, on the other hand, the alkaline-earth metals must be removed.

EXPERIMENTAL.

The following observations amplify the descriptions already given of some of the salts of 6-chloro-5-nitro-*m*-toluenesulphonic acid and of their methods of preparation.

In the conversion of the sulphonyl chloride into the corresponding acid, boiling for three hours is sufficient to bring about complete hydrolysis of the ester intermediately formed. The hydrogen chloride produced is removed by concentration on the water-bath (or by distillation), followed by dilution with water, and by repeating this procedure several times. The sulphonic group is not hydrolysed

at all under these conditions, for the solution is completely free from sulphuric acid, even when the evaporation on the water-bath has been carried on for a period of twenty-four hours. Such a solution is converted into any desired salt by treatment with the hydroxide or carbonate of the corresponding metal. When the desired salt is only slightly soluble in cold water, it is conveniently obtained by double decomposition from an already prepared soluble salt. The potassium, ammonium, and barium salts are best obtained from the sodium salt in this way. The attempted preparation of salts of 6-chloro-5-nitro-*m*-toluenesulphonic acid by boiling the sulphonyl chloride with an aqueous solution of alkaline hydroxides resulted in considerable replacement of the nuclear chlorine atom by hydroxyl (Davies, *loc. cit.*, p. 790).

The *ammonium* salt (made by double decomposition) contains, like the sodium and potassium salts, no water of crystallisation. It usually consists of glistening laminae, but like the potassium salt, when slowly crystallised from hot solutions, it sometimes separates in needles (Found: $\text{H}_2\text{O} = 0.3$ per cent. 1.1763 of the anhydrous salt gave 1.2412 of the corresponding potassium salt.* Theory requires 1.269). The *magnesium* salt is formed by treating the free sulphonic acid with excess of magnesium carbonate and concentrating the filtered solution almost to dryness. It consists of minute, compact crystals containing 2 mols. of water (Found: $\text{H}_2\text{O} = 6.3$. $\text{C}_{14}\text{H}_{10}\text{O}_5\text{N}_2\text{Cl}_2\text{S}_2\text{Mg} \cdot 2\text{H}_2\text{O}$ requires $\text{H}_2\text{O} = 6.4$ per cent. 0.6185 of the anhydrous salt gave 0.7367 of potassium salt.† Theory requires 0.7515). At 15° , 3.5 c.c. of water rapidly dissolve 2.0 grams of the hydrated salt, hence the solubility (considerably exceeding 50 per cent.) of the salt at this temperature is probably too great for the presence of moderate amounts of magnesium to cause interference in the estimation of potassium. The magnesium salt is extremely soluble in hot water, and readily soluble in ethyl alcohol, hot and cold. Like the *aluminium* salt, it is too soluble to be conveniently obtained by double decomposition.

* The ammonium salt was dissolved in 25 c.c. of hot water, 80 c.c. of a 15 per cent. potassium chloride solution were added, and the solution was boiled. The precipitate formed after twenty hours was washed with 15 c.c. of cold water.

† The magnesium salt was dissolved in 10 c.c. of water and treated as above with 15 per cent. potassium chloride (31 c.c.). The precipitate was washed with 10.5 c.c. of water. These and other results show that in the analysis of salts of 6-chloro-5-nitro-*m*-toluenesulphonic acid by converting them into the potassium salt, it is advisable to use as reagent excess of an almost saturated solution (at the ordinary temperature) of potassium chloride, and to wash the solution with only a small quantity of water, or better with a moderate amount of a cold saturated solution of the potassium sulphate (see p. 2981).

Residues of the potassium salt are best reconverted into the sodium salt via the sulphonyl chloride in the following way: A mixture of the dry potassium salt (6 grams) with phosphorus pentachloride (9 grams) and phosphoryl chloride (4 grams) is heated in a boiling water-bath with exclusion of moisture, and after an hour the oily contents are poured into 200 c.c. of water. After standing for several hours, the chlorine derivatives of phosphorus are decomposed, and the residual solid sulphonyl chloride is washed with water and dried on a porous plate. The yield is almost theoretical. The product is quite pure, melts at 50°, and is converted into the sodium sulphonate in the way already described.

Solubility of the Potassium, Ammonium, and Sodium Salts.—Solutions saturated at definite temperatures were obtained by keeping initially supersaturated solutions in contact with the solid substance for a period of fifteen to twenty-four hours. Some of the solution was decanted or filtered from the precipitate, the solution evaporated, and the solid dried at 110°. The solubilities recorded for the temperature 12·3° are not very trustworthy, owing to the difficulty of maintaining the thermostat constant at that temperature. The temperature range investigated is from 0° to 30°; the curves, however, are probably of the same type up to 100°, since all the salts are more soluble at this temperature than at 30°. The solubility curves are of the usual simple type. The following solubility data represent grams of the salt dissolved in 100 grams of water.

Solubility of Salts of 6-Chloro-5-nitro-m-toluenesulphonic Acid in Water.

Temperature.	Potassium.	Ammonium.	Sodium.
0°	0·235	0·935	10·4
12·3	0·30	1·48	12·0
16·45	—	—	13·3
20·1	0·405	1·77	15·05
30	0·57	2·58	20·0

Qualitative Investigation of the Reagent.—The addition of several drops of a concentrated solution of the reagent to *N*/50 or stronger solutions of potassium chloride at once causes a precipitation of the potassium sulphonate, which separates in characteristic, voluminous scales. *N*/60 to *N*/100—Solutions of potassium chloride slowly give precipitates on keeping, and, in fact, precipitation from *N*/100-potassium chloride is extremely slow, and in warm weather does not take place. Such a solution contains 1 part of potassium in about 2,500 parts of water.

When the solution to be tested contains ammonium, it is sufficient if the ammonia is expelled by boiling sodium hydroxide solution

and the reagent added to the cold alkaline solution. The reagent can be used in cold concentrated sodium hydroxide solution (for moderately dilute solutions, see Davies, *loc. cit.*, p. 790; this vol., p. 2981), and also in the presence of dilute mineral acids. As might be expected, however, the potassium salt is moderately soluble in concentrated mineral acids.

Quantitative Investigation of the Reagent.—The estimation of potassium in potassium chloride, potassium sulphate, sodium potassium tartrate, and potassium alum has been undertaken in order to determine the best experimental conditions. The potassium chloride and potassium sulphate used were Kahlbaum's products ("zur Analyse mit Garantieschein") and were used without further purification. The potassium alum and Rochelle salt (Kahlbaum) were crystallised twice from water and air-dried at room temperature until no further loss of weight occurred. Some characteristic results are tabulated below.

Estimation of Potassium in Different Salts.

Salt.	Weight (grams).	Wt. of potassium sulphonate.		Percentage of potassium.	
		Found.	Theoretical.	Found.	Theoretical.
KCl	0.5815	2.2391	2.260	51.9	52.31
	0.87534	3.4033	3.401	52.35	
$\text{KNaC}_4\text{H}_4\text{O}_6 \cdot 4\text{H}_2\text{O}$	1.16765	1.1942	1.189	13.87	13.83
"	"	1.1940	"	13.87	"

$\text{KAl}(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$	2.5271	1.5581	1.544	8.30	8.23
"	0.87534	3.3998	3.401	52.34	52.31
KCl	0.43767	1.7015	1.7005	52.38	
K_2SO_4	0.4515	1.5184	1.502	45.3	44.9

In the cases where at least two weights of a given salt are identical, a standard solution of the salt has been prepared, and the potassium found in an aliquot part. In the other cases, the solid potassium salt has been analysed directly. The general method adopted is as follows: A hot solution of the potassium salt in 15 to 25 c.c. of water (in about the proportion of 1.5 of potassium to 100 of water) is treated with 25 to 40 c.c. (at least 30 per cent. excess of theory) of a solution of the sodium sulphonate saturated at the ordinary temperature, and gently boiled for at least five minutes until the precipitate dissolves, more water being added if necessary. After remaining for twenty-four hours at the ordinary temperature, the potassium sulphonate is collected on a Gooch crucible, well drained, slowly washed with two to three times its weight of water, and dried at 110° until its weight is constant.

The first analysis (KCl) was carried out under too dilute conditions, the salt having been dissolved in 20 c.c. of water and 40 c.c. of

about a 7 per cent. reagent solution added. The precipitate was washed with 5 c.c. of water. The second analysis of potassium chloride, those of Rochelle salt, and that of potassium alum were carried out under the more concentrated conditions already indicated. It is noticeable that all the values in the case of Rochelle salt and that in the case of potassium alum are a trifle high. These and other experiments show that when the original salt contains much sodium or other metals, it is advisable to wash, not with a small quantity of water, but with a few c.c. of a solution of a potassium sulphonate solution saturated at the ordinary temperature.

The two analyses of potassium chloride near the bottom of the table constitute an attempt to estimate potassium in the presence of a large amount of sodium hydroxide solution, by the use of which it was hoped to reduce the excess of sodium sulphonate otherwise required. In the first case, potassium chloride in 25 c.c. of water was treated with 35 c.c. of a saturated solution of the reagent, and, on cooling, 25 c.c. of a 10 per cent. sodium hydroxide solution were added and stirred with the semi-solid mass. The precipitate was collected after twenty-four hours and washed with 10 c.c. of water. The excellent result is supported by another estimation with half the quantity of potassium chloride. This interesting modification of the process has not been further pursued, as it is to be expected that the effect of the increase in the concentration of the common ion (Na), might, especially when sodium is initially present in the salt under analysis, be sometimes detrimental. The use of sodium hydroxide solution, however, would involve no pitfalls in stereotyped estimations of substances of approximately the same composition.

In the final result, potassium sulphate was dissolved in 20 c.c. of water and treated with 40 c.c. of a saturated solution of the reagent, and the precipitate after twenty-four hours was well pressed and drained with suction, but not washed with pure water at all. This was done in order to measure the effect of washing in other cases. The result, which is only a little higher than theory (0.016 on 1.502), indicates that it is not necessary to wash the precipitate with a large volume of water when potassium is initially the only metal present.

It will be noticed that the amount of precipitate is extremely large. This is because it was felt desirable in preliminary experiments to work with a moderate quantity (40 to 70 c.c.) of filtrate for "washing" purposes. With the aid of small beakers, however, there should be no difficulty in estimating the potassium (say 0.078 gram) in a salt dissolved in 5 c.c. of water, which would give

5 G*

the comparatively small precipitate of 0.579 gram. But the best way when working with relatively small quantities will be to add the weighed solid salt to the saturated solution of the reagent, dilute with the requisite volume of water (in this case 5 c.c.), boil the solution until it is clear, and then proceed as above. In this connexion, it should be remembered that the factor of the potassium salt for potassium is small, namely, 0.1347.

Summary.

(I) Potassium 6-chloro-5-nitro-*m*-toluenesulphonate at the ordinary temperature is less soluble than most of the ordinary potassium salts used for the detection of potassium. The sodium salt is about forty times more soluble than the potassium salt at the ordinary temperature, and in the absence of ammonium is a useful and inexpensive reagent for potassium in neutral, alkaline, or dilute mineral acid solution. By its means, 1 part of potassium in about 2,500 parts of water can be detected. The aluminium and magnesium sulphonates are very soluble.

(II) The reagent gives satisfactory results in the estimation of potassium in the presence of sodium or aluminium (and presumably of magnesium), and of sulphate. The method is at least as trustworthy as the chloroplatinate method, and in some cases may be even more convenient than the perchlorate process.

CCCLIV.—*Derivatives of the Four Isomeric Sulphonic Acids of m-Tolyl Methyl Ether.*

By ROBERT DOWNS HAWORTH and ARTHUR LAPWORTH.

AN investigation of the products obtained by sulphonating *m*-cresol which has been in progress in these laboratories for some time presented problems which rendered it necessary to make a careful study of derivatives of *m*-cresolsulphonic acids by means of which identification and, if necessary, separation of the isomerides could readily be effected.

A suggestion made by Professor H. E. Armstrong to one of us in 1895 in connexion with the characterisation of sulphonic acids of β -naphthol (compare P., 1895, **11**, 49) led to most satisfactory results, and the authors decided to adopt the principle in the present instance. The suggestion was to replace in each case the phenolic hydrogen atom by an alkyl group, when the resulting compounds,

unlike the parent acids, could be converted into the corresponding sulphonyl chlorides, amides, etc., which are usually well adapted for characterisation purposes.

In order to identify the resulting products, it was thought most satisfactory to prepare the sulphonic acids of *m*-tolyl methyl ether synthetically by methods which would leave no doubt as to their true structures. The present paper contains an account of the main results obtained in effecting the required syntheses.

The authors have been successful in synthesising all four possible derivatives of *m*-tolyl methyl ether in which one hydrogen in the aromatic nucleus is replaced by means of their salts, their chlorides, and other derivatives. The 4:6-disulphonic acid (or rather a series of its derivatives) has also been made, and in addition a number of other new compounds have been prepared and their properties defined.

3-Methoxytoluene-6-sulphonic acid (I) corresponds with the only monosulphonic acid of *m*-cresol which has hitherto been described (Claus and Krauss, *Ber.*, 1887, **20**, 3089), namely, *m*-cresol-6-sulphonic acid, which was isolated from the products of sulphonation of *m*-cresol.

During the work described in the present paper the acid (I) and its three isomerides were synthesised from the corresponding nitro-*m*-cresol, which was first converted into its methyl ether, the nitro-group in which was then reduced to the amino-group. The amino-group was then replaced by the sulphinic acid group, Gattermann's method being used, and the resulting sulphinic acid was subsequently oxidised to the sulphonic acid.

The structures assigned in this paper to the four isomeric 3-methoxytoluenesulphonic acids thus depend mainly on those adopted for the nitro-compounds from which they were prepared. The orientation of three out of the four possible nitro-*m*-cresols has recently been discussed by Gibson (this vol., pp. 1269 *et seq.*), whose work renders it unnecessary for the present authors to justify the structures which they assign to the 6-sulphonic acid (I), the 2-sulphonic acid (II), and the 4-sulphonic acid (III).

The structure (IV) assigned to the fourth acid follows first from the fact that it is distinct from the other three isomerides and, secondly, from its synthesis; as it was prepared from 3:5-dinitro-

toluene, one nitro-group in which was replaced by methoxyl and the other by the sulphonyl group.

Gibson (*loc. cit.*) describes 2-nitro-*m*-cresol for the first time, his description anticipating the present authors, who had made the compound and its methyl ether in 1921. The melting points given by Gibson were in some cases decidedly higher than those observed by the present authors; but a direct comparison of samples proved complete identity and the discrepancies have been traced to the inaccuracy of the thermometer used by Gibson. Apart from this feature, observations of the present authors are generally in good agreement with those of Gibson and confirm his definite rejection of the earlier data recorded for 2-nitro-*m*-cresol and its methyl ether (Khotinsky and Jacopson-Jacopmann, *Ber.*, 1909, 42, 3097). The present authors did not make any attempt to confirm the structure assigned to their 2-nitro-*m*-cresol, as the other three possible isomerides were already known; independent evidence provided by Gibson removes any possible doubt which may have remained.

The course of the reaction by means of which Gibson made 2-nitro-*m*-cresol is by no means self-evident. The process devised by the present authors represents a synthesis in which each step is quite clear. For this reason and also because the same principle may prove applicable in other similar syntheses, it is worth giving in full, especially as a number of alternative syntheses, apparently much simpler, of the compound were tried unsuccessfully.

m-Tolyl methyl ether, in carbon disulphide or chloroform solution, was sulphonated with chlorosulphonic acid, yielding mainly the 6-sulphonic acid (I). This was converted *in situ* into its sulphonyl chloride (V), which is readily soluble in chloroform. The solution of the sulphonyl chloride in the last-named solvent was treated with another molecular proportion of chlorosulphonic acid, and thus converted into the half chloride (VI) of 3-methoxytoluene-4:6-disulphonic acid. This mixture was again converted *in situ* by means of phosphorus pentachloride into the disulphonyl chloride (VII), which was easily isolated and purified.

By nitrating the disulphonyl chloride, the 2-nitro-derivative (VIII) was readily obtained and when hydrolysed either by means of acids or alkalis gave practically pure 2-nitro-*m*-cresol.

In addition to the preceding, attempts were made to sulphonate 4:6-dibromo-*m*-cresol (IX) and also its methyl ether (X). It was somewhat remarkable to find that chlorosulphonic acid had no appreciable action on the dibromo-ether at the ordinary temperature. Fuming sulphuric acid, at 70°, caused disruption of the molecule, the only organic product detected being tribromo-*m*-cresol; the action of sulphuric acid on the free dibromocresol itself also caused profound decomposition with formation of some tribromocresol.

The extraordinary resistance of dibromocresol to further sulphonation was shown by the fact that chlorosulphonic acid merely converted it into the corresponding dibromotolyl hydrogen sulphate (XI).

The nitration of 4:6-dibromocresol (IX) has already been studied by Gibbs and Robertson (T., 1914, 105, 1885), who observed a migration of the bromine atom from position 6 to position 2, a nitro-group entering the place vacated. A second nitro-group displaces the 4-bromine atom.

Yet another synthesis of 2-nitro-*m*-cresol was attempted from 3-hydroxy-*p*-toluic acid, through the 6-bromo-2-nitro-3-hydroxy-*p*-toluic acid (Gibbs and Robertson, *loc. cit.*) detected among the nitration products of 6-bromo-3-hydroxy-*p*-toluic acid. After heating and reducing the crude nitration product of 6-bromo-3-hydroxy-*p*-toluic acid, a small quantity of a yellow nitro-compound, volatile in steam, was isolated; this was probably 2-nitro-*m*-cresol, but the yield was much too small for the purposes of the present research.

EXPERIMENTAL.

General Remarks and Methods.

One or two general methods adopted may be described at this point with the object of avoiding unnecessary repetition.

The *m*-cresol used in the experiments was either the excellent product prepared by Graesser and Co. or one which we have ourselves made from lower grade *m*-cresol; both contain at least 97 per cent. of pure *m*-cresol (estimated by the standard method devised by Raschig) with probably traces of *p*-cresol and *o*-cresol.

The sodium or potassium salts of the sulphonic acids were methylated by boiling the alkaline solution (water 10 parts, alkali hydroxide 2 mols.) with methyl sulphate (1 mol.) until a neutralised sample

developed no violet coloration with ferric chloride; the time required for this varied considerably. The filtered solution was concentrated and fractionally crystallised.

Methylation of Nitrocresols.—The methyl ethers (yield about 90 per cent.) were prepared as follows: A mixture of the nitro-cresol (75 grams), xylene (300 c.c.), and dry potassium carbonate (110 grams) was boiled under a reflux condenser, and methyl sulphate (80 grams) slowly added; after eighteen to twenty-four hours, the yellow colour of the solution had usually disappeared. The whole was then cooled, mixed with 100 c.c. of water containing 2 or 3 grams of sodium hydroxide, and distilled with steam, the break in the speed of distillation when the xylene had passed over being readily observed. In the residue, on cooling, the nitrotolyl ether solidified and was filtered off and washed with water. The quantity of nitrocresol recoverable from the alkaline fluid was very small and as a rule not worth securing.

Conversion of Amino-derivatives of m-Tolyl Methyl Ether into the Corresponding Sulphinic Acids.—For this purpose, Gattermann's method (*Ber.*, 1899, **32**, 1136) was adopted. For the success of the method it was found essential that the copper powder should be freed from all traces of grease by washing it thoroughly first with alcohol and then with ether. The sulphinic acids were usually isolated by extraction with ether. The extracts were shaken with sodium hydroxide solution, the aqueous extract was acidified in the cold with dilute sulphuric acid, and the sulphinic acid again dissolved in ether. Thomas's method (*T.*, 1909, **95**, 342) was not found generally applicable, as the ferric salts were not as a rule precipitated on addition of ferric chloride to the acid solutions.

Conversion of 3-Methoxytoluenesulphinic Acids into the Corresponding Sulphonic Acids.—Gattermann's method (*loc. cit.*) was followed, but the present authors found it more convenient first to prepare the barium salts, from which other salts are very readily made. A filtered solution of the barium salt prepared from 10 grams of 3-methoxytoluenesulphinic acid was heated with a slight excess of 1 per cent. solution of barium permanganate. The oxidation was complete after a few minutes, after which time a little alcohol was added to destroy unchanged permanganate, the whole being then filtered and the residue of manganese dioxide well washed with hot water. The crystalline barium salt, obtained in excellent yield by concentrating the filtrate, was purified by recrystallisation.

3-Methoxytoluene-6- and 4-sulphonic Acids (I and III).

m-Cresol (100 grams), nitrated by Staedal's method (*Annalen*, 1883, **217**, 49; 1890, **259**, 208), yielded 26 grams of 4-nitro-*m*-

cresol, m. p. 55–56°, and 52 grams of 6-nitro-*m*-cresol, m. p. 127–128°. The methylation of the two nitrocresols was carried out as described on p. 2986. 6-Nitro-*m*-tolyl methyl ether crystallised from alcohol in white needles, m. p. 54–55°, and the isomeric 4-nitro-compound melted at 60–61° (compare Reissert and Schenck, *Ber.*, 1898, **31**, 394).

6-Amino-*m*-tolyl methyl ether was made by heating the nitro-ether (60 grams) on the steam-bath with stannous chloride (270 grams) dissolved in concentrated hydrochloric acid (350 c.c.) diluted with water. After three hours, the clear solution was rendered strongly alkaline with sodium hydroxide and distilled with steam. The chloroform extract of the distillate yielded a residue which, on distillation in a vacuum, gave 41 grams of 6-amino-*m*-tolyl methyl ether, b. p. 188–189°/25 mm. The *acetyl* derivative, prepared by leaving the base with acetic anhydride dissolved in glacial acetic acid for an hour in presence of fused sodium acetate, separated from alcohol in colourless needles, m. p. 132° (Found: N = 8.0. $C_{10}H_{13}O_2N$ requires N = 7.8 per cent.).

3-Methoxytoluene-6-sulphinic Acid.—Ten grams of 6-amino-*m*-tolyl methyl ether, dissolved in sulphuric acid (30 grams) and water (100 c.c.), were diazotised at –5° by sodium nitrite (5.25 grams) in water (25 c.c.). A mixture of sulphuric acid (40 grams) and water (40 grams) was then added, and the diazo-compound converted into sulphinic acid by saturating the solution with sulphur dioxide and adding copper powder during a period of one and a half hours, with constant stirring, the temperature being kept below 0° throughout. The filtered solution was finally extracted with ether and the acid isolated from the extract with the precautions described above and removal of the ether in a vacuum. The acid (11 grams) crystallised from dilute alcohol in colourless needles, m. p. 84–85° (Found: C = 51.4; H = 5.9. $C_8H_{10}O_3S$ requires C = 51.6; H = 5.8 per cent.). It differed from its isomerides in quickly becoming sticky when exposed; even in a vacuum desiccator over sulphuric acid it became tarry in time. The same deterioration was noticed when the ethereal extract of the crude acid was evaporated with the aid of heat. The sticky material gave excellent sulphinic acid on oxidation.

Salts of 3-Methoxytoluene-6-sulphinic Acid (I).—The barium salt, decomp. 150°, crystallised in white, anhydrous, rhombic plates and was soluble to the extent of 2.5 grams in 100 grams of water at 18°. It was but sparingly soluble in hot and almost insoluble in cold alcohol. Its aqueous solution gave no coloration with ferric chloride. There was no loss of weight when it was heated at 100° for six hours [Found: Ba = 25.3. $(C_8H_9O_4S)_2Ba$ requires Ba = 25.5 per cent.].

The *potassium* salt, prepared both by Gattermann's original method and also from the barium salt, crystallised from water in well-defined, square plates. Twelve grams of the anhydrous salt dissolved in 100 grams of water at 18°. It was moderately soluble in hot but nearly insoluble in cold alcohol (Found: $\text{H}_2\text{O} = 7.0$; $\text{K} = 15.3$. $\text{C}_8\text{H}_9\text{O}_4\text{SK}, \text{H}_2\text{O}$ requires $\text{H}_2\text{O} = 7.0$; $\text{K} = 15.1$ per cent.).

The *sodium* salt crystallised in square plates.

3-Methoxytoluene-6-sulphonyl chloride (V) was prepared (a) by triturating the anhydrous potassium salt of the acid with phosphorus pentachloride and working up in the usual manner, and (b) by passing chlorine through an alkaline solution of the corresponding sulphinic acid in 10 per cent. sodium hydroxide solution (T., 1909, 95, 342).

It dissolved freely in the cold in most of the usual organic media, including light petroleum; when cooled in the ice-chest, the compound solidified and after being drained for some time on porous earthenware, melted at 23°. It appeared to be highly stable towards cold water (Found: $\text{C} = 43.5$; $\text{H} = 4.2$. $\text{C}_8\text{H}_9\text{O}_3\text{ClS}$ requires $\text{C} = 43.5$; $\text{H} = 4.1$ per cent.).

The *sulphonamide* was prepared (a) by heating the chloride with excess of solid ammonium carbonate, and (b) in slightly better yield by passing chlorine gas through a solution of the corresponding sulphinic acid in excess of ammonia. It crystallised from hot water in white needles melting at 129–130° (Found: $\text{C} = 47.5$; $\text{H} = 5.5$. $\text{C}_8\text{H}_{11}\text{O}_3\text{NS}$ requires $\text{C} = 47.8$; $\text{H} = 5.5$ per cent.).

The *sulphonanilide* was prepared by dissolving the chloride (1 mol.) in cold ether, adding aniline (2½ mols.), and, after half an hour, distilling off the solvent and removing excess of aniline from the residue by means of dilute hydrochloric acid. The compound crystallised from alcohol in white prisms melting at 104° (Found: $\text{C} = 60.2$; $\text{H} = 5.6$. $\text{C}_{14}\text{H}_{15}\text{O}_3\text{NS}$ requires $\text{C} = 60.6$; $\text{H} = 5.5$ per cent.).

4-Amino-m-tolyl methyl ether, prepared in 85 per cent. yield by reduction of the 4-nitro-ether in the same manner described for the 6-isomeride, was a colourless oil, darkening rapidly on exposure to the atmosphere. It boiled at 179–180°/46 mm. and dissolved completely in cold dilute mineral acid and the usual organic media. Its acetyl derivative formed white needles melting at 131° (compare Khotinsky and Jacopmann, *Ber.*, 1909, 42, 3103).

3-Methoxytoluene-4-sulphinic acid, made from the preceding compound, formed large, colourless needles melting at 110–111°. It was found more stable than the 4-isomeride and could be kept in the crystalline condition for some weeks. An acid solution did

not give a precipitate of ferric salt on addition of ferric chloride (Found: C = 51.5; H = 5.8. Calc. for $C_8H_{10}O_3S$, C = 51.6; H = 5.8 per cent.).

Derivatives of 3-Methoxytoluene-4-sulphonic Acid (III).—The barium salt, made from the preceding compound, formed small, colourless needles. A saturated solution at 19° contained 18 grams of the anhydrous salt in 100 grams of water. In its behaviour towards alcohol, ferric chloride, and mineral acids, the salt closely resembled the barium salt of the 6-sulphonic acid [Found: $H_2O = 14.5$. $(C_8H_9O_4S)_2Ba \cdot 5H_2O$ requires $H_2O = 14.3$ per cent. Found: in the dried salt, Ba = 25.3. Calc., Ba = 25.4 per cent.]. The potassium salt crystallised in long needles. At 19° a saturated solution contained 31 grams in 100 grams of water. The salt was slightly soluble in cold alcohol and more readily in hot. It was anhydrous, and was quite stable at 130° (Found: K = 16.2. $C_8H_9O_4SK$ requires K = 16.3 per cent.). The sodium and ammonium salts crystallised in white needles.

3-Methoxytoluene-4-sulphonyl chloride solidified readily and separated from carbon disulphide in colourless plates melting at 79°. It was stable towards cold water and dissolved freely in cold benzene, chloroform, or light petroleum (Found: C = 43.4; H = 4.4. $C_8H_9O_3ClS$ requires C = 43.5; H = 4.1 per cent.).

3-Methoxytoluene-4-sulphonamide crystallised from hot water in white needles melting at 167–168° (Found: C = 47.4; H = 5.6. $C_8H_{11}O_3NS$ requires C = 47.8; H = 5.5 per cent.).

3-Methoxytoluene-4-sulphonanilide crystallised from alcohol in white needles melting at 142° (Found: C = 60.5; H = 5.7. $C_{14}H_{15}O_3NS$ requires C = 60.6; H = 5.5 per cent.).

3-Methoxytoluene-5-sulphonic Acid (IV).

Aceto-*p*-toluidide was converted into its 3:5-dinitro-derivative by Staedel's method (*Annalen*, 1883, 217, 187), a yield of 70 per cent. of recrystallised product melting at 189° being obtained. Removal of the acetyl group was effected by hydrolysis with 50 per cent. sulphuric acid (compare Jackson and Ittner, *Amer. Chem. J.*, 1897, 19, 5), as alcoholic potassium hydroxide, the agent used by Staedel, brought about elimination of ammonia and formation of much dinitro-*p*-cresol. The dinitroacetotoluidide (100 grams) was suspended in 50 per cent. sulphuric acid, and the whole stirred vigorously while being heated to boiling. The amine did not go wholly into solution, but the solid swelled considerably and its colour changed from yellow to orange. When no further alteration could be detected, the whole was cooled, diluted with water, and the solid amine filtered off and washed. The amine (yield about

98 per cent.), after recrystallisation from alcohol, melted at 168°. It was converted into 3:5-dinitrotoluene by Staedel's method (*loc. cit.*, p. 153), the yield of the latter compound, pale yellow needles, m. p. 91—92°, being 60 per cent. of the theoretical.

5-Nitro-*m*-toluidine was obtained from 3:5-dinitrotoluene in 55 per cent. yield by adopting the following procedure (Staedel, *loc. cit.*, records 85 per cent., but Neville and Winther, *Ber.*, 1882, 15, 2984, on repeating Staedel's experiment, only secured a yield of 50 per cent.).

3:5-Dinitrotoluene (5 grams) was mixed with methylated spirit (30 c.c.), and dry gaseous ammonia passed in until the gain in weight was 1.5 grams. A rapid stream of dry hydrogen sulphide was then applied, when the temperature rose considerably, and after half an hour the mixture was heated on a steam-bath for a few minutes and then poured into an equal volume of water. By extracting the washed solid with dilute hydrochloric acid, the amino (2.5 grams) was readily separated from sulphur and was obtained from hot water as brownish-red needles melting at 98°.

5-Nitro-*m*-cresol was obtained by the following process, which gave much better results than the method used by Neville and Winther (*loc. cit.*, p. 2984). 5-Nitro-*m*-toluidine (10 grams), dissolved in a mixture of sulphuric acid (50 c.c.) and water (50 c.c.) kept below 0°, was diazotised with solid sodium nitrite, the resulting solution dropped into boiling diluted sulphuric acid (b. p. 125—130°), and the cooled, filtered solution, after twelve hours, was extracted with ether. The solid on the filter was united with that obtained by extraction and the whole recrystallised from boiling water with the addition of some animal charcoal. 5-Nitro-*m*-cresol was obtained as pale yellow needles, melting at 60—61°, which, according to Neville and Winther, is the melting point of the monohydrate, the yield being 55 per cent. of the theoretical. When methylated by the general process previously described (p. 2986), it gave a 95 per cent. yield of 5-nitro-*m*-tolyl methyl ether, yellow needles, m. p. 70° (compare Blanksma, *Rec. trav. chim.*, 1908, 27, 26).

5-Amino-*m*-tolyl methyl ether was made in 95 per cent. yield by reducing 5-nitro-*m*-tolyl methyl ether with stannous chloride and hydrochloric acid (compare p. 2987). It formed a colourless oil, b. p. 150—152°/22 mm., which solidified to a mass of needles melting at 46—47°. The *sulphate* is much less readily soluble in water than are the sulphates of the three isomeric bases, and crystallises from water in long colourless prisms. The *acetyl* derivative crystallises from dilute alcohol in colourless needles, m. p. 110—111° (Found: N = 8.1. Calc. for $C_{10}H_{13}O_3N_2$, N = 7.8 per cent.).

3-Methoxytoluene-5-sulphinic acid, prepared from 5-amino-*m*-tolyl methyl ether by the general process (p. 2986) in excellent yield, crystallises from water containing a few drops of hydrochloric acid, in colourless needles, m. p. 94—95°. It dissolves in the usual organic media and, unlike the isomeric acids, gives a sparingly soluble ferric salt on addition of ferric chloride to its aqueous solution.

Derivatives of 3-Methoxytoluene-5-sulphonic Acid (IV).—The barium salt is more readily soluble in water than the barium salt of the isomeric 6-sulphonic acid, but less readily soluble than that of the 4-sulphonic acid. In its behaviour to ferric chloride, alcohol, and to mineral acids, it resembles the barium salts of the 4- and 6-sulphonic acids. The potassium salt is readily soluble in water and also in hot alcohol; it crystallises in needles with rosettes or fern-like growths.

3-Methoxytoluene-5-sulphonyl chloride solidifies readily and separates from carbon disulphide or light petroleum in colourless, rhombic prisms, m. p. 47—48°. It dissolves freely in benzene, chloroform, carbon disulphide, or light petroleum (Found: C = 43.2; H = 4.3. $C_8H_7O_3ClS$ requires C = 43.5; H = 4.1 per cent.).

3-Methoxytoluene-5-sulphonamide is freely soluble in aqueous ammonia, but is deposited when the gas is expelled by heating. It crystallises in needles, m. p. 118—119° (Found: C = 47.5; H = 5.6. $C_8H_{11}O_3NS$ requires C = 47.8; H = 5.5 per cent.).

3-Methoxytoluene-2-sulphonic Acid (II).

3-Methoxytoluene-4:6-disulphonyl Chloride (VII).—*m*-Tolyl methyl ether, dissolved in cold carbon disulphide, was slowly treated with freshly distilled chlorosulphonic acid (1 mol.). The solvent, containing any unchanged tolyl ether, was decanted, the mixed insoluble sulphonic acids were covered with chloroform, phosphorus pentachloride was added, and the whole warmed. The clear solution obtained was cooled, shaken thoroughly with cold water until freed from phosphoryl chloride, dried, and the solvent removed by distillation on the steam-bath. The crude residual oil, which was fairly pure 3-methoxytoluene-6-sulphonyl chloride (V) containing perhaps a little of the isomeric 4-sulphonyl chloride, was used for the second sulphonation process.

The crude sulphonyl chloride (50 grams), dissolved in chloroform (100 c.c.), was sulphonated by addition, drop by drop, of chlorosulphonic acid (16 c.c.), warmth being finally used to promote the reaction. In a short time, a white solid separated, when more chloroform (50 c.c.) was added and the warming continued for thirty minutes. The white solid (mostly VI) so formed was

excessively deliquescent, as were the similar ethoxynaphthalene-disulphonic acid monochlorides prepared by Lapworth (P., 1895, 11, 49) at the suggestion of Professor Armstrong. On adding the solid to water, rapid dissolution took place, and by warming the resulting solution with excess of lead carbonate, cooling, and filtering from lead chloride, the lead salt of 3-methoxytoluene-4:6-disulphonic acid was easily obtained and could readily be converted into the corresponding sodium, potassium, and barium salts, all of which, however, were extremely soluble in water and could only be isolated in caramel-like masses.

The disulphonyl chloride was prepared directly from the crude chloroform suspension of the above white solid by adding phosphorus pentachloride (50 grams), when the solids dissolved with evolution of hydrogen chloride. The reaction was completed by warming until no more gas was evolved, when the resulting solution was shaken with water repeatedly and when free from phosphoryl chloride was dried over calcium chloride and evaporated. The oil which was left solidified on standing and yielded a homogeneous compound (48 grams) without difficulty when washed with light petroleum, and recrystallised from a mixture of benzene and light petroleum.

3-Methoxytoluene-4:6-disulphonyl chloride (VII) is very stable towards cold water and is hydrolysed relatively slowly even by hot aqueous solutions of sodium hydroxide. It melts at 111–112°. The same compound was obtained by treating synthetic 3-methoxytoluene-4-sulphonyl chloride with chlorosulphonic acid and phosphorus pentachloride successively as above described. The constitution of the compound is therefore not in doubt (Found: C = 29.9; H = 2.6. $C_8H_9O_5Cl_2S_2$ requires C = 30.1; H = 2.5 per cent.).

3-Methoxytoluene-4:6-disulphonamide crystallises from water in small, colourless needles melting at 259–260° (Found: C = 34.0; H = 4.6. $C_8H_{12}O_5N_2S_2$ requires C = 34.3; H = 4.3 per cent.).

2-Nitro-3-methoxytoluene-4:6-disulphonyl Chloride (VIII).—The foregoing disulphonyl chloride (20 grams) was dissolved in concentrated sulphuric acid (100 c.c.) and 100 per cent. nitric acid (3 c.c. = 1 mol.) was added while the whole was stirred vigorously and the temperature kept below 35°. A pale yellow solid was deposited and after two hours the mixture was poured on ice and the solid separated. The nitro-compound was crystallised from a mixture of benzene and light petroleum, when it appeared as very pale yellow needles melting at 147–148° (yield 90 per cent. of the theoretical) (Found: C = 26.4; H = 2.0. Calc. for $C_8H_7O_7NCl_2S_2$, C = 26.4; H = 2.0 per cent.).

While it is evident that the disulphonyl chlorides must be fairly resistant to hydrolysis in sulphuric acid solution, the nitro-compound, in contrast with the preceding compound, is quickly attacked by cold aqueous sodium hydroxide, dissolving with evolution of heat and formation of a brown solution.*

2-Nitro-3-methoxytoluenedisulphonamide crystallises from alcohol in pale yellow needles, m. p. 235° (Found: C = 29.4; H = 3.5. $C_8H_{12}O_7N_2S_2$ requires C = 29.5; H = 3.4 per cent.).

Preparation of 2-Nitro-m-cresol from 2-Nitro-3-methoxytoluenedisulphonyl Chloride (VIII).—The nitrodisulphonyl chloride may be hydrolysed by heating it in a closed tube with concentrated hydrochloric acid for seven hours at 130° . The product, when distilled in a current of steam, yields 2-nitro-*m*-cresol as a volatile yellow oil which solidifies to a mass of bright yellow needles melting at $37-38^{\circ}$ and is completely soluble in aqueous sodium hydroxide.

For moderately large quantities, the following process was found very convenient. The nitrodisulphonyl chloride is hydrolysed by warming with the calculated quantity of 20 per cent. aqueous sodium hydroxide and the resulting brown solution,* doubtless containing the sodium salt of the nitrodisulphonic acid of *m*-cresol, is mixed with such an excess of concentrated sulphuric acid that a mixture boiling at about 150° is obtained. This mixture is then distilled in a current of superheated steam at 150° . The distillate consists of an aqueous solution of 2-nitro-*m*-cresol, in quantity corresponding with 80 per cent. of that theoretically possible. It may be isolated by extraction with ether or other suitable means.

2-Nitro-*m*-cresol crystallises from benzene in bright yellow needles melting at 39° (not 44° as stated by Gibson, this vol., p. 1273) (Found: C = 54.6; H = 4.6. Calc., C = 54.9; H = 4.5 per cent.).

The methyl ether was made in almost quantitative yield by the general method (p. 2986), eighteen hours' boiling in xylene being required for complete methylation. In this instance, the xylene removed by steam distillation from the bulk of the product should be distilled in a vacuum, otherwise there is a marked drop in the yield of nitro-ether owing to its marked volatility in steam. The compound crystallised from dilute alcohol or acetic acid in long, white needles and melted at 49° (not 54° as stated by Gibson, *loc. cit.*, p. 1274) (Found: C = 57.3; H = 5.5. Calc., C = 57.5; H = 5.4 per cent.).

* The case with which the methoxyl group suffers hydrolysis during treatment with alkali in this case, as contrasted with that of the unnitrated compound (VII), provides another example of the marked influence of the nitro-group in certain positions on the stability of phenol ethers.

2-Amino-*m*-tolyl methyl ether was prepared from the preceding compound by reduction with stannous chloride and hydrochloric acid (p. 2987). It boiled at 119–121°/16 mm. and melted at 31° as stated by Gibson (*loc. cit.*). Its *acetyl* derivative crystallises from dilute alcohol in white needles, m. p. 167–168° (Found: N = 8.0. $C_{10}H_{13}O_2N$ requires N = 7.8 per cent.).

3-Methoxytoluene-2-sulphinic acid, prepared from the preceding amino-compound by the general method (p. 2986), crystallises from dilute alcohol in colourless needles, m. p. 94–95°. This isomeride is fairly stable to air, and its aqueous solution does not yield a precipitate on addition of ferric chloride (Found: C = 51.4; H = 5.7. $C_8H_{10}O_3S$ requires C = 51.6; H = 5.8 per cent.).

Derivatives of 3-Methoxytoluene-2-sulphonic Acid (II).—The *barium* salt, prepared from the preceding sulphinic acid by oxidation with barium permanganate (p. 2986), crystallises from water in small tufts of needles. A saturated solution at 15° contains 16 grams of anhydrous salt in 100 grams of water [Found: H_2O = 25.1; Ba = 19.1. $(C_8H_9O_4S)_2Ba \cdot 10H_2O$ requires H_2O = 25.0; Ba = 19.1 per cent.]. The *potassium* salt crystallises from water in rhombic prisms, and at 18° is soluble in water to the extent of about 10 per cent. It is moderately soluble in hot alcohol, but nearly insoluble when cold (Found: H_2O = 3.7; K = 15.8. $C_8H_9O_4SK \cdot \frac{1}{2}H_2O$ requires H_2O = 3.6; K = 15.7 per cent.).

3-Methoxytoluene-2-sulphonyl chloride crystallises from carbon disulphide in colourless plates, m. p. 51–52°, and is fairly stable to cold water (Found: C = 43.3; H = 4.3. $C_8H_9O_3ClS$ requires C = 43.5; H = 4.1 per cent.).

3-Methoxytoluene-2-sulphonamide was made by heating the chloride with aqueous ammonia until dissolved, expelling excess of ammonia by heat, and then cooling the solution, when the amide separated in white needles. Recrystallised from alcohol, it melted at 127–128° (Found: C = 47.7; H = 5.6. $C_8H_{11}O_3NS$ requires C = 47.8; H = 5.5 per cent.).

3-Methoxytoluene-2-sulphonanilide crystallises from alcohol in characteristic, rhombic prisms, m. p. 131–132° (Found: C = 60.5; H = 5.6. $C_{14}H_{15}O_3NS$ requires C = 60.6; H = 5.5 per cent.).

Addenda.—The following observations collected during early unsuccessful attempts made to synthesise 3-methoxytoluene-2-sulphonic acid may be recorded.

*Action of Sulphonating and Nitrating Agents on 4 : 6-Dibromo-*m*-cresol (IX) and its Methyl Ether (X).*—4 : 6-Dibromo-*m*-cresol (Gibbs and Robertson, T., 1914, 105, 1885) dissolves in cold concentrated sulphuric acid, giving a pink solution, without being sulphonated. When the solution is gently warmed, a reaction

takes place, but the only product which could be isolated was tribromo-*m*-cresol.

The dibromocresol was treated in carbon disulphide with chlorosulphonic acid (1 mol.) at -10° . Hydrogen chloride was evolved and on extracting the acid product with water, neutralising the aqueous extract with barium hydroxide, and filtering, a solution was obtained which, when evaporated on the steam-bath, quickly deposited barium sulphate, indicating the presence of a salt of dibromotolylsulphuric acid (XI). The *potassium* salt of this acid was ultimately isolated as a white, flaky mass; it is more readily soluble in hot water than in cold, and soluble in boiling alcohol. It gave no coloration with ferric chloride and was rapidly hydrolysed by water containing a little mineral acid, 4 : 6-dibromocresol being formed. These properties together with the great stability of the salt towards cold alkaline permanganate show clearly that the salt is derived from the tolylsulphuric acid and not a cresolsulphonic acid.

4 : 6-Dibromo-*m*-tolyl methyl ether (X) was made by adding bromine (300 grams) in glacial acetic acid (135 c.c.) to a solution of *m*-tolyl methyl ether (100 grams) in glacial acetic acid (100 c.c.), the temperature being kept below 10° . After one and a half hours, the white crystals of the dibromotolyl ether formed were filtered off and crystallised from alcohol. The compound separated from alcohol in rectangular plates melting at $75-76^{\circ}$ (Found : Br = 56.7, 56.1. Calc. for $C_8H_8OBr_2$, Br = 57.1 per cent.). When dealkylated by heating with a mixture of strong aqueous hydrobromic acid and glacial acetic acid, it was converted into 4 : 6-dibromo-*m*-cresol (IX).

Concentrated sulphuric acid dissolved this substance, giving a pink solution; but no further change took place until the mixture was warmed. If the solution in slightly fuming sulphuric acid is warmed at 70° , the original pink colour disappears, a slight evolution of sulphur dioxide and hydrogen bromide occurs, and white crystals appear on cooling; when the product is poured over ice, a white solid soluble in dilute alkalis, easily identified as tribromo-*m*-cresol, is deposited.

4 : 6-Dibromo-*m*-tolyl methyl ether, dissolved in glacial acetic acid, is rapidly attacked by fuming nitric acid, but again profound change takes place, as evidenced by the liberation of bromine and hydrogen bromide.

Summary.

The methods of preparation and the properties of a number of derivatives of *m*-cresol, including the isomeric monosulphinic and monosulphonic derivatives of its methyl ether, are described.

The authors desire to express their thanks to the Department of Scientific and Industrial Research, to the Commissioners of the 1851 Exhibition, and to the Research Fund Committee of the Chemical Society for grants which materially assisted in carrying out the work described in the present paper.

CCCLV.—*The Corrosion of Iron in Water and in Neutral Salt Solutions.*

By JOHN ALBERT NEWTON FRIEND.

ONE of the great difficulties met with in the study of the corrosion of iron, completely submerged in water or in solutions of inorganic salts, lies in the fact that it has hitherto proved almost impossible to obtain satisfactory "repeat" results at different times. The rates of corrosion exhibit marked variation, which may amount to 100 per cent. even when the experimental conditions appear to be identical, fluctuations in temperature and illumination being carefully guarded against. The variant most difficult to control over prolonged periods is the atmosphere, the pressure and humidity of which are liable to considerable fluctuation. Since the rate of corrosion is directly proportional to the partial pressure of the oxygen and hence, within small limits, to the barometric height, the necessary oxygen correction can easily be applied. But the humidity is not allowed for in this way, and it does not appear to have occurred to investigators that possibly herein lies the cause of the above-mentioned discrepancies. (The present author directed attention to this possibility in his Carnegie Memoir, *Iron and Steel Inst.*, 1922, 11, 118.) It has been usual to account for them as resulting from eccentricities in the specimens of iron themselves rather than to seek an external cause. The recent work of Adeney and his co-workers (*Sci. Proc. Roy. Dublin Soc.*, 1922, 17, 19) suggests that fluctuation in atmospheric humidity is probably a very much more important factor than has hitherto been supposed. Thus Adeney finds that the dry gases are absorbed at room temperature about twice as rapidly as the gases saturated with moisture. The reason appears to be that evaporation of water into the dry gas cools the saturated surface layers, which continuously sink or "stream" into the bulk of the liquid, thereby inducing circulation and more rapid aëration.

It is to be anticipated, therefore, that the corrosion of iron,

when completely immersed in water, will be influenced by the rate of solution of oxygen from the atmosphere. This is supported by the fact that when iron plates are suspended in aqueous solutions and allowed to rust, the initial corrosion frequently takes the form of vertical streaks of rust, more or less parallel with one another and extending down the metal. It appeared of interest, therefore, to study the reaction quantitatively. To this end, small plates of mild steel were immersed in water in glass jars connected in series by means of glass tubes. A steady stream of air was drawn through the jars over the surface of the water for varying periods; the air admitted to half of them was saturated with moisture, but before admission to the others it was dried with calcium chloride.

FIG. 1.

At the conclusion of the experiments, the plates were removed, rubbed clean, and weighed, the loss of weight being regarded as a measure of corrosion. It was found that in every case the water exposed to dry air was approximately twice as corrosive as that exposed to air saturated with water vapour, a result in entire harmony with that of Adeney. It would appear, therefore, that if the humidity could be controlled, as well as the pressure and other well-known factors, satisfactory "repeat" results might be obtained.

Adeney, investigating the rates of solution of nitrogen in dilute solutions of sodium chloride, finds that the rate increases to a maximum with about 1 per cent. of sodium chloride, after which it falls (Fig. 1). Owing to evaporation, the surface layers not only

become cooler, but more concentrated, and the density variation is proportionately enhanced.

As the dissolution of nitrogen is a purely physical phenomenon, and oxygen has been found by Adeney to behave just like nitrogen in his other experiments, it seems reasonable to suppose that oxygen would yield a closely similar, if not indeed identical, curve. It now becomes possible, therefore, to offer for the first time a fairly complete and satisfactory explanation of the relative rates of corrosion of iron, immersed in solutions of different salts at varying concentrations. When these are plotted, a curve is obtained like *ACD* (Fig. 1), which may be regarded as typical for the majority of stable salts. The first addition of the salt increases the corrosion, which reaches a maximum at the *critical* concentration, after which it steadily falls. If the fall *CD* is steep, for example, in the case of sodium carbonate, the curve may cut the abscissa axis before saturation is reached, and at all concentrations above this *limiting* concentration the corrosion will be nil. In the majority of cases, saturation is reached before this.

The relative rate of corrosion, *C*, is determined by four main factors :

1. Chemical action of the dissolved salts, χ . With ammonium salts, owing to hydrolysis, this is severe, and *AC* rises steadily. With chlorides and sulphates of the alkali metals, it is relatively small.
2. Solubility of oxygen, β . $C \propto \beta$.
3. Rate of solution of oxygen, *R*. As shown above, $C \propto R$.
4. Rate of precipitation of the corrosion catalyst, namely, colloidal iron hydroxide, by the negative ions, ϕ . This tends to retard corrosion (Friend, T., 1921, 119, 932).

Assuming $C \propto \chi$ and $1/\phi$, we have $C \propto \chi\beta R/\phi$. Of these factors, χ and ϕ are less easily determined than β and *R*. For dilute solutions of sodium chloride, χ and ϕ are small and approximately constant. Hence at any concentration, *m*, of the salt,

$$C_m = \beta_m R_m,$$

where β and *R* are expressed as percentages of the values for distilled water under otherwise identical conditions.

To test this equation, experiments have been carried out in which mild steel plates were suspended by glass hooks in jars containing various concentrations of sodium chloride, and maintained for three weeks at a mean temperature of 14°. The losses of weight were determined after cleaning. The tests were carried out in triplicate to minimise the disturbing effect of the individual variation so characteristic of corrosion phenomena. The results, expressed relatively to the loss in distilled water, were as follow :

NaCl per cent.	0	0.5	1.0	2.0	3.0
Mean relative corrosion...	100	126.7	122.1	102.3	95.4
β *	100	97	94	88.5	85
R †	100	115	136	115	102
Calculated corrosion ...	100	112	128	103	86

* Calculated from MacArthur, *J. Physical Chem.*, 1916, **20**, 495.

† Calculated from Adeney's curve for nitrogen.

These results are shown in Fig. 1.

It will be observed that the curve for the calculated corrosion, *AEF*, closely approximates to that actually found, namely, *ACD*. Complete coincidence is not to be expected. Apart from the fact that χ and ϕ are not absolutely constant, the data for *R* really apply to nitrogen, and to that gas at constant humidity, whereas the humidity of the atmosphere necessarily fluctuated slightly during the protracted corrosion tests. The agreement, however, is too close to be due to mere coincidence, and the above theory may be regarded as substantiated.

If this is accepted, an important corollary follows, namely, that other metals may be expected to yield analogous curves when allowed to corrode under similar conditions. In a series of experiments carried out by Mr. J. S. Tidmus in conjunction with the author, which it is hoped to describe at a later date, this has been proved to be the case.

CCCLVI.—*Alkyl Hypochlorites.*

By FREDERICK DANIEL CHATTAWAY and OTTO GUIDO BACKEBERG.

THE alkyl hypochlorites have been little studied, on account of their explosive properties, since Sandmeyer prepared the first two members of the series (*Ber.*, 1885, **18**, 1767; 1886, **19**, 857). In the present paper, normal and *isopropyl*, primary, secondary, and tertiary butyl, and tertiary amyl hypochlorites are described.

The alkyl hypochlorites are yellow, mobile, volatile liquids of a strong and irritating odour. They give off vapours which attack the eyes and mucous membranes violently.

The primary and secondary hypochlorites are very unstable. When exposed to bright light, they decompose explosively, with production of flame. Even if light is carefully excluded, they decompose rapidly at the ordinary temperature and after leaving for a few minutes boil spontaneously, owing to the heat developed.

The tertiary hypochlorites, on the other hand, are remarkably

stable. *tert*-Butyl hypochlorite, for example, can be distilled without change, and if it is not exposed to bright light may be kept for months at the ordinary temperature with scarcely any decomposition. It is sufficiently stable for its vapour density to be determined by Victor Meyer's method. The molecular weight thus obtained agrees with that determined cryoscopically, and shows that both in the state of vapour and when dissolved in benzene it has the simple formula $(\text{CH}_3)_3\text{COCl}$. This affords additional evidence that the molecular formula of hypochlorous acid is HOCl . The action of the acid on compounds, such, for example, as the sulphonamides, containing hydrogen attached to nitrogen, when this hydrogen is replaced by chlorine with elimination of water, shows that it has the constitution $\text{H}-\text{O}-\text{Cl}$ and contains a chlorine atom united to a hydroxyl group.

When the primary and secondary hypochlorites are kept at a suitable temperature, they decompose quietly and slowly, yielding as primary products aldehydes or ketones. The tertiary hypochlorites undergo a similar decomposition when sufficiently heated or exposed to bright sunlight:

EXPERIMENTAL.

All the alkyl hypochlorites described in this paper were prepared by a slight modification of Sandmeyer's method (*loc. cit.*).

The requisite alcohol (1 mol.) was added to a strong solution of sodium hydroxide (about 2 mols.) and the resulting liquid diluted with water until a clear, homogeneous solution was obtained. This was placed in a long separating funnel jacketed and kept cool by iced water. Light was carefully excluded and the tap-funnel suitably inclined. Chlorine was then passed in beneath the liquid through the tap as long as it was freely absorbed. The insoluble alkyl hypochlorites, which were produced in practically theoretical amounts, separated as they were formed and rose to the surface, where they collected as yellow, mobile layers. When action was complete, they were separated and rapidly dried over fused calcium chloride, being kept as cold as possible during the operations.

When an alkyl hypochlorite is brought into contact with a solution of potassium iodide acidified with acetic acid, iodine is set free quantitatively and the alcohol reformed according to the equation

The estimation of the iodine thus liberated affords a ready method of analysis.

n-Propyl hypochlorite, $\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{OCl}$, is a yellow, mobile liquid with a penetrating and characteristic odour which violently attacks the eyes and mucous membranes (Found: $\text{Cl} = 37.49$. $\text{C}_3\text{H}_7\text{OCl}$ requires $\text{Cl} = 37.51$ per cent.). When exposed to light, it explodes almost at once with a yellow flame. Unless kept very cold and in the dark, it undergoes rapid change. Even if light is excluded, it cannot be preserved at the ordinary temperature. Placed in a small distilling flask and allowed to reach the laboratory temperature, it decomposes quickly with evolution of heat, and after some minutes boils spontaneously. As in other similar decompositions, if this boiling is allowed to proceed unchecked the distillate contains both unchanged hypochlorite and some of the products of the decomposition, the amount of unchanged hypochlorite distilling over varying with the vigour of the decomposition. Hydrogen chloride and propaldehyde are the primary products of its decomposition.

*iso*Propyl hypochlorite, $(\text{CH}_3)_2\text{CH}\cdot\text{OCl}$, is a yellow, mobile liquid even less stable than the normal ester. Indeed, explosions may occur during its preparation if the cooling is inadequate (Found: $\text{Cl} = 36.98$ per cent.). On exposure to light, it immediately explodes, with a yellow flame and deposition of carbon. Even if light is carefully excluded, it can only be preserved for a short time at a low temperature. If the ester is placed in a distilling flask and allowed to assume the laboratory temperature as in the case of the normal isomeride, rapid decomposition and spontaneous ebullition occur. Hydrogen chloride and acetone are the primary products of the decomposition.

n-Butyl hypochlorite, $\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{OCl}$, is a pale yellow, mobile liquid of irritating odour (Found: $\text{Cl} = 32.46$. $\text{C}_4\text{H}_9\text{OCl}$ requires $\text{Cl} = 32.67$ per cent.). When exposed to light, it almost immediately explodes with a yellow flame and the deposition of carbon. If allowed to assume the ordinary temperature, it decomposes and after a few minutes boils spontaneously. The primary products of decomposition are hydrogen chloride and *n*-butaldehyde.

sec-Butyl hypochlorite, $\text{CHMeEt}\cdot\text{OCl}$, is a pale yellow, mobile liquid less stable than its normal isomeride (Found: $\text{Cl} = 31.87$ per cent.). When exposed to light, it explodes with a yellow flame and the deposition of carbon. It can only be kept unchanged even for a brief period at a very low temperature. Allowed to rise to the ordinary temperature, it rapidly decomposes and after a short time boils spontaneously owing to the heat evolved. The primary products of the decomposition are hydrogen chloride and methyl ethyl ketone.

tert-Butyl hypochlorite, $(\text{CH}_3)_3\text{C}\cdot\text{OCl}$, is a pale yellow, mobile

liquid with a characteristic irritating odour. It violently attacks the eyes and mucous membranes. It is very stable, and if protected from bright light can be kept for months at the ordinary temperature with little or no decomposition. It boils at $79.6^{\circ}/750$ mm. and has d_4^{25} 0.9583.

A complete analysis was made, the chlorine being estimated volumetrically as described above and also by Carius's method (Found: C = 43.95; H = 8.44; Cl = 32.67, 32.64. C_4H_9OCl requires C = 44.22; H = 8.35; Cl = 32.67 per cent.). The molecular weight determined by the lowering of the freezing point of benzene was found to be 109.6, and by Victor Meyer's method at 100° , steam being used as the jacketing vapour, 110.9 (C_4H_9OCl requires M = 108.64). When exposed to bright sunlight, *tert.*-butyl hypochlorite decomposes quietly but with considerable evolution of heat, methyl chloride and acetone being the chief primary products.

tert.-Amyl hypochlorite, $CMe_2Et \cdot OCl$, is a yellow, mobile liquid closely resembling the corresponding tertiary butyl compound. It boils with considerable decomposition; a thermometer in the vapour recorded $76^{\circ}/752$ mm., but this cannot, of course, be regarded as a boiling point. It has d_4^{25} 0.8547 (Found: Cl = 28.66. $C_5H_{11}OCl$ requires Cl = 28.90 per cent.). The molecular weight determined by the lowering of the freezing point of benzene was found to be 120 ($CMe_2Et \cdot OCl$ requires M = 122.46). After keeping at the ordinary temperature for two months, the ester was found to be practically unchanged (Found: Cl = 28.30 per cent.). When exposed to bright sunlight, *tert.*-amyl hypochlorite decomposes quietly with evolution of heat, leaving behind a colourless liquid. The nature of this decomposition is being studied. The chief product is acetone, but the decomposition is not a simple one.

The action of chlorine on benzyl alcohol under similar conditions has been examined. Thirty-six grams of benzyl alcohol were dissolved in a solution of 24 grams of sodium hydroxide in 2 litres of water. After cooling, a stream of chlorine was passed in until no further rapid absorption took place. During the passage of the chlorine, drops of yellow, oily liquid rose to the surface and decomposed with a crackling sound such as would be expected from small explosions. Finally, about 33 grams of a nearly colourless oil sank to the bottom of the vessel. This smelt strongly of benzaldehyde, but a slight odour of benzoyl chloride was also recognised. It was separated, washed with water, dried, and distilled. It was found to boil at 178° , and consisted almost entirely of benzaldehyde. It is evident that, as with other primary

alcohols, a benzyl hypochlorite was first formed and immediately decomposed with evolution of hydrogen chloride and formation of benzaldehyde:

THE QUEEN'S COLLEGE, OXFORD.

[Received, October 23rd, 1923.]

CCCLVII.—Yohimbine (Quebrachine). Part III. Esterification of Yohimbic Acid.

By ELLEN FIELD.

IN Part II of this series (Barger and Field, this vol., p. 1038) it was pointed out that no evidence had so far been obtained which permitted of a choice between the formulæ $\text{C}_{22}\text{H}_{28}\text{O}_3\text{N}_2$ and $\text{C}_{21}\text{H}_{26}\text{O}_3\text{N}_2$ assigned to yohimbine by Spiegel (*Ber.*, 1904, 37, 1759) and Fournneau and Page (*Bull. Sci. Pharmacol.*, 1914, 21, 7), respectively. Before proceeding with further work on the constitution of the alkaloid, it appeared desirable to come, if possible, to a definite decision on this subject. The difficulty of distinguishing with certainty between the two formulæ lies in the small differences in their elementary composition. This is well illustrated by the analytical results already published. Thus Spiegel (*loc. cit.*) obtained results for the free base and for its hydrochloride which are in good agreement with the higher formula; those for the nitrate, however, lie midway between the values required for this and the lower formula. In Part I of this series (Barger and Field, *T.*, 1915, 107, 1025) analyses were recorded which agreed well with Spiegel's formula. On the other hand, Fournneau and Fiore (*Bull. Soc. chim.*, 1911, [iv], 9, 846) and Fournneau and Page (*loc. cit.*), in establishing the identity of yohimbine with quebrachine, have analysed the alkaloid itself, as well as a number of its salts, and their results all agree equally well with the C_{21} formula, which, moreover, had previously been assigned to quebrachine by Hesse. In view of the work already done, it seemed obvious that some method other than that of the direct analysis of yohimbine and its salts would have to be adopted to decide the question.

Spiegel (*Ber.*, 1903, 36, 169) has obtained from yohimbine a monobasic acid (yohimbic acid), to the hydrated and anhydrous forms of which he assigns the formulæ $\text{C}_{20}\text{H}_{26}\text{O}_4\text{N}_2$ and $\text{C}_{20}\text{H}_{24}\text{O}_3\text{N}_2$, respectively. Fortunately, the composition of this acid is not in dispute. It is in agreement with the formulæ for anhydroyohimbic acid sulphuric ester, and for apoyohimbic acid hydrochloride established in Part II of this series, and it has further been confirmed in

the present investigation by analysis of the anhydrous form of the acid. Yohimbic acid is readily obtained by hydrolysis of yohimbine with alkalis, and on esterification with methyl alcohol is reconverted into the original alkaloid. Assuming the correctness of the formula for yohimbic acid, it appears on the basis of the C_{21} formula for yohimbine that the alkaloid is the methyl ester of the anhydrous acid. This accords very well with the facts that a Zeisel estimation reveals the presence of only one methoxyl group in the alkaloid, and that the third oxygen atom, as shown in a previous paper, is present in the form of a non-phenolic hydroxyl group. On the basis of the C_{22} formula, however, Spiegel's view must be accepted, that whilst acid (HI) hydrolysis removes only one methyl group, alkaline hydrolysis removes two, and, further, that these are readily replaced by simple esterification. Spiegel (*loc. cit.*) has sought to confirm this view by esterification of yohimbic acid with ethyl, propyl, and isobutyl alcohols, and he claims that two alkyl groups are added in each case. This phenomenon seems sufficiently anomalous to require adequate confirmation, especially as the analyses published by Spiegel in support thereof are not in very good agreement with his claim. It was therefore decided to submit this point to re-examination, with the hope that a final decision between the alternative formulæ for yohimbine would thereby be rendered possible.

A series of esters of yohimbic acid has accordingly been prepared. In each case the analytical results leave no doubt that only one alkyl group has been added. They may therefore be regarded as simple monoalkyl esters of yohimbic acid, and, since there is no apparent reason why esterification with methyl alcohol should take place anomalously, it accordingly follows that yohimbine is the monomethyl ester of the anhydrous form of yohimbic acid, and has the formula $C_{21}H_{26}O_3N_2$ first assigned to it by Fourneau and Fiore. It is therefore proposed to adopt this formula for the alkaloid in future. *apo*Yohimbine will then have the corresponding formula, $C_{21}H_{24}O_2N_2$, and deoxy-yohimbine, $C_{21}H_{26}O_2N_2$.

EXPERIMENTAL.

The yohimbic acid used for the experiments described below was prepared according to Spiegel's method, 10 grams of potassium hydroxide in 100 c.c. of 70 per cent. alcohol being used for each 10 grams of yohimbine. Recrystallised from water, the acid melted at 256° and agreed in all respects with Spiegel's acid of the formula $C_{20}H_{26}O_4N_2$. When this acid was shaken with methyl or ethyl alcohol, it passed rapidly into solution; almost immediately,

however, a crystalline precipitate was rapidly deposited. This was filtered and when recrystallised from methyl or ethyl alcohol melted at 296° and gave analytical results corresponding with Spiegel's yohimbic acid anhydride (*Ber.*, 1905, **35**, 2830) (Found: C = 70.33; H = 7.08. Calc. for $C_{20}H_{24}O_3N_2$, C = 70.59; H = 7.06 per cent.). Evidently the first stage in the esterification of yohimbic acid by these alcohols is the formation of anhydroyohimbic acid (yohimbic acid anhydride of Spiegel). On the other hand, the solutions in propyl and butyl alcohols did not give any separation of anhydrous acid even on standing, and corresponding with this the propyl and butyl esters retain water, the butyl ester, like the isobutyl ester prepared by Spiegel, containing 1 mol. of water of crystallisation, which is removed only after prolonged heating in a vacuum at 70° .

Esterification of Yohimbic Acid.—The methyl and ethyl esters were prepared by suspending 2 grams of yohimbic acid in 20 c.c. of the respective alcohols and saturating with gaseous hydrogen chloride. During this process the solid slowly dissolved, and as the solution cooled the sparingly soluble ester hydrochloride separated in considerable amount. This was removed by filtration and the filtrate evaporated to dryness under diminished pressure. The total solid was then suspended in water, made alkaline with ammonia, and the ester removed by repeated extraction with ether.

The propyl and butyl esters were similarly prepared. In these cases, however, no separation of the ester hydrochloride took place until the alcohols were evaporated. On evaporation of the ether, the esters were obtained in almost pure condition. They were recrystallised in each case from aqueous alcohol.

The *ethyl* ester melted at 190° (Found: in material dried at 120° , C = 71.65; H = 7.61. $C_{22}H_{28}O_3N_2$ requires C = 71.68; H = 7.66. $C_{24}H_{32}O_3N_2$ requires C = 72.66; H = 8.14 per cent.).

The *propyl* ester melted at 137° (Found: in material dried at 110° , C = 71.99; H = 7.85. $C_{23}H_{30}O_3N_2$ requires C = 72.22; H = 7.85. $C_{26}H_{36}O_3N_2$ requires C = 73.52; H = 7.85 per cent.). Loss of water on the air-dried product was 3.54 per cent. $C_{23}H_{30}O_4N_2$ requires H_2O = 4.5 per cent.

The *butyl* ester, hydrated, melted somewhat indefinitely between 119° and 122° . Anhydrous, it melted at 127° (Found: in material dried in a vacuum at room temperature, C = 69.29; H = 7.89. $C_{24}H_{34}O_4N_2$ requires C = 69.57; H = 8.21. $C_{28}H_{42}O_4N_2$ requires C = 71.43; H = 8.99 per cent.). Loss of water on drying over phosphorus pentoxide at 70° in a vacuum = 4.26. $C_{24}H_{34}O_4N_2$ requires H_2O = 4.34 per cent.

The material required for this investigation was purchased with a grant from the Earl of Moray Research Fund of this University, for which grateful acknowledgment is made.

CCCLVIII.—*Studies of Electrovalency. Part III. The Catalytic Activation of Molecules and the Reaction of Ethylene and Bromine.*

By RONALD GEORGE WREYFORD NORRISH.

THE view originally put forward by Arrhenius (*Z. physikal. Chem.*, 1889, 4, 226; 1890, 28, 317) that chemical action is necessarily preceded by a process of molecular activation has found extensive support from many authors, and is considered to be necessary to explain the high temperature coefficient exhibited by most reactions. Although there are many diverse views as to the mechanism by which molecular activation may be brought about, many authors appear to be agreed upon one point, namely, that it involves an absorption of energy by the molecule, so that the activated form is in a more highly energised state than the non-reactive, resting form.

In this connexion, however, there is one important fact of chemical reactivity which, up to the present, does not appear to have received the consideration it merits, namely, the fact that even the most reactive substances become inert upon complete desiccation, and will then regain completely their lost activity by the addition of a trace of some polar substance.* In other words, all chemical

* Only a few of the best established cases are quoted here. On desiccation the following reactions are suspended:

$2\text{CO} + \text{O}_2 = 2\text{CO}_2$	Dixon, <i>Phil. Trans.</i> , 1884.
$2\text{NO} + \text{O}_2 = 2\text{NO}_2$	Baker, T., 1894, 65, 611.
$2\text{H}_2 + \text{O}_2 = 2\text{H}_2\text{O}$	Dixon, <i>Phil. Trans.</i> , 1884; v. Meyer, <i>Ber.</i> , 1883.
$\text{H}_2 + \text{Cl}_2 \xrightarrow{\text{Light}} 2\text{HCl}$	Mellor and Russel, T., 1902, 81, 1272.
$\text{K} \text{ or } 2\text{Na} + \text{O}_2 \longrightarrow \text{Na}_2\text{O}_2 \text{ or } \text{K}_2\text{O}_4$..	Holt and Simms, T., 1894.
$2\text{Na} + \text{Cl}_2 \longrightarrow 2\text{NaCl}$	Wanklyn, <i>Chem. News</i> , 1869, 20, 271.
$\text{HCl} + \text{NH}_3 = \text{NH}_4\text{Cl}$	Baker, <i>loc. cit.</i>
$\text{NH}_4\text{Cl} = \text{NH}_3 + \text{HCl}$	" "
$\text{CaO} + \text{SO}_3 = \text{CaSO}_4$	Veley, T., 1892.
$\text{CaO} + \text{CO}_2 = \text{CaCO}_3$	Huges, <i>Phil. Mag.</i> , 1893.
$\text{H}_2\text{S} + \text{metallic salts} = \text{metallic sulphides}$..	Huges and Wilson, <i>Phil. Mag.</i> , 1892.
$2\text{HCl} + \text{CaCO}_3 = \text{CaCl}_2 + \text{H}_2\text{O} + \text{CO}_2$..	

Most of the above reactions are quoted in an appendix given by Baker at the end of his paper on the influence of moisture on chemical change (*loc. cit.*). For a further bibliography, see Mellor and Russel, T., 1902, 81, 1272.

reactions appear to be catalytic in nature. Except in the case of a few truly thermal decompositions of solids or liquids such as potassium chlorate, silver oxide, and lead acetate, the formation of ozone by the electric discharge, and possibly some unimolecular photochemical decompositions, this loss of reactivity on desiccation would appear to be a general rule of chemical reactivity, and, if accepted as such, it necessitates a revision of our views of activation; the resting form of a molecule must be a far more inert substance than hitherto supposed, and require the association of some polar molecule before activation can take place. When we remember that the main characteristic of a polar molecule is its strong unbalanced field of force, it appears very probable that its function as a catalyst is to weaken, by close association, the intra-molecular forces of the resting molecule, and to render it more easily disintegrable.

We may thus consider those molecules which have formed a close association with molecules of the catalyst to be at any rate partly activated, inasmuch as *they alone* are capable of any further chemical action. Whether this is the complete stage or only a preliminary stage of activation it is not proposed to consider here, but there would appear to be no difficulty in the explanation of all the phenomena of chemical reactivity by the kinetic theory coupled with this view of activation alone, and without recourse to other hypotheses, as, for example, the "radiation theory."

The catalytic effect of traces of polar substances on gaseous reactions is only one manifestation of a much more general phenomenon, and it may be said that whenever any strong local disturbing force can be applied to a molecule, so as to distort its stable configuration, that molecule becomes more vulnerable to attack. Thus the very numerous class of reactions which take place in solution probably owe their existence to the action of the solvent, which exerts a weakening effect on the internal molecular forces of the solute, that may result, in extreme cases, in complete ionisation. Again, the phenomena of surface catalysis, and surface reactions, are manifestations of the same nature, and owe their existence to the high electrical fields of force which must exist unbalanced at the surfaces of most solids and liquids, and result in the adsorption and weakening of the structure of the reactant molecules.

We may thus regard molecular activation as occasioned by a definite change of configuration or distortion of the molecule, brought about by close association with some polar catalyst. Such a change of configuration must take place with the absorption of energy, and thus the activated molecules will be in a more highly energised state than the resting molecules.

These views are in harmony with those developed by Lowry in his work on the electronic theory of valency. In a comparative study of the reactions of unsaturated organic compounds (this vol., p. 832), he has drawn the conclusion that substances containing the double bond usually react as if one of the bonds were a covalence and the other an electrovalence. On this basis, the formation of ethylene dichloride from ethylene and chlorine involves an unsymmetrical instead of a symmetrical process of activation thus:

$\text{CH}_2=\text{CH}_2$ and $\text{Cl}-\text{Cl}$ give $\overset{+}{\text{C}}\text{H}_2-\overset{-}{\text{C}}\text{H}_2$ and $\overset{+}{\text{Cl}}\ \overset{-}{\text{Cl}}$ as an intermediate stage, rather than $-\text{CH}_2-\text{CH}_2-$ and 2Cl^- . The chlorine is here represented as being broken into two ions instead of two neutral atoms, in the disruption which must precede or accompany its attachment to the ethylene. The unsymmetrical rupture or opening out of the double bond of the ethylene gives rise to an analogous process of intramolecular ionisation, since the two charged atoms are not free but bound. The final interaction between the two activated molecules is then reduced to a mere neutralisation

of opposite ions. It differs from the union of $\overset{+}{\text{Ag}}$ with $\overset{-}{\text{Cl}}$ mainly in that the ions yield covalent bonds on neutralisation instead of undissociated ionic pairs. The analogy between the development of an electrovalence on the one hand and the process of activation on the other is so complete as to suggest that the two phenomena are identical.

The view set forth above, that molecular activation is a catalytic process of a polar character, is susceptible of direct experimental testing in the case of the gaseous reaction of ethylene and bromine, which has been investigated by Stewart and Edlund (*J. Amer. Chem. Soc.*, 1923, 45, 1014). These two authors have shown that (1) ethylene and bromine at 0° , when dry, do not react together in the gaseous phase, but only on the glass walls of the container, and (2) there is no indication of a preliminary gaseous reaction such as might be expected if a few of the ethylene and bromine molecules were already activated in the gaseous phase.

So far, these experiments are completely in accord with the hypothesis that activation of the ethylene molecule is due to polarisation induced in the ethylene molecule by association with some polar catalyst; but they are also capable of being explained on a merely physical basis, for example, by adsorption of the two gases on the surface of the glass, without reference to the chemical character of that surface.

It is, however, evident that if dry ethylene and bromine could be enclosed in a vessel with *completely non-polar* walls, it might be possible, if the above hypothesis of polar activation is correct, to

retard the reaction very greatly, or even to suppress it altogether, although it is by no means certain that in all cases such a suppression could be looked for. The results which are contained in the experimental section of the paper must be taken as strong confirmatory evidence in favour of this hypothesis. It has, for instance, been found that on enclosing the dry gases by a vessel the interior of which is coated with stearic acid, the reaction proceeds even more quickly than when the glass walls are bare, whilst, when paraffin wax is substituted for stearic acid, the reaction practically ceases to take place. Now the work of Hardy (Fourth British Association Report on Colloid Chemistry, 1922, 185. Also *Proc. Roy. Soc.*, 1922, [A], 86, 610), Harkins (*J. Amer. Chem. Soc.*, 1917, 39, 354, 541), and Langmuir (*Met. Chem. Eng.*, 1916, 15, 468; *J. Amer. Chem. Soc.*, 1917, 39, 1848) has led us to regard the former of these two substances as a particularly polar molecule, whilst the paraffins constitute probably the best approach to a completely non-polar substance. Thus, in spite of their great physical similarity, a stearic acid surface brings about the combination of bromine and ethylene, whilst a paraffin wax surface does not, and this difference in their behaviour can only be attributed to difference of polarity in the surfaces of the two substances occasioned by the marked chemical differences between their molecules.

EXPERIMENTAL.

The method of experiment consisted in bringing equivalent quantities of pure dry ethylene and pure dry bromine, by way of separate delivery tubes, into the reaction chamber at 0°, and, after allowing the gases to stream through for some minutes, shutting all the stop-cocks, and observing the rate of change of pressure in the reaction chamber by means of a paraffin manometer.

The pressure of the bromine was arranged to be less than that of the vapour pressure of liquid bromine at the temperature of the experiment, and that of the ethylene was made approximately equal to that of the bromine, so that the gases were present in the reaction chamber as approximately equivalent quantities. This was done by diluting the two gas streams with dry air, free from carbon dioxide.

Preparation of the Pure Ethylene.—The ethylene was prepared by the action of sulphuric acid on ethyl alcohol, the evolved gas being passed through a purification train composed as follows: (1) Empty flask immersed in a freezing mixture at -15°. (2) Woulfe bottle, containing water and fitted with a pressure release. (3) Three wash-bottles containing concentrated caustic soda solution. (4) A soda-lime tower. (5) A tube cooled by solid carbon dioxide and

ether. Twelve litres of the gas were collected and stored in an aspirator over dilute caustic soda solution.

Preparation of Pure Bromine.—The bromine used was distilled twice from potassium bromide, and twice from phosphoric oxide, in an all-glass apparatus, the middle fraction, boiling at $61.5-62^\circ$, being collected on each occasion. It was finally distilled directly into the saturator in which it was stored during the experiment. This saturator consisted of three small wash-bottles with shortened delivery tubes made all in one piece as shown in Fig. 1(a). To obtain a stream of dry bromine at the desired pressure, it was only necessary to aspirate a stream of dry carbon dioxide-free air through the saturators cooled to the temperature at which bromine has a vapour pressure equal to the pressure required.

FIG. 1.

In Fig. 1 (b), the general arrangement of the apparatus is sketched. Pure ethylene was stored in the aspirator, C, and displaced by way of the taps O and F by running in the caustic soda solution from E. The three-way tap, F, enabled accurate volumes of ethylene to be measured by means of the gas burette, G, and introduced by way of the two-way tap, I, into a known volume of carbon dioxide-free air stored over caustic soda solution in the 6-litre aspirator, A, which was calibrated to 50 c.c. In this way, the ethylene could be diluted to a known partial pressure. The 6-litre aspirator, B, contained carbon dioxide-free air, stored over caustic soda solution. The gases in A to B could be displaced by way of the taps I and V by running in the caustic soda solution from the 12-litre aspirator, D, to which both were connected. This method of connecting both A and B to the same aspirator ensured that the head of liquid displacing the gases was the same for both aspirators. The gas streams from A and B passed through two identical purifying and drying

trains, composed as follows: *H,H*, wash-bottles containing concentrated soda; *J,J*, wash-bottles containing concentrated sulphuric acid; *K,K*, and *M,M*, U-tubes containing granulated calcium chloride; *L,L*, U-tubes containing soda-lime; *N,N*, long U-tubes (each limb being 1 foot in length) containing phosphoric oxide sprinkled on glass wool.

After issuing from the phosphoric oxide drier, *N*, the air stream from *B* passed through the bromine saturator, *P*, cooled by a freezing mixture to the requisite temperature. The two gas streams, the one consisting of bromine diluted with air to a known partial pressure and the other of ethylene equally diluted, now passed through the spiral coolers, *Q,Q*, immersed in the thermostat, *T*, and in this way were brought to the temperature of the thermostat; they then finally entered the reaction chamber, *R*, by way of the stopcocks *X* and *Y*, and, mixing therein, were allowed to stream through the apparatus at the rate of about 150 c.c. per minute. Finally, the stopcocks *X* and *Y* were rapidly closed, then the exit tube of the reaction chamber (not shown in the diagram), and the rate of change of pressure on the paraffin manometer, *U*, was recorded every half minute or minute. The thermostat was filled with a mixture of half ice and half water, and kept rapidly stirred by means of the stirrer, *S*. The temperature under these conditions never departed from 0° by more than 0.1°.

In Fig. 2 the reaction chamber is shown in detail. Two of these, of about 300 c.c. capacity and identical in size and shape, were employed, so that comparative experiments with different wall coatings could be rapidly carried out under the same conditions. The gas streams entered by the tubes *C* and *D* by way of the stopcocks *X* and *Y*, and the effluent gases passed out at *Z*. The tube *A* was connected by a paraffin wax-coated tube with the manometer, whilst the tube *B* was used for inserting either liquid paraffin wax or other substance with which the walls were to be coated. The process of coating the walls was carried out as follows: the whole apparatus was heated at about 60° in an oven, a thistle funnel with a narrow stem being inserted through the tube *B*, and passing to the interior of the vessel. About 20 grams of clear melted paraffin wax were then run into the vessel, and the whole was vigorously

shaken in order to wet the tubes *C* and *D* with wax; the apparatus was then carefully turned round and round as the wax solidified, forming a uniform coating on the interior of the vessel; finally, the tube *B* was closed with a gas-tight plug of paraffin wax. With a little practice, vessels could be easily coated in this way with either paraffin wax, stearic acid, or cetyl alcohol. The stopcocks were carefully cleaned to remove any solidified wax, and then lubricated with a little vaseline.

The bromine saturators were immersed in a cooling bath maintained by ice and salt at -15° . At this temperature, bromine has a vapour pressure of 23.5 mm. and thus the stream of air contained

FIG. 3.

3 per cent. of bromine vapour by volume. The composition of the ethylene-air mixture was regulated to 3 per cent. of ethylene by volume, and the partial pressures of bromine and ethylene in the reaction chamber, when the two gas streams were regulated to equal flow rates, were therefore each approximately $23.0/2 = 11.5$ mm. of mercury. Complete combination of ethylene and bromine would thus occasion a total fall of pressure of about 23 mm. of mercury in the bulb.

In Fig. 3, examples are given of the experimental curves obtained when the fall of pressure is plotted against time, whilst in Table I (in which p = diminution of pressure measured in cm. of paraffin, x = fraction of total reaction completed, and k = bimolecular reaction coefficient), the data of a number of experiments are given,

in which the walls of the reaction vessels consisted of glass, stearic acid, paraffin wax, and cetyl alcohol, respectively. The figures shown under p in the table are not observed values, but in order to effect economy of space in tabulation were read off from curves (of which Fig. 3 is a fair sample), constructed from the experimental values.

Discussion of Results.

It will be seen from Fig. 3 that the diminution of pressure approaches asymptotically to a maximum value which corresponds to the completion of the reaction. If we denote this asymptotic value by a , and the diminution of pressure in the vessel at any time, t minutes, after the commencement by p , then it follows that the fraction of the ethylene or bromine which has reacted at time t , as compared with that present at the commencement, when $t = 0$, is given by $x = \frac{p^{1/2}}{a^{1/2}}$, since a equals the sum of the initial partial pressures of the two reactants, which were present in equivalent quantities.

Hence, if the reaction follows a bimolecular law, as observed by Stewart and Edlund,

$$dx/dt = k'(1 - x)^2 = k(a - p)^2, \text{ where } k = 2k',$$

whence $k = 1/t \cdot p/a(a - p)$.

In the table, x and k have been tabulated beside the corresponding values of p , and it will be seen that the relative constancy of k confirms the statement of Stewart and Edlund that the reaction is bimolecular.

It is of interest to note that in the case of the paraffin wax surface (Fig. 3) the reaction shows an induction period of about one minute duration, during which no change of pressure is observed. This observation is of importance, as it suggests that *no reaction* whatever takes place at the *paraffin* surface. The subsequent action may be a result of diffusion of the reactants through cracks in the wax to the underlying glass surface, since initially a certain time would elapse before the reactants reached the glass, giving rise to the period of induction observed. This explanation is corroborated by the observation that in most cases the jagged outline of the main cracks in the wax was marked by the ethylene bromide formed therein, coloured by dissolved bromine. On account of this induction period, the values of the bimolecular velocity coefficient for the paraffin wax reactions have been calculated from the point $t = 1$ and not $t = 0$, as is the case for the others. Incidentally the induction period serves to emphasise the great difference in the catalytic activity of the paraffin surface and the other polar surfaces.

Thus in the case of the glass surface the reaction is approximately half completed at the end of the first minute, whilst the paraffin wax reaction has not even commenced.*

There is one possible source of error in the above experiments which has not yet been mentioned, namely, the possibility that the coating of the wall may of itself adsorb or react with either the bromine or ethylene in quantity, thus causing a "fictitious" reduction of pressure. This possibility was tested and eliminated by a series of blank experiments, in which one only of the reactants (ethylene or bromine) was enclosed in the reaction vessel. It was found that in no case was a diminution of pressure observed when ethylene alone was enclosed in the reaction vessel. In the case of bromine, small reductions were observed both for paraffin wax and stearic acid, but these diminutions of pressure were so slow and of such an order as not to reduce the reaction coefficients by more than 1 per cent. in either case.

TABLE II.

Values of bimolecular reaction coefficient when walls of reaction vessel are coated with

Number of expt.	Glass.	Stearic acid.	Paraffin wax.	Cetyl alcohol.
1	0.0587	0.0723	0.0025	0.0258
2	0.0553	0.0711	0.0020	0.029
3	0.0493	0.0932	0.0023	0.0272
4	0.0393	0.1092	0.0052	
Mean k =	0.0506	0.0864	0.0030	0.0266

The most interesting feature of these results is the variation in the bimolecular reaction coefficient with the nature of the inner coating of the reaction vessel. Table II, in which the velocity coefficients have been collected, shows that insulation of the glass surface by the non-polar paraffin wax slows the reaction down to about one-seventeenth of its original velocity in the glass vessel, whilst a stearic acid coating increases the velocity. A cetyl alcohol surface is not so active as either a stearic acid or a glass surface in promoting the reaction, but is ten times more effective than a paraffin wax surface. It is probable that had the drying of the gases been more complete, and the paraffin wax surface free from small cracks which admitted the reacting gases to the glass surface beneath, the

* The difference is really even more marked, for during the time taken to close the stopcocks, an appreciable fraction of the reaction is completed, in the case of the stearic acid, glass, and cetyl alcohol surfaces, and is never measured by the pressure diminution. Thus at $t = 0$ the concentrations of ethylene and bromine in contact with the above three surfaces are about 0.8 times their concentration in contact with the paraffin wax surface. To this is due the higher values of the asymptote α observed in the case of paraffin wax.

reaction velocity in the paraffined vessel would have been even less than that observed. To a similar cause we may attribute the variation of the velocity coefficient for a given surface. The variation of rate of flow of the gases through the drying train and reaction chamber would inevitably affect the state of desiccation of the gases and thus cause secondary variation of the bimolecular coefficients for different experiments. The mean values of the bimolecular velocity coefficient for the four experiments are collected at the bottom of Table II, and they place the catalytic efficiency of the surfaces investigated in a certain order. It will be observed that this order is independent of the particular velocity coefficient chosen from the experimental figures to represent the surface, so that these variations are only of secondary importance.

It is thus evident that the velocity coefficient of this reaction is a function of the chemical character of the walls of the containing vessel, and it should be possible to use the reaction as a measure of the polarity of surfaces, by a development of the accuracy of the method employed above. Such a comparative study of the polarity of a number of different surfaces with reference to their chemical constitution should yield many interesting results.

A very simple demonstration of the non-reactivity of dry bromine and ethylene gases in contact with a non-polar surface was obtained as follows: The two gases, purified, dried, and diluted with air as already described, were passed by way of separate paraffin wax-coated tubes into a tightly corked paraffined test-tube. Thence the gas stream, after slow mixing in the paraffined tube, passed into a clean glass test-tube, provided also with an outlet tube. The whole system was immersed in an ice-bath. It was found, on passing about 2 litres of 4 per cent. bromine-air mixture and 2 litres of 4 per cent. ethylene-air mixture through the apparatus in forty-five minutes, that no ethylene dibromide was formed in the paraffined tube (except for a trace where the wax was cracked), whilst about 0.25 gram of liquid ethylene dibromide collected at the bottom of the glass test-tube.

The importance of the experimental results recorded in this paper is considered to lie in the fact that they provide evidence of a new character in favour of the theory that molecular activation is not only of a catalytic character, but consists in an induced polarisation of the reactant molecules by association with some polar catalyst, either in the gaseous, surface, or liquid phase. They also confirm Lowry's deduction that molecules of unsaturated compounds may exist both in a non-polar "resting form" and in a polar reactive form, and further show that the conversion of the former into the latter may be brought about by a polar catalyst.

This phenomenon is probably purely electrical in character, consisting simply in the production of an electrovalence from a covalence by a displacement of one of the electrons constituting the double bond, under the action of the electrical field of the catalyst.

Summary.

(1) The hypothesis is advanced that molecular activation is at any rate partly a catalytic process consisting in the polarising of the reactant molecule by association with the molecule of a polar catalyst, either in a gaseous, surface, or liquid phase.

(2) This is supported by the fact that complete desiccation of reactants suspends reaction in the great majority of the cases investigated.

(3) Lowry's view that the molecules of unsaturated organic compounds which are unreactive in their resting form may become reactive by developing an electrovalence in the double bond, for example, by contact with some polar substance (gaseous or otherwise), is a special form of this hypothesis in which the complete ionisation of the bond is postulated.

(4) The hypothesis is tested experimentally by investigation of the reaction of ethylene and bromine. It is shown that the dried gases practically cease to react when enclosed by "non-polar" walls of paraffin wax, but that they react rapidly when enclosed by a "polar" surface of glass, stearic acid, or cetyl alcohol.

(5) The reactivity of the gases as measured by the bimolecular velocity coefficient varies with the chemical nature of the enclosing surface, being greatest for stearic acid, the substance which may be considered the most polar of those investigated.

(6) On passing dry ethylene and bromine diluted with air through a paraffined tube, and then through a glass tube, no ethylene dibromide was observed in the paraffined tube, whilst about 0.3 gram collected in the glass tube.

(7) These results are considered as evidence in favour of the contention that molecular activation is normally associated with a process of catalytic polarisation.

The author is indebted to Professor T. M. Lowry for suggesting this problem for research. He wishes to thank him and Dr. E. K. Rideal for their sympathetic interest in the course of the work. His thanks are also due to the Department of Scientific and Industrial Research for a maintenance grant which has made the work possible.

CCCLIX.—*Cadmium Sulphide and the Estimation of Cadmium.*

By ALFRED CHARLES EGERTON and FRANK VICTOR RALEIGH.

THE observations recorded in this paper were made during some work on the vapour pressures of cadmium-zinc alloys, and were the outcome of an attempt to obtain a quick method of analysis of the alloys by precipitation of cadmium as sulphide. This in turn led to some observations of the behaviour of cadmium sulphide. So this note divides itself into two sections, analytical, and some qualitative observations on cadmium sulphide.

Analytical.—The two metals are separated by precipitation of the cadmium as sulphide under definite conditions. The cadmium is estimated as sulphide (containing a fixed quantity of a complex salt), and the zinc is precipitated from the filtrate according to the usual method.

Fresenius (*J. pr. Chem.*, 1858, **73**, 241) advised double precipitation of the cadmium in order to remove zinc which may be carried down with cadmium sulphide, but when small quantities of zinc are present this seems to be unnecessary. It has, indeed, not been found to be necessary even when fairly large amounts of zinc are present at the dilutions employed in this work (for example, alloy 2).

The conditions under which satisfactory results are obtained are as follows. A solution of about 0.2 gram of the alloy in the least quantity of concentrated hydrochloric acid is neutralised with ammonia, diluted to 100 c.c., and then acidified with 4 c.c. of concentrated hydrochloric acid in order to give the solution a fixed acidity. The solution, heated at 80°, is saturated with hydrogen sulphide and the orange-red, granular precipitate of cadmium sulphide is collected in a Gooch crucible, washed well with a definite quantity of water, dried at 110–120°, and weighed. The filtrate is examined for zinc and estimated by the ammonium phosphate method. Under these fixed conditions, the composition of the cadmium sulphide obtained appears to be sufficiently constant. The method, moreover, is quick, and does not entail redissolving the sulphides or converting to sulphate or phosphate—operations which require time and provide opportunity for losses which are important when dealing with small quantities.

If the precipitate so obtained is treated as being pure cadmium sulphide, the results would work out from 2 to 3 per cent. too high. Treadwell ("Quantitative Analysis," 1st edn., p. 151) states that cadmium sulphide is not pure, but contains a basic salt, $\text{CdS} \cdot \text{CdCl}_2$. The presence of such a salt would account for high results. The

amount of chlorine in several samples of precipitated cadmium sulphide estimated by means of silver nitrate was: (1) 3.61, (2) 3.46, (3) 3.64 per cent. These results serve to show that the percentage of chlorine present in the precipitated cadmium sulphide is constant when the conditions under which the precipitation is carried out are maintained the same.

A calculation made on the basis that the cadmium sulphide contained the salt $\text{CdS}, \text{CdCl}_2$ from the above figures showed that this salt ought to be present to the extent of 8.16 per cent. of the whole. The weight of the precipitate corresponding to 112.4 grams of the cadmium would therefore be 147.4 instead of 144.47 for pure cadmium sulphide.

Experiments made with pure cadmium (redistilled in a vacuum as a check on the method) gave the following results :

Gram of cadmium taken (W).	Gram of sulphide.	Weight calculated $\left(\frac{147.4}{112.4}\right)W$.	Cd per cent.
0.10944	0.14350	0.14350	100.00
0.10425	0.13686	0.13670	100.11
0.10820	0.14205	0.14190	100.10

These figures justify the use of the value adopted for the molecular weight of the precipitate, which evidently has a constant composition provided the precipitation is carried out under the same conditions.

The alloys made to the approximate composition given below were analysed by the above method with the following results (zinc was estimated by the phosphate method) :

Alloy.	Approximate composition.	Analysis.		
		Cd.	Zn.	
1	72 : 28	71.45	28.55	100.00
2	60 : 40	59.89	40.09	99.98
3	80 : 20	80.18	19.97	100.16
4	90 : 10	90.66 90.75	9.86 8.43	100.32 99.18
5	65 : 35	64.76 64.74	34.35 34.63	99.10 99.37

The values for the zinc were not in satisfactory agreement in the case of alloys 4 and 5, owing to the small quantity of zinc present in the solution (about 0.02 gram); it will be noted, however, that the cadmium results agree well in the two separate analyses for each of these alloys.

It follows from the above results that the separation of cadmium as sulphide in a 4 per cent. acid solution at the dilution chosen is sufficiently complete to make double precipitation unnecessary.

The errors which would be so introduced would be greater than those due to possible incompleteness of precipitation.

Cadmium Sulphide.—During the course of this work, certain observations were made on cadmium sulphide. Allen, Crenshaw, and Merwin (*Amer. J. Sci.*, 1912, **34**, 341) have described similar results, so we find, in their work on the "Crystalline Forms and Genetic Conditions of Zinc, Cadmium, and Mercury Sulphides," but in view of recent work on lead oxide (Glasstone, T., 1921, **119**, 1689, 1914) and Applebey and Reid (T., 1922, **121**, 2129), it may be of interest to record some of the observations made.

Cadmium sulphide can be obtained in an orange-red and in a yellow form. The yellow form is obtained when a solution of cadmium, to which a small quantity (2 c.c. per 100 c.c. of solution) of strong hydrochloric acid has been added, is saturated with hydrogen sulphide. The suspended precipitate changes to red on heating and turns yellow again on rapid cooling. Under similar conditions, the same volume of concentrated sulphuric acid will yield an orange precipitate, which deepens colour on heating but returns to the light orange shade on cooling. The red form (or orange-red) is obtained when the cadmium sulphide is precipitated hot (80°) from such a sulphuric acid solution or one containing twice the volume of hydrochloric acid. The yellow is also obtained when alkaline sulphides are employed in the cold, also from alcoholic solutions. If the yellow sulphide is maintained wet in the presence of hydrogen sulphide, it becomes orange.

Follenius first noted this difference of colour of precipitated cadmium sulphide, but ascribed it to impurities such as chloride and sulphate of cadmium carried down with the sulphide. Buchner (*Chem. Ztg.*, 1887, **11**, 1087) and Beng (*ibid.*, p. 536; 1891, **15**, 329) considered, on the contrary, that cadmium sulphide was pure and existed in two forms, the yellow and the red. Klobukow (*J. pr. Chem.*, 1889, [ii], **39**, 413) stated that the densities of the two modifications were slightly different. The following experiments were made to investigate the behaviour of these two varieties of cadmium sulphide.

(1) Analytical results gave the same composition for the red and yellow sulphides.

(2) On heating, the dried yellow sulphide changes to the red shade and on cooling it returns to the yellow shade again. On heating the red, the colour tends to deepen, but on cooling changes to yellow. The change is not monotropic.

(3) The yellow form was heated in air on a strip of platinum, the resistance of which served to measure the temperature. The strip could be viewed under the microscope while heating. The

sulphide appeared to deepen to orange at 120° and to red between 310° and 340°. Above 400°, the sulphide commenced to decompose and blacken. There was no definite transition point marking the colour change.

The particles do not appear, under a high power magnification, to alter as to state of aggregation when changing colour. The smaller the aggregates, however, the less their colour seems to change. The yellow variety is generally composed of smaller particles than the red.

(4) Examined with a spectroscope, the light reflected from the red variety shows absorption of violet and blue and to some extent of green light; that of the yellow reflects more green, but otherwise no difference was observed.

(5) Rubbed in a mortar, the yellow form goes dark ochre-orange and remains that colour. Examined under the microscope, the general effect is that the smallest particles this time have become the darkest. On heating the rubbed material, it darkens and on cooling returns to an ochre-yellow, not a lemon-yellow.

(6) Dry cadmium sulphide can be vaporised by heating in a vacuum and condenses in the lemon-yellow form, which changes to the red on heating.

Midst the complicated phenomena exhibited by oxides, sulphides, etc. which occur in differently coloured varieties, the following properties seem to be in common in those cases which have been proved to show poly- or di-morphism.

(1) *Mode of Formation*.—The more strongly alkaline the solution from which the substance is precipitated, the greater the amount of stable form produced. Acid solutions tend to give the unstable form. This is the case for lead oxide (Applebey and Reid, *loc. cit.*; Ruer, *Z. anorg. Chem.*, 1906, **50**, 225; and others), for mercury sulphides and zinc sulphides (see Allen and Crenshaw, *loc. cit.*), also for mercury oxide, etc.

(2) *Behaviour towards Heat*.—When it is heated dry, the stable form changes over to unstable, thus red to yellow monoxide, or red to yellow mercuric iodide. The transition is often characterised by a very small energy change, making observation of a transition point difficult. The reverse change is slow even in the case of wurtzite (ZnS) at 1020° (Allen and Crenshaw).

(3) *Behaviour on Crushing*.—The unstable forms give the stable forms on crushing.

Differences of solubility, of density, and of crystalline form are apt to lead to erroneous conclusions, unless the different forms are obtainable in the pure state.

Alongside these definite conclusions we can compare the behaviour of cadmium sulphide.

(1) The yellow form is obtained from alkaline or cold solutions, the orange from hot or acid solutions.

(2) The yellow goes to the orange-red on heating, the reverse change taking place readily on cooling.

(3) The yellow changes to a dark orange on crushing.

The first and second observations would lead by analogy to the conclusion that the yellow is composed mainly of the stable form and the red of the unstable, if such different forms exist. On the other hand, the behaviour of the sulphides is akin to the behaviour of lead oxide described by Glasstone (*loc. cit.*), of mercury oxide by Ostwald (*Z. physikal. Chem.*, 1900, **34**, 495), and of precipitated mercuric sulphide by Allen and Crenshaw (*loc. cit.*). The colour change is ascribed by these workers to difference in state of aggregation, the larger particles being generally associated with the deeper colour. Allen and Crenshaw's work and the observations here described seem to support the view that size of particle and change of absorption of the light with temperature could together account for the observed change of colour of cadmium sulphide. The yellow would change to red on heating because the general absorption would extend further towards the red on rise of temperature.

There are difficulties, however, in this view. In each of the other cases (PbO, HgO, and probably HgS), definite dimorphism has been proved and the colour changes can be ascribed to partial change of one form into the other. It is probable enough that changes of state of aggregation in the case of the amorphous precipitates would affect the colour even granting they are mixtures of two definite forms. The evidence, however, is conflicting. Applebey and Reid found that the red form of lead monoxide had a smaller particle, while Glasstone considered the red form to be larger than the yellow particles obtained by crushing, and if the red form of cadmium sulphide is produced by agglomeration, the change to the yellow colour of lead monoxide cannot be well ascribed to the same cause.

In the case of cadmium sulphide and mercuric sulphide (below 325°), the colour is very easily reversed by simply heating and cooling, whereas with the pure lead monoxide and mercuric oxide (Schoch, *Amer. Chem. J.*, 1903, **29**, 319) the changes are probably monotropic, indicating perhaps a different cause for the change of colour.

Allen and Crenshaw found that mercury sulphide became permanently black at 445°, due to a thin coating of the black form (HgS). They ascribed change of colour below this temperature to increase of light absorption with temperature, but may not this increase be also

due to changes within the molecule which imply momentary formation of the other form? In spite of many unsuccessful efforts to prepare a pure crystalline unstable red form of cadmium sulphide, it seems quite possible that it may be capable of existence.

Summary.

(1) A constant proportion of cadmium chloride in cadmium sulphide obtained under certain conditions of precipitation renders possible estimation of cadmium as sulphide.

(2) Observations on the yellow and red forms of cadmium sulphide are discussed.

CLARENDON LABORATORY, OXFORD.

CCCLX.—*The Vapour Pressure of Cadmium and its Alloys with Zinc.*

By ALFRED CHARLES EGERTON and FRANK VICTOR RALEIGH.

APART from measurements of the vapour pressures of mercury amalgams, the effect of one constituent of a binary alloy upon the vapour pressure of the other does not appear to have been investigated quantitatively. This paper is an account of some preliminary work undertaken to investigate the mutual influence of metals on the properties which determine their vapour pressures.

In the case of molten alloys, two completely miscible metals the molecules of which influence each other in the same way as they influence themselves in respect of the domain occupied and the forces acting between them, may be expected to obey Raoult's law, the vapour pressure of the mixture being simply dependent on the concentration of the constituents. If these influences are different

the vapour pressure of the mixture being simply dependent on the lead to further complication. In some cases, as has been shown by Berry (*Proc. Roy. Soc.*, 1911, **86**, A, 67), the compound itself will vaporise. If these complications do not enter, then departures from Raoult's law should provide means of determining constants which would depend on the mutual forces between the atoms of the respective metals.

In the case of solid eutectics, the change of surface concentration would render measurements of vapour pressure very difficult. Vanstone (*T.*, 1910, **97**, 429) showed that the vapour pressure of

two miscible solids (camphor and borneol) followed the ordinary mixture law.

In this work, which follows on that by Egerton on the vapour pressure of cadmium, zinc, and mercury (*Phil. Mag.* 1917 [vi], **33**, 33; 1920, [vi], **39**, 1), two metals, namely, cadmium and zinc, were used, one of which (zinc) is hardly vaporised at the temperature used compared with the other. The experiments carried out on pure cadmium agree with the results previously obtained in apparatus arranged differently: it has therefore been possible to check again the values of the chemical constant. For the alloys, it appears that Raoult's law is obeyed, and it is probable that the interatomic forces between the atoms of cadmium and zinc are not very different from those between the atoms of cadmium alone.

EXPERIMENTAL.

The vapour pressure was measured by the method of effusion through a hole into a high vacuum. The apparatus used has been described by Egerton (*Proc. Roy. Soc.*, 1923, [A], **103**, 469). The same selenium cell temperature control was employed and the average range of temperature variation for experiments 1—15 of the alloy series was $\pm 0.27^\circ$. The iron-constantan thermo-couple was standardised several times during the course of the experiments against the standard platinum-platinum-rhodium couple. A borosilicate glass tube and a pot of slightly different shape (so as to hold about 10 grams of metal) were used instead of the quartz tube and small pots. It was necessary to have a fairly large amount of alloy, otherwise its composition would change appreciably during the experiment. The area of the hole in the lid of the conical-shaped pot was measured in the same manner as before, and was about 1 mm. in diameter. A disk of mica was placed inside, on which metal deposited which would otherwise have condensed on the upper portions of the tube. The deposit had to be analysed in order to correct for the density of the vapour, and this disk was necessary to prevent loss of metal. The weight of metal vaporised was ascertained by weighing the pot before and after the experiment, as in the work on the vapour pressure of lead, to which reference should be made for other experimental details.

At the end of the experiment, the alloy in the pot was dissolved in acid and analysed. Knowing also the composition and the weight of the metal vaporised and deposited in the tube, the composition of the alloy at the beginning of the experiment was calculated. A mean of these two values was taken as being the composition of the alloy for that particular experiment. The alloys were made in quantities of at least 100 grams at a time from cadmium (99.9 per cent.

purity) and zinc (99.99 per cent.) by melting the requisite quantity of zinc in a graphite crucible and adding the cadmium with stirring.

The method employed for estimating the cadmium in the alloys is described in the preceding paper (this vol., p. 3019). The approximate compositions of the alloys investigated were: 90Cd,10Zn; 80Cd,20Zn; 72Cd,28Zn; 65Cd,35Zn; 60Cd,40Zn. The actual compositions are given in the table of results (see Table I).

(Photomicrographs were made of the various alloys showing the change of structure with increase in percentage of zinc.)

Vapour Pressure of Alloys.—The vapour pressures of the cadmium and zinc alloys have been measured at two temperatures, namely, 295.1° and 303.7°. It appears that the vapour pressures in the molten state obey Raoult's law. The straight line drawn in the graph represents the values to be obtained if Raoult's law held.

FIG. 1.

The points obtained by experiment are shown. Raoult's law is obeyed within the error so long as the molten metal is in the base of the pot and the temperature is above that at which a solid condensate can deposit. When the temperature and the composition are such that a solid alloy may be present in the pot,* the equilibrium in the pot is disturbed and the vapour pressure seems to have become near that for the metal with the higher vapour pressure. The method is not applicable to the measurement of the vapour pressures of solid alloys, as the surface concentration is changed by the vaporisation of the more easily vaporised component.

Margules's equation cannot be usefully applied in this case.

* An alloy containing 60 per cent. of cadmium melts at 309°, so that it is solid at the above temperatures; an alloy containing 70 per cent. of cadmium melts at 293° and remains liquid during the measurements (see Lorenz and Plumbridge, *Z. anorg. Chem.*, 1913, **83**, 232; Bruni and Sandonnini, *ibid.*, 1912, **78**, 273; Hindrichs, *ibid.*, 1907, **55**, 417). The pure metals crystallise out from the alloys; no compounds or mixed crystals are formed. The eutectic (82.5 per cent. of cadmium) melts at 263°.

TABLE I.

Ex. Alloy.	Time (mins.).	Weight. Gram.	$W_1 + W_2$	Temp.	Vapour pressure $\times 10^{-2}$.	Log P.	Composition (% Cd).	Composition of vapour (% Cd).

TABLE II.

<i>Cadmium.</i>				Log P from pre- vious results.	
Ex.	Time (mins.).	Weight. Gram.	Resistance. $W_1 + W_2$	Mean temp.	Vapour pressure $\times 10^{-2}$.
1	388.86	0.03867	197.09	249.9°	-2.32
2	358.8	0.07107	197.09	262.4	-2.01
3	475.8	0.01357	197.09	225.4	-2.87
4	180.0	0.24345	238.53	303.7	-1.08

The equations are given by Porter (*Trans. Faraday Soc.*, 1921, 16, 336) in the form

$$\begin{aligned}\log \pi &= \log \pi_{\text{Cd}} + \log \mu_a + \beta(1 - \mu_a)^2 \\ \log \pi &= \log \pi_{\text{Zn}} + \log(1 - \mu_a) + \beta(\mu_a)^2\end{aligned}$$

where π is the vapour pressure of the alloy, π_{Zn} and π_{Cd} are the vapour pressures of zinc and cadmium at the same temperature, μ_a is the molecular concentration, and β is a constant depending on forces of attraction and repulsion between the unlike atoms in the alloy. In this case, $\beta = 0$ and the expression reduces to that of Raoult.

It is interesting to compare this result with the work that has been done on amalgams. Ramsay (*T.*, 1889, 55, 521) first studied the vapour pressure of amalgams; he concluded that "the atoms of metals were identical in solution with the molecule." He observed, however, departures from the law of Raoult, the lowering of vapour pressure being sometimes greater and sometimes less than expected. Hildebrand and his co-workers (*J. Amer. Chem. Soc.*, 1913, 35, 501; 1914, 36, 202; 1915, 37, 2452; 1920, 42, 542) have measured the deviation from Raoult's law for many amalgams (Au, Bi, Cd, Tl, Zn, Pb, and Sn). In some cases the deviations appear to be attributable to association (Zn), sometimes to compound formation (Cd, Hg), but more often (Pb, Sn) to the causes indicated in van Laar's theory of binary mixtures (*Z. physikal. Chem.*, 1910, 72, 723). This theory takes into account the volumes occupied by the solute and solvent molecules and the heat change on mixing; Raoult's law then only holds when molecules of the solute can move about in the same way in the solvent as in the solute itself and can escape from it as easily. Hildebrand found that only in the case of the dilute silver amalgam Raoult's law accorded with the experimental measurements. He considers (*J. Amer. Chem. Soc.*, 1916, 38, 1452) that the law is only obeyed when the internal pressure of the solute is the same as that of the solvent metal. In our case, therefore, it would follow that the internal pressure of cadmium is much the same as that of zinc at the temperature investigated, as is indicated by their compressibilities and expansion coefficients at lower temperatures.

Vapour Pressure of Cadmium.—The results obtained in this work for the vapour pressure of cadmium are in general agreement with the results previously obtained by Egerton (*Phil. Mag.*, 1917, [vi], 33, 33). Small quartz pots were used in the first three experiments. In experiment 4, a large glass pot was used and the result is not in close agreement with the others owing to lack of temperature equilibrium within the pot.

It is satisfactory that these measurements in a differently arranged apparatus support the results obtained in the work carried out at South Kensington in 1914, for the latter observations have been used by one of the authors (*Phil. Mag.*, 1920, [vi], **39**, 1) and also by Heidhausen (*Z. Elektrochem.*, 1921, **27**, 69) for the calculation of the chemical constant of cadmium. It is of importance to have confirmation of the theoretical deduction that $C = 1.5 \log M + C_0$, and it was shown in the papers cited that agreement was obtained within the experimental error. Since then the results of the careful work by Braune (*Z. anorg. Chem.*, 1920, **111**, 109) on the vapour pressure and specific heat of molten cadmium and zinc have been published, from which he also has calculated their chemical constants.

FIG. 2.

Measurements carried out by Ruff and Bergdahl (*ibid.*, 1919, **106**, 76) appear to be of less value from the point of view of consistency and accuracy. The graph (Fig. 2), reduced from a large-scale plot, indicates the measurements which have been made on the vapour pressure of cadmium and zinc: $\log P$ is plotted against the reciprocal of the temperature.

The vapour pressure of the solid plotted in this way is a straight line which cuts, as it should, the vapour pressure curve of the liquid at the melting point, so that the work of Braune on the liquid is in close agreement with that obtained by the authors for the solid.* The vapour pressure of cadmium has thus been accurately

* Bennewitz (*Ann. Physik*, 1919, **59**, 193) has measured the rate of evaporation from a clean surface of cadmium and obtains the ratio of the apparent pressure to the saturation pressure extrapolated from the measurements by

observed over the range 10^{-5} mm. to 10^3 mm. and appears to agree with the equations

$$\log P = -\frac{5891}{T} + 6.053 \text{ for the solid (Egerton)}$$

and

$$\log P = -\frac{5763}{T} + 1.28 \log T + 12.282 \text{ for the liquid (Braune).}$$

In Table III are given the values deduced by Heidhausen from Egerton's results, the observed results, and the results calculated from the straight line through the points given by the above equation; also the comparison of the results obtained by Braune and by Egerton by extrapolation in opposite directions to the melting point.

TABLE III

(m. p.).				

The specific heat of cadmium is not known with certainty at very low temperatures.* Braune takes the value 147 for β , similar to the value used by Egerton; both figures were calculated from Lindemann's melting-point formula using rather different suppositions. Heidhausen gives 172, showing that this figure agrees best with the specific heat measurements of Dewar at low temperatures and of

Liebig. The following table shows that his experiments are in very much better agreement on the basis of the author's values than on that of the extrapolated values he assumed to be correct. The omission coefficient becomes unity:

Temp.	Bennewitz- Liebig.	Bennewitz- Egerton.	The value obtained for mercury was 0.808. Knudsen has shown that if the metal is perfectly clean the coefficient becomes 1, but the slightest trace of impurity (grease, etc.) will reduce the value enormously.
198.5°	0.42	0.91	
203.8	0.39	0.78	
213.3	0.36	1.21	
234.5	0.65	1.10	
Mean	0.45	0.98	

* Recent measurements at low temperatures by Rodebush (*J. Amer. Chem. Soc.*, 1923, 45, 1413) confirm those of Dewar and support the higher value of β adopted by Heidhausen and Schrödinger.

Wüst at higher temperatures. Schrödinger, in a critical survey (*Physikal. Z.*, 1919, 20, 450), from Griffith's and Ewald's measurements deduces a similar figure, 168.

Chemical Constant of Cadmium.—The following are the values of the constant calculated from the experimental data: Egerton 1.65, Heidhausen 1.52, Braune 1.54,* Theory $(3.076-1.589) = 1.487$. Using Braune's vapour pressure measurements and the value for β_v experimentally determined (168), the constant has the low value 1.36; on the other hand, using the present author's results, $\lambda_{T_m} = 26484$ instead of Braune's $\lambda_{T_m} = 26370$, and the same value (168) for β_v , the constant becomes 1.41. Either the experimental value of β_v is a little high or λ is not quite high enough to obtain exact agreement—for this, λ_0 would have to be 27124 cal. and $\lambda_{T_m} = 26680$ cal., taking the mean (Braune, Egerton) value of $p_{T_m} = 0.105$ mm., and $C_p = f\left(\frac{168}{T}\right) + 1.22 \times 10^{-3}T$. The experimental work which has been done on this point clearly demonstrates that C lies between 1.5 and 1.4; in fact, the theoretical figure is well confirmed.

Chemical Constant of Zinc.—The few measurements made on the vapour pressure of zinc (see Fig. 2) during this work were not in quite such good agreement with those previously obtained; they were all higher to the same extent and the values do not agree so well with Braune's result. The error is probably a degree or two in the temperature measurements. It is unnecessary to discuss these further, as the experiments are being repeated. It is important to obtain an accurate measure of the vapour pressure of zinc, for the uncertainty in the value of the specific heat is less than in the case of cadmium. The line representing the vapour pressure of zinc deduced by Heidhausen from Egerton's previous measurements does not cut the Braune curve exactly at the melting point; on the other hand, the following, $\log P = -6997.7/T + 6.403$, agrees more closely with the observed results and satisfies Braune's value at the melting point. Both Egerton and Braune took 235 as the value of β_v , whereas Heidhausen takes the later value of Nernst, 228. This makes the constant slightly greater. The values calculated are 1.23 (Egerton), 1.108 (Heidhausen), 1.114 (Braune). If Braune's values are combined with the later value of β_v (228), the value obtained is 1.19. The theoretical value, 1.134, lies between these last figures.

Taking into consideration the constant calculated from the vapour pressure of mercury and of argon, the theoretical deduction

* The figures quoted by Braune (*loc. cit.*) which lead to his figure for the constant 1.54 appear to add to 1.558 and not 1.54; a recalculation, however, of the separate figures leads to a result, 1.543, confirming his conclusion.

of the constant of a monatomic substance is being well supported by experiment.

Summary.

(1) The vapour pressures of molten cadmium and zinc alloys have been measured at two temperatures and Raoult's law is found to rule.

(2) Measurements of the vapour pressure of cadmium are critically studied and the value for the chemical constant of cadmium has been confirmed and agrees closely with the theoretical value.

CLARENDON LABORATORY, OXFORD.

[Received, August 25th, 1923.]

CCCLXI.—*Products of the Destructive Distillation of Sodium Anthraquinone-1- and -2-sulphonates.*

By ARTHUR GEORGE PERKIN and WILLIAM GAWAN SEWELL.

IN a communication of 1885 (A. G. and W. H. Perkin, T., 47, 679) it was shown that on dry distillation sodium anthraquinone-2-sulphonate yielded anthraquinone, 2-hydroxyanthraquinone, and a sparingly soluble, orange-red compound (compound A), apparently free from sulphur, to which the formula $C_{28}H_{14}O_6$ was assigned. This substance, characterised by the magenta colour of its sulphuric acid solution, gave anthracene by distillation with zinc dust, and by alkali fusion, alizarin. With cold nitric acid (d 1.5), it was oxidised to the colourless substance, $C_{28}H_{14}O_7$, which yielded a brownish-yellow, crystalline salt with aniline and when fused with alkali was in part converted into alizarin and in part reduced to the compound $C_{28}H_{14}O_6$. Oxidation with chromic acid gave the compound $C_{28}H_{14}O_8$ or $C_{14}H_6O_4$, and this also, by alkali fusion, gave alizarin. More recently, the suspicion again arose that the substance $C_{28}H_{14}O_6$ contains sulphur and especially so as it closely resembles in properties 2:2'-dianthraquinonyl sulphide (D.R.P. 255591, 1912). A trace of the original preparation being available, it was re-examined, and although by means of barium chloride and nitric acid, as on the previous occasion, no sulphur could be detected, the sodium nitroprusside test proved it to be present. There was therefore little doubt that the compounds designated as $C_{28}H_{14}O_6$, $C_{28}H_{14}O_7$, and $C_{28}H_{14}O_8$ consisted, respectively, of a dianthraquinonyl sulphide, $C_{28}H_{14}O_5S$, the sulfoxide, $C_{28}H_{14}O_6S$, and the sulphone, $C_{28}H_{14}O_8S$, and these formulæ are in full agreement with the many carbon and hydrogen analyses given in the original paper. In the earlier experiments, the "silver" salt,

contained in an iron tube, was placed between the bars of an old-fashioned grate containing a hot fire, but in the present investigation a combustion furnace only was available. Curiously enough, this slower-heating process gives a distillate much more difficult to separate into its constituents than was formerly the case, and it has only been possible, after very numerous experiments, to obtain the compound $C_{28}H_{14}O_8$?, now known to be $C_{28}H_{14}O_4S$, pure enough to give analytical numbers similar to those obtained originally. This difficulty, it has been found, is due to the fact that a considerable quantity of the hitherto unknown 2:2'-dianthraquinonyl ether (I) is present,

and although this substance is even more sparingly soluble than the substance $C_{28}H_{14}O_4S$, its marked tendency to form super-saturated solutions has rendered its complete separation from the latter, by fractional crystallisation, practically impossible.

Examination showed that this oxide is readily hydrolysed to 2-hydroxyanthraquinone by the action of baryta or weak alkali at 180° , and by means of stronger alkali is converted into alizarin. This hydrolysis, it was ascertained, takes place less easily in the case of the compound $C_{28}H_{14}O_4S$ (*loc. cit.*), and by carefully making use of this method of preferential hydrolysis the latter substance was eventually obtained free from the oxide, and found to melt at 289° .

The anthraquinone oxides previously described are the 1:2'- (D.R.-P. 216268, 1909) and the 1:1'-derivative (D.R.-P. 283482, 1915), the former being prepared from 1-chloro- and 2-hydroxy-anthraquinones, sodium acetate, and copper powder in presence of boiling nitrobenzene.

In preparing the 2:2'-derivative from the 2-chloro- and 2-hydroxy-anthraquinones in a similar way, it was found that a much higher temperature is necessary, and the combination is best effected by using 2-chloroanthraquinone as solvent at 250 — 260° . The 2:2'-compound can thus be obtained in good yield and is identical with that present in the distillation products of sodium anthraquinone-2-sulphonate.

The anthraquinonyl sulphide, melting at 289° , corresponds with the 2:2'-compound described in D.R.-P. 255591, 1912, but the melting point is there given as 275 — 276° . Adopting the method

of preparation there recommended, it was, however, ascertained that the 2:2'-sulphide (II) in reality melts at 290.5–291° and is, without doubt, identical with the substance (A) obtained, as above stated, from sodium anthraquinone-2-sulphonate by distillation.

From the synthetical 2:2'-sulphide, by means of fuming nitric acid and chromic acid in presence of acetic acid, the *sulphoxide*, $\text{SO}(\text{C}_{14}\text{H}_7\text{O}_2)_2$, and the *sulphone*, $\text{SO}_2(\text{C}_{14}\text{H}_7\text{O}_2)_2$, not hitherto described in the literature, were respectively obtained.

These compounds were again prepared from the 2:2'-sulphide obtained from the distillation of sodium anthraquinone-2-sulphonate, and they corresponded exactly in their properties with the compounds " $\text{C}_{28}\text{H}_{14}\text{O}_7$ " and " $\text{C}_{28}\text{H}_{14}\text{O}_8$ " described in the former communications. Interesting is the fact that the sulphoxide, as was originally noted, gives a coloured, crystalline salt with aniline, and, as it has now been found, with allied bases; the *o*-toluidine compound, $\text{C}_{28}\text{H}_{14}\text{O}_5\text{S}, \text{C}_7\text{H}_7\text{N}$, forming lustrous orange-red needles. These salts, which are not given by the sulphone and are decomposed by dilute acid, boiling alcohol, or by heating at 140° and above, with regeneration of the sulphoxide, may, it is suggested, contain the grouping $\text{NHPh} \cdot \overset{\cdot}{\underset{\cdot}{\text{S}}} \begin{smallmatrix} \text{H} \\ \text{O} \end{smallmatrix}$.

The sulphone cannot give such compounds because there the sulphur is sexavalent.

* As was formerly ascertained, the sulphoxide, on fusion with alkali, is in part reduced to the sulphide with the simultaneous formation of alizarin, and it has now been found that in certain cases it behaves as an oxidising agent; thus, for example, when it is boiled with commercial acetic acid or dimethylaniline, an almost quantitative production of the sulphide occurs. The sulphoxide itself has now been isolated from the product of the distillation of sodium anthraquinonesulphonate, so that the distillate obtained by the method given above consists essentially of 2-hydroxyanthraquinone, 2:2'-dianthraquinonyl ether, the 2:2'-sulphide, the 2:2'-sulphoxide, and anthraquinone. The reactions involved in the formation of 2:2'-dianthraquinonyl ether and the 2:2'-sulphide during the distillation would appear to consist in the production, in the first place, of 2-hydroxyanthraquinone and anthraquinone 2-mercaptan, 2 mols. of the former yielding the oxide,

and 1 mol. of each, or 2 mols. of the latter, yielding the sulphide:

Experiment has shown that whilst potassium anthraquinone-2-sulphonate on destructive distillation gives some quantity of the 2:2'-sulphide, the corresponding ammonium and aniline salts give, under these conditions, merely anthraquinone. On the other hand, the distillate from sodium anthraquinone-1-sulphonate contains, in addition to anthraquinone, a trace of 1-hydroxyanthraquinone, but no 1:1'-sulphide is present. This difference between the behaviour of the sodium 1- and 2-sulphonates may be due to the higher decomposition temperature of the former. Preliminary experiments have been made on the preparation of the anthranol (III) of 2:2'-dianthraquinonyl sulphide,

and a crystalline acetyl compound, apparently derived from this substance, is described in this paper.

EXPERIMENTAL.

Commercial sodium anthraquinone-2-sulphonate in quantities of 100 grams, contained in a copper tube welded at one end and into the aperture of which was screwed a copper pipe bent at right angles, was destructively distilled by means of a combustion furnace. The distillate condensed in a large flask averaged 35 per cent.

In the earlier experiments of the present investigation, the distillate, freed from 2-hydroxyanthraquinone by means of dilute alkali, was extracted repeatedly with boiling acetic acid, 27 fractions being thus obtained. Fractions 1 to 7 consisted mainly of anthraquinone, whereas fractions 8 to 19 formed orange needles, which melted at about 276° and were soluble in sulphuric acid with a magenta coloration. Fractions 11, 12, and 14 contained, respectively, 5.65, 5.64, and 5.52 per cent. of sulphur, whereas fraction 18 gave C = 72.67; H = 3.54 per cent., the latter figures being very different from those formerly obtained (*loc. cit.*; C = 75.25; H = 3.38 per cent.) for the substance $C_{28}H_{14}O_6$?. Recrystallisation from pyridine revealed the presence of two compounds, a mixture of needles and leaflets being thus obtained, the latter being present in much larger amount in the fractions 20 to 27. As fraction 25, which melted at 312°, gave by analysis but 1.96 per cent. of sulphur, it appeared evident that the main constituent therein was free from sulphur. A complete separation of these two compounds by

this method, however, proved to be impossible and the employment of acetic acid and xylene, as solvents, was now studied.

From 150 grams of the distillate, 7 grams of 2-hydroxyanthraquinone were removed and subsequently, by seven extractions employing in each case 600 c.c. of boiling acetic acid, 55 grams of nearly pure anthraquinone were obtained. By means of boiling xylene the residue was now separated into 6 fractions:

			M. p.	Coloration with H_2SO_4 .
1	28 grams	Non-crystalline	266—271°	Red magenta
2	15.5 "	" "	276	" "
3	13.4 "	Needles	280	Magenta
4	5.2 "	Needles and leaflets	313	Red brown
5	5.0 "	" "	over 315	" "
6	1.0 "	Leaflets	" "	Yellow brown

Isolation of 2:2'-Dianthraquinonyl Ether.—Fractions 4, 5, and 6 (11.2 grams) were repeatedly extracted with boiling acetic acid until the residue (8.7 grams) melted at 314—317°. Finally, after numerous crystallisations from pyridine, the product, at first a mixture of plates and needles, was obtained as yellow needles melting at 326°. These were very sparingly soluble in all solvents and dissolved in sulphuric acid with a yellowish-brown coloration (Found: C = 77.9; H = 3.51. $\text{C}_{28}\text{H}_{14}\text{O}_5$ requires C = 78.1; H = 3.26 per cent.).

This compound, suspected to consist of 2:2'-dianthraquinonyl ether (I), was heated under pressure with baryta water at 180—200° for eight hours. The product, diluted with water, on neutralisation deposited dull yellow flocks, which were extracted with dilute alkali. Addition of baryta water to the extract caused the deposition of the barium derivative of alizarin, which was removed and the filtrate acidified. The yellow precipitate gave an acetyl compound melting at 158°, and consisted, without doubt, of 2-hydroxyanthraquinone.

After numerous trials, this hitherto unknown compound was prepared in bulk as follows: A mixture of 2-chloroanthraquinone (15 grams), 2-hydroxyanthraquinone (7.5 grams), anhydrous sodium acetate (6 grams), and copper powder (3 grams) was gradually heated with stirring from 230° to 250—260° during twelve hours. To avoid charring the mass, which must remain throughout of necessity in the fluid condition, the temperature is kept as low as possible. The dark-coloured product was extracted with benzene to remove 2-chloroanthraquinone, then with water to remove sodium salts, and was subsequently freed from copper powder by decantation (yield 10 grams or 66 per cent.). It melted at 324° after repeated crystallisation from pyridine, and was identical

with 2:2'-dianthraquinonyl ether isolated from the distillate. From dilute pyridine solutions it is deposited in boat-shaped crystals, from stronger solutions in pale yellow needles (Found: C = 78.24; H = 3.49 per cent.).

By means of cold nitric acid (*d* 1.5), in which it slowly dissolves, this oxide yields at least two crystalline nitro-derivatives, one sparingly soluble in acetic acid and melting at about 278°, and the other more easily soluble and melting at about 290°.

Isolation of 2:2'-Dianthraquinonyl Sulphide.—For this purpose, the xylene fraction 1 referred to above was first employed. From this, by repeated crystallisation, employing successively benzaldehyde, dimethylaniline, and acetic acid as solvents, a further amount of the dianthraquinonyl ether was removed, and 1 gram of the more pure sulphide, melting at 284°, isolated. This, however, still contained some of the oxide, the complete removal of which could only be effected by the action of alkali solution at a higher temperature.

The substance (0.5 gram), rendered colloidal by solution in sulphuric acid and reprecipitation with water, was heated in a small iron autoclave with caustic soda (7 grams) in water (18 c.c.) at 185° for six hours. The product, diluted with water, was acidified, filtered, the residue washed with dilute alkali to remove alizarin, and finally crystallised from acetic acid. It was thus obtained in lustrous, orange-red needles melting at 289°, and it possessed the properties of the compound $C_{28}H_{14}O_6$ * described in the earlier communication (*loc. cit.*) (Found: C = 75.14; H = 3.28; S = 6.68. Calc. for $C_{28}H_{14}O_4S$, C = 75.31; H = 3.16; S = 7.18 per cent.).

Further amounts of this substance, evidently 2:2'-dianthraquinonyl sulphide (II), were obtained in the same way from the xylene fractions 2 and 3 described above. To identify this compound with certainty, 2:2'-dianthraquinonyl sulphide was prepared by a modification of the method given in the patent (D.R.-P. 225371), which proved to be the most suitable for laboratory use.

A mixture of 2-chloroanthraquinone (60 grams), potassium xanthate (60 grams), copper powder (1 gram),† and amyl alcohol (600 c.c.) was heated at the boiling point for sixteen hours with thorough stirring, it being of advantage to add an additional 5 grams of 2-chloroanthraquinone every four hours. After removal

* The average of the five analyses of this substance given in the former paper is C = 75.25; H = 3.38 per cent.

† The employment of copper powder, not mentioned in the patent, was found to be important.

of unattacked 2-chloroanthraquinone by means of benzene, the residue was repeatedly crystallised from xylene. The product (30.8 grams) melted at $290.5\text{--}291^\circ$, and not at $275\text{--}276^\circ$, as is stated in the patent (Found: C = 75.3; H = 3.29; S = 7.23. Calc. for $\text{C}_{28}\text{H}_4\text{O}_4\text{S}$, C = 75.31; H = 3.16; S = 7.18 per cent.).

A mixture of this preparation with the sulphide obtained by the distillation of sodium anthraquinone-2-sulphonate melted at $290\text{--}291^\circ$.

2 : 2'-Dianthraquinonyl Sulphoxide.—2 : 2'-Dianthraquinonyl sulphide was dissolved in cold nitric acid ($d\ 1.5$), and the solution poured into water. The colourless product was crystallised first by solution in hot aniline, followed by the cautious addition of hot alcohol, and finally from acetic acid. It formed small, colourless needles melting at 261.5° , and was identical with a preparation obtained in the same manner from the sulphide isolated from the distillate (Found: C = 72.9; H = 3.1; S = 7.06. $\text{C}_{28}\text{H}_{14}\text{O}_4\text{S}$ requires C = 72.7; H = 3.05; S = 6.94 per cent.).

This compound, evidently the sulphoxide, is that originally designated as $\text{C}_{28}\text{H}_{14}\text{O}_7$, which, as shown in the former communication, gave on analysis C = 73.01; H = 3.45 per cent.

By prolonged digestion with boiling commercial acetic acid or dimethylaniline, it is reconverted into the sulphide, which crystallises on cooling, and therefore is evidently a powerful oxidising agent. By the action of strong aqueous sodium hydroxide at $180\text{--}200^\circ$, it yields alizarin and the sulphide.

The *o*-toluidine salt, $\text{C}_{28}\text{H}_{14}\text{O}_5\text{S}\cdot\text{C}_7\text{H}_7\text{N}$, separated in orange needles on addition of benzene to a hot solution of 2 : 2'-dianthraquinonyl sulphoxide in *o*-toluidine. It was collected and washed with benzene. Heated at 140° , it is reconverted into the sulphoxide, and it is slowly decomposed by contact with boiling alcohol, or more quickly by means of dilute acid.

To a suspension of 0.4500 gram of the salt in water, a little hydrochloric acid was added and the mixture boiled for five minutes. There was thus obtained 0.3656 gram of sulphoxide or a loss of weight of 18.76 per cent., the theoretical loss for 1 mol. of *o*-toluidine being 18.80 per cent.

The orange-brown *aniline* salt and pale brown *p*-toluidine salt decompose, respectively, when heated, at 190° and 150° .

2 : 2'-Dianthraquinonyl sulphoxide is itself present to a small extent in the distillate from sodium anthraquinone-2-sulphonate, and was isolated from the xylene fraction 1, above referred to. This, by solution in hot commercial benzaldehyde, on cooling deposited crystals of the impure sulphide, which were removed, and from the filtrate, on keeping, pale yellow needles separated. These,

after recrystallisation, melted at 263° (Found: C = 72.52; H = 3.15 per cent.). The identity of this compound with the sulphoxide was confirmed by a mixed melting-point determination. As a proof of its actual recurrence in the distillate, it was ascertained that no conversion of the sulphide into sulphoxide occurs, even after a prolonged treatment of the former with boiling commercial benzaldehyde.

2 : 2'-Dianthraquinonylsulphone.—This compound, to which the formula $C_{28}H_{14}O_8$ or $C_{14}H_6O_4$ was originally given (Found: C = 70.35; H = 3.15 per cent.), is obtained by digesting a solution of either the sulphide or sulphoxide in boiling acetic acid with chromic acid. The yield is almost quantitative, 2.8 grams of the sulphone being produced from the sulphide (2.5 grams), acetic acid (250 c.c.), and chromic acid (30 grams). It crystallises from acetic acid in colourless needles melting at 303.5° (Found: C = 70.45; H = 3.13; S = 6.55. $C_{28}H_{14}O_6S$ requires C = 70.27; H = 2.95; S = 6.71 per cent.).* The sulphoxide is here the first product of the oxidation of the sulphide, and it can be thus prepared by the action of a minimum of chromic acid on a very dilute glacial acetic acid solution of this substance.

Reduction of 2 : 2'-Dianthraquinonyl Sulphide.—When the sulphide in the colloidal condition was digested with a boiling solution of stannous chloride in hydrochloric acid, reduction ensued, but was incomplete. By heating, however, the sulphide (1 gram) with stannous chloride (10 grams) and hydrochloric acid (10 c.c.) in a sealed tube at $140-150^{\circ}$ for five hours, a pale yellow product resulted. This yielded an *acetyl* derivative, which crystallised from acetone in pale yellow needles melting at $198-205^{\circ}$ (Found: C = 76.7; H = 4.7. $C_{32}H_{22}O_4S$ requires C = 76.5; H = 4.4 per cent.). Apparently, therefore, this compound consists of the diacetyl derivative of dianthranol-2 : 2'-sulphide (III).

On the other hand, by reducing the sulphide with aluminium powder and sulphuric acid in the usual manner, and acetylating the product in the presence of pyridine, a compound which crystallised in yellow needles was obtained. This gave the same figures on analysis (C = 76.75; H = 4.24 per cent.), but possessed no definite melting point. The examination of these compounds is reserved for further study.

1 : 1'-Dianthraquinonyl Sulphide.—This substance, which accord-

* Estimations of sulphur in both the sulphoxide and sulphone by the Carius method were unsatisfactory, some insoluble matter being invariably present after the operation. The process finally adopted consisted in the use of sodium peroxide (5 grams) and potassium hydroxide (10 grams) at 80° for one hour, and subsequent fusion.

ing to the literature has hitherto been prepared by the interaction of 1-chloroanthraquinone with anthraquinone 1-mercaptan, can be more readily obtained in the laboratory by the xanthate method. A mixture of 1-chloroanthraquinone (4 grams), potassium xanthate (4 grams), copper powder (0.5 gram), and amyl alcohol (40 c.c.) was boiled for twenty-four hours. After removal of 1-chloroanthraquinone, and crystallisation of the residue from pyridine, red, rectangular prisms melting at 321.5° were obtained (yield 2.35 grams). No melting point of this compound appears in the patent (D.R.-P. 274357, 1911), which merely states that it dissolves in sulphuric acid with an olive-green colour (Found: C = 75.54; H = 3.24; S = 7.16. Calc. for $C_{28}H_{14}O_4S$, C = 75.31; H = 3.16; S = 7.18 per cent.).

1:1'-*Dianthraquinonyl sulphoxide* is readily obtained from the 1:1'-sulphide by means of nitric acid (*d* 1.5) and crystallises from acetic acid in orange needles melting at 309.5° . It gives a yellow coloration with sulphuric acid (Found: C = 72.64; H = 3.1. $C_{28}H_{14}O_5S$ requires C = 72.69; H = 3.05 per cent.). It resembles the 2:2'-sulphoxide, and gives with aromatic bases coloured salts. The *o*-toluidine compound forms small, red needles, which at about 200° become colourless, with evolution of *o*-toluidine.

1:1'-*Dianthraquinonylsulphone*, prepared from the sulphide or sulphoxide by means of chromic acid, forms yellow needles melting at 321° and is soluble in sulphuric acid with a yellow coloration (Found: C = 70.39; H = 3.08. $C_{28}H_{14}O_6S$ requires C = 70.27; H = 2.95 per cent.).

In the anticipation of obtaining 1:1'-dianthraquinonyl sulphide from sodium anthraquinone-1-sulphonate, 58 grams of the latter were destructively distilled and yielded 15 grams of a greenish-yellow product. This consisted of anthraquinone admixed with a small amount of 1-hydroxyanthraquinone, no sulphide being present.

The distillates obtained from both ammonium and aniline anthraquinone-2-sulphonates (Perkin and Sewell, *J. Soc. Chem. Ind.*, 1923, 42, 277) consist almost entirely of anthraquinone.

CCCLXII.—*The Relationship between Colour and Constitution in the Nitrobenzaldehydehydrazones.*

By FREDERICK DANIEL CHATAWAY and GEORGE ROGER CLEMO.

THE brilliant colour of many of the nitro-substituted hydrazones,* the existence of a large number in polymorphic modifications, and the exceptional beauty of the crystals give to these compounds a peculiar interest. Those containing a nitro-group in the ortho- or para-position in the aldehyde residue generally have an intense red colour, varying from scarlet to garnet-red, the ortho-compound as a rule showing a more orange shade than its para-isomeride. On the other hand, those containing the nitro-group in the meta-position are almost † without exception orange or yellow, for example,

Bright scarlet prisms.

Bright yellow prisms.

Deep scarlet prisms.

The scarlet or red colour of these compounds is associated with the crystalline state only, since it differs in shade in polymorphic modifications and since all the nitrobenzaldehydehydrazones without exception give pure yellow solutions on sufficient dilution.

The presence of negative substituents in the hydrazine residue as a rule † without effect on the yellow colour of the *m*-nitrobenzaldehyde compounds, but affects markedly the colour of their ortho- and para-isomerides.

This influence depends in a striking manner on the position of the substituent. Thus, a substituent in the ortho-position causes the red colour to become more orange, whilst the presence of two substituents in the ortho-position causes the red or scarlet colour to disappear, a yellow hydrazone being obtained alike in the ortho-, meta-, or para-series.

* Hydrazones containing other substituting groups are generally colourless or pale yellow.

† The presence of a nitro-group in the ortho-position of the hydrazine residue gives rise to red *m*-nitrobenzylidene derivatives. Thus, *m*-nitrobenzaldehyde-*o*-nitrophenylhydrazone exists in bright scarlet prisms.

The following series of halogen-substituted hydrazones illustrate the general influence of substitution in the hydrazone residue.

By comparison with this marked effect of ortho-substitution on the colour of the crystals, meta-substitution exerts only a slight influence.

Thus

All the nitro-substituted benzaldehydehydrazones show a characteristic and distinctive behaviour towards alkalis.

Speaking generally, when a saturated solution of potassium hydroxide in alcohol is added to an alcoholic solution of a nitro-substituted benzaldehyde primary hydrazone, if the nitro-group is in the aldehyde residue in the ortho-position a vivid green, in the meta-position a brown, and in the para-position a brilliant cobalt-blue colour is produced. When the nitro-group is in the

hydrazine residue, if it is in the ortho-position a violet, if in the meta a brown, and if in the para a magenta colour is produced.

When alcoholic potash is added to a saturated alcoholic solution of a nitrobenzaldehydehydrazone derived from an unsymmetrical secondary hydrazine* little or no alteration in colour is produced whether the nitro-group occupies an ortho-, meta-, or para-position in the aldehyde residue.

In all cases except where the action of the alcoholic potash has been so prolonged as to cause profound decomposition, the hydrazone can be recovered unchanged from the coloured solution by the addition of acid.

With the primary *o*-nitrobenzaldehydehydrazones at the ordinary temperature, brown or olive-green solutions are often obtained which become bright green on warming or increasing the concentration of alkali, the shade reverting to brown or olive-green on cooling or dilution with alcohol.

With the primary *m*-nitrobenzaldehydehydrazones, the brown colour produced at the ordinary temperature deepens on warming or addition of a large excess of alkali and reverts to the paler shade on cooling or dilution with alcohol.

With the primary *p*-nitrobenzaldehydehydrazones, the colour produced at the ordinary temperature is sometimes green or greenish-blue, the intense blue colour only appearing on warming or adding a large excess of alkali.

All these vividly coloured alkaline solutions, whether green, brown, or blue, become pure yellow on sufficient dilution with alcohol, the degree of dilution necessary varying with the nature of the substituents in the hydrazine residue.

Generalising from the large number of examples studied, when the nitro-group is in the aldehyde residue it is necessary for the production of vivid colour not only that the nitro-group should occupy the ortho- or para-position with regard to the $-\text{CH}-$ group of the aldehyde residue, but also that a hydrogen atom should be attached to the nitrogen atom contiguous to the cyclic residue of the hydrazine,† that is, the hydrazone must be derived from a primary hydrazine. When, however, the nitro-group is in the hydrazine residue, although it must occupy the ortho- or para-position with respect to the nitrogen chain, the presence of a hydrogen

* So far, we have not prepared hydrazones from secondary hydrazines containing a nitro-group, such, for example, as $\text{NO}_2\text{C}_6\text{H}_4\text{N}(\text{CH}_2)_2$.

† The only exceptions which have been encountered to this rule are the nitrobenzaldehydehydrazones derived from 2:5-dichloro-6-nitrobenzaldehyde. Thus 2:5-dichloro-6-nitrobenzaldehydephenylhydrazone gives no trace of a green colour with alcoholic potash.

atom attached to the carbon atom of the chain is not necessary, as vivid colours are produced by the *o*- and *p*-nitrophenylhydrazones derived from ketones such as acetone, acetophenone, benzophenone, and cyclohexanone.

Thus in, say, *o*-nitrobenzaldehydephenylhydrazone,

the imino-hydrogen atom is necessary for the production of vivid colour, whilst in benzaldehyde-*o*-nitrophenylhydrazone,

the methine hydrogen is not necessary for such colour production.

This is borne out by the behaviour of *o*- and *p*-nitrobenzylideneazines, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{N}\cdot\text{N}\cdot\text{CH}\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$, and of *o*- and *p*-nitrobenzylideneanils, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{N}\cdot\text{C}_6\text{H}_5$, not one of which gives any marked colour with alcoholic potash.

A simple explanation of the production of the vivid green, blue, or violet colours from the ortho- and para-substituted hydrazones by alkalis suggests itself.

Although a quinonoid configuration is not a necessary condition of colour, intense colour is frequently associated with it and it seems reasonable to assume that those under discussion are due to the presence of such a configuration within the molecule. Highly coloured salts, having a quinonoid structure,* are probably produced from the tautomeric forms of the nitrohydrazones, for example,

Some further alteration in structure appears to be necessary for the production of the intense green or blue colour by alkalis when the nitro-group is in the ortho- or para-position in the aldehyde residue, for the assumption of tautomeric change gives no explanation of the fact that these colours are not given by the similarly constituted derivatives of unsymmetrical secondary hydrazines. It can scarcely be due to an alteration of basicity, since methyl phenylhydrazine and diphenylhydrazine behave similarly in giving hydrazones in which the colour with alkali is suppressed. This being so, it seems likely that the explanation must be sought in the greater mobility of the imino-hydrogen atom, which migrates to the carbon atom of the aldehyde group with the consequent production of an azo-linking between the nitrogen atoms.

* The work of Lifschitz (*Ber.*, 1915, **48**, 1730; 1922, **55**, [B], 1613) may be recalled in this connexion. He attributes the intense colour produced by the action of alkalis on such *o*- and *p*-nitro-substituted compounds as *p*-nitrobenzyl cyanide and *o*- and *p*-nitrodeoxybenzoin to the formation of salts having the quinonoid structure.

Thus, for example—

An alternative explanation, postulating the formation of an additional ring system on the addition of the alkali in the following manner,

cannot be sustained, since on this basis it would be expected that the hydrazones derived from, say, *o*-nitroacetophenone would show a similar colour reaction, which they do not, and further, this explanation would not account for the colours given by the *p*-nitro-benzylidene compounds.

An equally simple explanation of the production of a deep brown colour by alkalis when a nitro-group is present in the meta-position only in either or both residues is not forthcoming.

It may possibly be due to a kind of salt formation by the addition of potassium ethoxide.* Thus, for example,

* The brown colours produced by the action of alcoholic potash upon simple aromatic nitro-derivatives such, for example, as the nitrotoluenes may be similarly explained:

The consistent variation of the colours of the crystals of the *o*-, *m*-, and *p*-nitrobenzaldehydehydrazones, and of the effect of negative substituents in the hydrazine residue upon them is not so easy to explain, although a theory plausible at first has been suggested. The colour of many of the *o*- and *p*-nitrobenzaldehydehydrazones is surprisingly like that of many azo-compounds. If the formulæ of such hydrazones are examined, it will be seen that an azo-linking between the nitrogens could be brought about by the migration of the imino-hydrogen atom:

If such a migration actually took place during the formation of these nitro-substituted hydrazones owing to the augmented negative affinity of the *o*- or *p*-nitrophenyl group of the aldehyde residue for the positive hydrogen atom, the brilliant scarlet colour of, say, *p*-nitrobenzaldehyde-*p*-chlorophenylhydrazone would be accounted for by its having the azo-structure,

On this assumption, not only should the benzaldehydehydrazones be pale yellow or colourless, as they are, but even in the case of the *o*- and *p*-nitrobenzaldehydehydrazones, if sufficient negative groups were introduced into the hydrazine residue, these should counteract the negative attraction of the *o*- or *p*-nitrophenyl group of the aldehyde residue. At first, this explanation seemed satisfactory, since, although the introduction of one or even two halogen atoms in the 2:4-positions scarcely altered the scarlet colour of the crystals, the introduction of two halogen atoms in the 2:6-positions or of three in the 2:4:6-positions changed the colour to a yellow scarcely distinguishable from that of the meta-isomeride. For example,

On this basis also, the *m*-nitrobenzaldehydehydrazones might be expected to be yellow, as indeed they are, since the presence of the nitro-group in the meta-position would, in accordance with the alternate polar theory, lessen the tendency of the methine carbon atom to attach an extra hydrogen atom.

This explanation cannot, however, be maintained. If the negative nitro-group in the aldehyde residue determined the position of the hydrogen atom, it might be expected that, in some cases at any rate, the presence of other negative substituents in place of the nitro-group would cause the hydrogen atom similarly to wander, with the consequent introduction of the azo-linking and production of red or scarlet colour. This, however, is not the case, such hydrazones being either colourless or of a very faint yellow colour.

Further evidence against the necessity for assuming that the red hydrazones have an azo-structure is furnished by the fact that the crystals of *o*-nitrobenzaldehydephenylmethylhydrazone,

in which there is no imino-hydrogen atom which could wander—are brilliant scarlet. Again, the nitrobenzylidene derivatives of bases like *p*-aminodimethylaniline closely resemble the nitrobenzaldehydehydrazones in colour—the *o*- and *p*-nitro-compounds being red or scarlet and the *m*-nitro-compounds yellow—which shows that red or scarlet colour similar to that of the *o*- or *p*-nitrobenzaldehyde compounds can be associated with the azomethine structure, $\cdot\text{CH}\cdot\text{N}$.

The fact that all the red or scarlet *o*- and *p*-nitrobenzaldehydehydrazones give pure yellow alcoholic solutions on sufficient dilution indicates that the colour only appears when the molecules are brought into close proximity in the solid state. The colours themselves recall the colours of the salts of the nitrophenols, and this suggests that they may be due to something analogous to salt formation, and that the loss of the scarlet or red colour in the case of the highly negatively substituted hydrazones may be owing to the loss of positive character by the hydrazine part of the molecule owing to the introduced negative substituents, aided perhaps by some steric hindrance, preventing a sufficiently near approach of the attracting groups.

An assumption which appears satisfactorily to account for what

is observed is that the colour is due to an attraction which acts effectively over a limited distance only, between the nitro-group of one molecule and the imino-group of another.

Owing to the configuration of the molecules, when the molecules of *o*- or *p*-nitrobenzaldehydhydrazones arrange themselves in crystals this kind of loose salt formation occurs. When the compounds are dissolved, this condition exists to some extent in strong solutions, hence their red colour. When, however, dilution separates the molecules widely, this attraction, or strain, or electronic oscillation is so weakened or prevented that no action upon light such as that which is exerted by the solid material can take place and the clear yellow, which may be termed the molecular colour of these compounds, appears.

The crystal units being built up differently in the polymorphic modifications, the relative positions of the acidic and basic groups in the crystals would be dissimilar, thus accounting for the different colours of the crystals of polymorphic modifications. It must be assumed that the position of the nitro-groups in the *m*-nitro-isomerides does not allow the potentially attracting groups to approach sufficiently near in the crystals for the condition producing the red colour to exist.

This view seems to be supported by the fact that any configuration which diminishes sufficiently the basic character of the hydrazine residue causes the disappearance of the scarlet or red colour; for example,

EXPERIMENTAL.

The nitrobenzaldehydhydrazones are all easily made by mixing equivalent amounts of the requisite nitrobenzaldehyde and hydrazine in alcoholic solution. Heat is generally evolved and the solid hydrazone separates as the alcoholic solution cools, although in some cases the reaction has to be completed by heating on the water-bath with the addition of a little acetic acid. The nitrobenzaldehydhydrazones almost always crystallise well, the crystals having strong and distinctive colours. Many exist in polymorphic modifications differing markedly in crystalline form and colour.

Those derived from primary hydrazines are sharply characterised

by the intense green, blue, violet, or brown colours produced by the addition of an alcoholic solution of potassium hydroxide to their saturated alcoholic solutions. In a few cases, to develop the colour fully it is necessary to add powdered potassium hydroxide. Heating also causes the full colour to develop, the shade first produced reappearing as the solution cools. In all cases, sufficient dilution of these alkaline, coloured solutions with alcohol gives a yellow solution.

On adding slight excess of an acid to the coloured alkaline alcoholic solution, the hydrazone is re-formed except in a few cases where heating or prolonged action of the alkaline hydroxide causes profound decomposition.

As, in order to study the effect of constitution upon the colour changes, many compounds had to be examined before any sort of generalisation could be made, it is necessary to describe them briefly, and in the following descriptions the name of each compound is given first, then in the case of a compound already known the reference to the paper where it was first described is given. A brief description of the colour and shape of the crystals is next given. When the compound exists in polymorphic modifications, the labile form is always described first. The colour produced by adding a saturated alcoholic solution of potassium hydroxide to its alcoholic solution is next given, and, finally, any further change of colour brought about by heating this coloured solution completes the description.

In the case of compounds not hitherto described, the melting point and analytical result are given after the name.

o-Nitrobenzaldehydephenylhydrazone. *Ber.*, 1887, 20, 1343. Crimson prisms. Bright green. Unaltered.

p-Nitrobenzaldehyde-3 : 4 : 5-trichlorophenylhydrazone. Vermilion-red, slender prisms. M. p. 305—308°. Found : Cl = 30.8. Deep clear cobalt-blue. Unaltered.

o-Nitrobenzaldehyde-2 : 4 : 6-tribromophenylhydrazone. Long, slender, pure yellow prisms. M. p. 169.5°. Found : Br = 50.1. Calc. 50.2. Bluish-green. Deeper green.

m-Nitrobenzaldehyde-2 : 4 : 6-tribromophenylhydrazone. Bright yellow, irregular plates. M. p. 171°. Found : Br = 50.3. Pale brown. Dark brown.

p-Nitrobenzaldehyde-2 : 4 : 6-tribromophenylhydrazone. Bright yellow, hair-like needles. M. p. 200°. Found : Br = 49.8. Intense cobalt-blue. Unaltered.

o-Nitrobenzaldehyde-2 : 4 : 5-tribromophenylhydrazone. Pale orange, long needles. M. p. 220—221°. Found : Br = 50.6. Dark olive-green. Unaltered.

m-Nitrobenzaldehyde-2 : 4 : 5-tribromophenylhydrazone. Bright orange-yellow plates. M. p. 251—252°. Found : Br = 50.4. Brown. Dark brown.

p-Nitrobenzaldehyde-2 : 4 : 5-tribromophenylhydrazone. Deep orange, slender needles. M. p. 261°. Found : Br = 50.0. Intense cobalt-blue. Unaltered.

o-Nitrobenzaldehyde-2-chloro-4-methylphenylhydrazone. Bright crimson, rhombic plates. M. p. 160°. Found : Cl = 12.0. Calc. = 12.2. Dark olive-green. Dark emerald-green.

m-Nitrobenzaldehyde-2-chloro-4-methylphenylhydrazone. Bright orange, flattened prisms. M. p. 174—175°. Found : Cl = 11.9. Slight brown. Unaltered.

p-Nitrobenzaldehyde-2-chloro-4-methylphenylhydrazone. Vivid scarlet prisms. M. p. 140°. Found : Cl = 12.1. Deep bluish-green. More blue in shade.

o-Nitrobenzaldehyde-4-chloro-2-methylphenylhydrazone. Bright crimson, slender prisms. M. p. 184—185°. Found : Cl = 12.2. Brownish-green. Dark olive-green.

m-Nitrobenzaldehyde-4-chloro-2-methylphenylhydrazone. Long, orange-yellow plates. M. p. 235—236°. Found : Cl = 12.2. Pale brown. Unaltered.

p-Nitrobenzaldehyde-4-chloro-2-methylphenylhydrazone. Long, slender, crimson prisms. M. p. 224°. Found : Cl = 11.9. Clear green. Bluish-green.

o-Nitrobenzaldehyde-4-iodo-2-methylphenylhydrazone. Labile form dark garnet-red needles. Stable form bright crimson, rhombic prisms. M. p. 179°. Found : I = 33.4. Calc. 33.3. Faint green. Clear dark green.

m-Nitrobenzaldehyde-4-iodo-2-methylphenylhydrazone. Orange

needles. M. p. 187.5°. Found: I = 33.3. Unaltered. Slightly brown.

p-Nitrobenzaldehyde-4-iodo-2-methylphenylhydrazone. Deep garnet-red, irregular plates. M. p. 195°. Found: I = 33.2. Olive-green. Bright green.

o-Nitrobenzaldehyde-2:6-dibromo-4-methylphenylhydrazone. Reddish-orange, irregular plates. M. p. 136—137°. Found: Br = 38.7. Calc. 38.7. Deep clear green. Darkens.

m-Nitrobenzaldehyde-2:6-dibromo-4-methylphenylhydrazone. Bright yellow plates. M. p. 141.5°. Found: Br = 38.5. Pale brown. Darker brown.

p-Nitrobenzaldehyde-2:6-dibromo-4-methylphenylhydrazone. Bright orange, hair-like needles. M. p. 186°. Found: Br = 38.7. Intense cobalt-blue. Unaltered.

o-Nitrobenzaldehyde-2:4:5-trimethylphenylhydrazone. Dark crimson, twinned rhombic prisms. M. p. 141.5°. Found: N = 14.8. Calc. 14.8. Dark brown. Olive-green.

m-Nitrobenzaldehyde-2:4:5-trimethylphenylhydrazone. Thin, reddish-brown plates. M. p. 171°. Found: N = 14.6. Brownish-yellow. Unaltered.

p-Nitrobenzaldehyde-2:4:5-trimethylphenylhydrazone. Dark garnet-red, slender prisms. M. p. 179°. Found: N = 14.6. Greenish-brown. Dark green, almost black.

o-Nitrobenzaldehyde-4-hydroxyphenylhydrazone. Dark purple, almost black, slender prisms. M. p. 192—193°. Found: N = 16.1. Calc. 16.3. Deep indigo-blue, changing in a few seconds to pale brown and then in a few minutes to a purple shade which becomes bluer on heating.

m-Nitrobenzaldehyde-4-hydroxyphenylhydrazone. Small, dark crimson prisms. M. p. 174—175°. Found: N = 16.2. Dark brown. On standing or more rapidly on heating, becomes deep indigo-blue.

p-Nitrobenzaldehyde-4-hydroxyphenylhydrazone. Dark purple, almost black prisms. M. p. 212°. Found: N = 16.0. Brilliant deep violet, which soon fades to a dirty brown and then changes to a pale indigo-blue, which soon darkens, especially on heating, to a deep clear blue which is unaltered on dilution.

In the three preceding cases, profound decomposition occurs on heating, and the original colours are not restored on cooling or dilution.

o-Nitrobenzaldehyde-2-methoxyphenylhydrazone. Thin, glistening, crimson plates. M. p. 133°. Found: N = 15.3. Calc. 15.5. Brown. Brownish-olive-green.

m-Nitrobenzaldehyde-2-methoxyphenylhydrazone. Labile form

reddish-orange, slender prisms. Stable form dark orange-red, stout prisms. M. p. 166.5°. Found: N = 15.3. Very pale brown. Unaltered.

p-Nitrobenzaldehyde-2-methoxyphenylhydrazone. Deep crimson, slender prisms. M. p. 161.5°. Found: N = 15.4. Greenish-brown. Olive-green.

o-Nitrobenzaldehyde-3-methoxyphenylhydrazone. Slender, garnet-red prisms. M. p. 150°. Found: N = 15.5. Brown. Olive-green.

m-Nitrobenzaldehyde-3-methoxyphenylhydrazone. Labile form deep yellow, slender prisms. Stable form short, stout, deep orange, rhombic plates. M. p. 127°. Found: N = 15.4. Brown. Dark brown.

p-Nitrobenzaldehyde-3-methoxyphenylhydrazone. Slender, bright scarlet prisms. M. p. 155°. Found: N = 15.6. Clear green. Unaltered.

o-Nitrobenzaldehyde-4-methoxyphenylhydrazone. Long, slender, brownish-red prisms. M. p. 183—184°. Found: N = 15.2. Greenish-brown. Dark olive-green.

m-Nitrobenzaldehyde-4-methoxyphenylhydrazone. Bright orange, rhombic plates. M. p. 130.5°. Found: N = 15.4. Brownish-orange. Clear dark brown.

p-Nitrobenzaldehyde-4-methoxyphenylhydrazone. Dark crimson, six-sided, rhombic plates. M. p. 182°. Found: N = 15.4. Dark olive-green. Indigo-blue.

o-Nitrobenzaldehyde-2-carboxyphenylhydrazone. Orange-red plates. M. p. 242—243°. Found: N = 14.8. Calc. 14.7. With 20 per cent. alcoholic potash, reddish-brown, unaltered; but with much stronger alcoholic potash, reddish-brown. Olive-green.

m-Nitrobenzaldehyde-2-carboxyphenylhydrazone. Pale yellow, slender prisms. M. p. 267°. Found: N = 14.9. Unaltered, even on heating.

p-Nitrobenzaldehyde-2-carboxyphenylhydrazone. Long, slender, reddish-orange prisms. M. p. 283—285°. Found: N = 14.8. Olive-green. Clear green.

o-Nitrobenzaldehyde-3-carboxyphenylhydrazone. Labile form small, brownish-crimson needles. Stable form short, compact, bright crimson prisms. M. p. 260° with decomposition. Found: N = 14.7. Greenish-brown. Dark olive-green.

m-Nitrobenzaldehyde-3-carboxyphenylhydrazone. Small, deep orange needles. M. p. 252°. Found: N = 14.5. Brownish-orange. Deepens in shade.

p-Nitrobenzaldehyde-3-carboxyphenylhydrazone. Bright orange-yellow, six-sided plates. M. p. 272° with decomposition. Found: N = 14.8. Clear green. Blue.

o-Nitrobenzaldehyde-4-carboxyphenylhydrazone. Small, reddish-orange prisms. M. p. 276° with decomposition. Found: N = 14.5. Deep olive-green. Unaltered.

m-Nitrobenzaldehyde-4-carboxyphenylhydrazone. Small, bright orange plates. M. p. 278°. Found: N = 14.9. Pale brown. Deep brown.

p-Nitrobenzaldehyde-4-carboxyphenylhydrazone. Compact, dull scarlet prisms. M. p. 285°. Found: N = 14.7. Deep clear green. Blue.

o-Nitrobenzaldehyde-*p*-diphenylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Dark reddish-brown prisms. Dark greenish-brown. Dark olive-green.

m-Nitrobenzaldehyde-*p*-diphenylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Labile form red, irregular nodules. Stable form pale yellow plates. Pale brown. Dark brown.

p-Nitrobenzaldehyde-*p*-diphenylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Orange-red, irregular plates. Clear green. Bright cobalt-blue.

o-Nitrobenzaldehyde- α -naphthylhydrazone. Small, elongated, deep crimson plates. M. p. 148°. Found: N = 14.3. Calc. 14.4. Greenish-brown. Dark olive-green.

m-Nitrobenzaldehyde- α -naphthylhydrazone. Six-sided, dark reddish-orange plates. M. p. 197°. Found: N = 14.5. Pale brown. Unaltered.

p-Nitrobenzaldehyde- α -naphthylhydrazone. Small, dark crimson plates. M. p. 205°. Found: N = 14.2. Dark greenish-blue. Clear cobalt-blue.

o-Nitrobenzaldehyde- β -naphthylhydrazone. Dark red, slender prisms. M. p. 208°. Found: N = 14.1. Greenish-brown. Dark olive-green.

m-Nitrobenzaldehyde- β -naphthylhydrazone. Thin, pale yellow plates. M. p. 202°. Found: N = 14.4. Brownish-yellow. Pale brown.

p-Nitrobenzaldehyde- β -naphthylhydrazone. Deep orange, six-sided plates. M. p. 232°. Found: N = 14.3. Greenish-blue. Deep cobalt-blue.

The nitrobenzaldehydehydrazones derived from secondary hydrazines are prepared similarly to those derived from the primary hydrazines and resemble them closely in appearance and general behaviour. Their alcoholic solutions, however, are not altered in colour when a saturated alcoholic solution of potassium hydroxide is added to them, whether the second radical of the hydrazine residue is of a positive character such as methyl or benzyl or of a negative character such as phenyl.

o-Nitrobenzaldehydephenylmethylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Brilliant scarlet, slender prisms. Unaltered, even on heating.

m-Nitrobenzaldehydephenylmethylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Bright scarlet, flattened prisms. Unaltered even on heating.

p-Nitrobenzaldehydephenylmethylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Deep orange, flattened prisms. Unaltered even on heating.

o-Nitrobenzaldehydediphenylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Orange-scarlet prisms. Unaltered even on heating.

m-Nitrobenzaldehydediphenylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Short, compact, pale yellow prisms. Unaltered even on heating.

p-Nitrobenzaldehydediphenylhydrazone. *Atti R. Accad. Lincei*, 1911, [v], 20, ii, 579. Reddish-orange, irregular plates. Unaltered even on heating.

o-Nitrobenzaldehydebenzylphenylhydrazone. *Atti R. Accad. Lincei*, 1913, [v], 22, ii, 76. Bright orange, flattened prisms. Unaltered even on heating.

m-Nitrobenzaldehydebenzylphenylhydrazone. *Atti R. Accad. Lincei*, 1913, [v], 22, ii, 76. Bright yellow, flattened prisms. Unaltered even on heating.

p-Nitrobenzaldehydebenzylphenylhydrazone. *Atti R. Accad. Lincei*, 1913, [v], 22, ii, 76. Slender, yellow prisms. Unaltered even on heating.

To decide whether the presence of two groups or only the absence of hydrogen attached to nitrogen in the hydrazine residue was the cause of the indifference to alcoholic potash of the nitrobenzaldehyde secondary hydrazones, the three nitrobenzaldehydecarbazyhydrazones have been prepared. It is interesting to note that none gives a colour with alcoholic potash and that the three isomerides are alike yellow in colour. The latter fact lends further support to the suggestion that red colour is due to a species of salt formation, the carbazyl radicle being only slightly negative in character.

o-Nitrobenzaldehydecarbazyhydrazone. Dull orange, elongated plates. *M. p.* 149°. Found: N = 13.5. Calc. 13.3. Unaltered even on heating.

m-Nitrobenzaldehydecarbazyhydrazone. Long, pale yellow hairs. *M. p.* 195°. Found: N = 13.5. Unaltered even on heating.

p-Nitrobenzaldehydecarbazyhydrazone. Long, slender, yellow prisms. *M. p.* 220°. Found: N = 13.6. Unaltered even on heating.

To determine whether the presence of a nitro-group either in the aldehyde or hydrazine residue is an essential condition for the appearance of marked colour in the crystals or in their alcoholic solutions in the presence of alcoholic potash, a number of hydrazones containing various other substituents in both residues have been prepared. It may be mentioned in support of the suggestion of the addition of potassium ethoxide to explain the brown colour produced with *m*-nitrobenzaldehydehydrazones, that a number of hydrazones not containing the nitro-group, although not showing any vivid green, blue, or violet colour on the addition of alcoholic potash, resemble the *m*-nitro-compounds in giving yellowish-orange solutions which deepen in shade on heating and again revert to the paler shade on cooling.

o-Chlorobenzaldehyde-*o*-chlorophenylhydrazone. Slender, colourless prisms. M. p. 121°. Found: Cl = 26.4. Calc. 26.8. Slight yellow. Bright yellow.

o-Nitrobenzaldehyde-*p*-sulphophenylhydrazone. Deep crimson, slender prisms. Deep green. Unaltered.

2 : 4-Dinitrobenzaldehyde-*p*-sulphophenylhydrazone. *Ber.*, 1902, **35**, 2705, 2711. Deep brilliant crimson prisms. Brilliant cobalt-blue. Unaltered.

p-Aminomethylaniline, like the hydrazines, reacts readily with the nitrobenzaldehydes with the elimination of water, giving well-

crystallised, highly coloured compounds. Their alcoholic solutions do not give vivid colours with alcoholic potash, as although there is the possibility of quinonoid structure being formed there is no imino-hydrogen atom which can wander to the aldehydic methine carbon atom.

CCCLXIII.—*A Quantitative Investigation of the Photochemical Interaction of Chlorine and Hydrogen.*

By MURIEL CATHERINE CANNING CHAPMAN.

IN a communication to this journal by Chapman and Whiston (T., 1919, 115, 1264) on the influence of mass on the interaction of hydrogen and chlorine the authors indicated that there was a discrepancy between their results and those previously published by Bodenstein and Dux (*Z. physikal. Chem.*, 1913, 85, 297). The latter investigators found that the reaction between equimolecular proportions of hydrogen and chlorine was of the second order. As a consequence, the rate of formation of hydrogen chloride should be given by the formula

$$d[\text{HCl}]/dt = k[\text{Cl}_2]^n [\text{H}_2]^m \quad . \quad . \quad . \quad . \quad (\text{A})$$

in which $n + m = 2$.

Chapman and Whiston, however, observed that the value of $m + n$ in the above equation was nearly equal to unity.

Moreover, experiments by Bodenstein and Dux with mixtures containing unequal volumes of chlorine and hydrogen indicated that $m = 0$ and $n = 2$ when the concentration of the hydrogen exceeded one-fourth of that of the chlorine. This implies that the hydrogen has no inhibitive effect, in contradiction to the results obtained by Chapman and Underhill (T., 1913, 103, 496), and confirmed in some unpublished work by O. P. Jones.

Therefore, in two particulars the results of the work done in this laboratory are in disagreement with those of Bodenstein and Dux. The first section of this experimental research is chiefly an examination of these discrepancies.

I have repeated under more favourable conditions the experiments of Chapman and Whiston, first using, as they did, white light as an illuminant and later repeating the experiments with light which had traversed 18 cm. of chlorine at atmospheric pressure.* The results I have obtained are in substantial agreement with theirs. My experiments indicated that working with electrolytic gas to which a small proportion of oxygen had been added between the pressures of half an atmosphere and one atmosphere, the rate of chemical change was given roughly by the formula (A), $m + n$ being in the mean equal to 1.15 and the constant, k , being, of course, inversely proportional to the concentration of the oxygen and dependent on the intensity of the light.†

An attempt was next made to obtain information concerning the values of m and n . As already stated, Bodenstein and Dux affirm that m is zero for mixtures of chlorine and hydrogen at moderately high concentrations. On the other hand, Chapman and Underhill assert that m is actually negative, or, in other words, that hydrogen acts inhibitive.

There are two methods of deciding which of these views is the correct one. In the first place, n can be determined and m deduced from the equation

$$m + n = 1.15.$$

In the second place, m can be directly determined by a method described below which demonstrates at the same time that any observed inhibitive effect of the hydrogen cannot be due to inhibitors introduced into the actinometer with the hydrogen.

The mean of several direct determinations of n furnished the result $n = 1.6$, and therefore m must be negative if the relation expressed by the above equation is correct.

The method adopted for directly determining m can be best explained by taking as an example one of the experiments performed. The results of the experiment are tabulated below:

	Pressure in cm. of mercury of			Sensitiveness.‡
	Chlorine.	Hydrogen.	Oxygen.	
(1)	17.2	34.8	0.5	52
(2)	34.1	34.4	"	166
(3)	17.5	17.8	"	71
(4)	17.3	35.6	"	51

* ‡ Relative rates of formation of hydrogen chloride induced by the same intensity of illumination.

* In all subsequent experiments the actinometer was illuminated by light which had been filtered through a sufficient depth of chlorine to remove most of the rays for which chlorine possesses a high coefficient of absorption.

† According to Baly and Barker (T., 1921, 119, 653), k must not be assumed to be proportional to the intensity of the light.

The mixture (2) was obtained by adding chlorine to the mixture (1). The mixture (3) was obtained from the mixture (2) by exposing the latter to light until the pressures had fallen by the amounts recorded. The mixture (4) was obtained from the mixture (3) by the addition of hydrogen.

Now by comparing row (3) with row (4), it will be seen that the result of doubling the concentration of the hydrogen is a reduction in sensitiveness of 20 units, and this reduction cannot be due to any inhibitor contained in the hydrogen, since the mixture (1) has approximately the same composition and the same sensitiveness as the mixture (4).

The values of n and m calculated from the numbers given in rows (2), (3), and (4) are, respectively, 1.720 and -0.452 , whence

$$m + n = 1.268 :$$

whereas from the measurements of the sensitiveness of electrolytic gas at different pressures it was estimated that

$$m + n = 1.15.$$

But as the equation (A) can only hold between limited ranges of pressure, an exact correspondence between the two values of $m + n$ cannot be expected.

The rest of my work is an attempt to express the rate of reaction by a formula which is true for all concentrations of the hydrogen, chlorine, and oxygen.

With this in view, the rate of photochemical change was measured when the actinometer contained (a) very little hydrogen, a variable but large amount of chlorine, and a constant amount of oxygen, (b) very little chlorine, a variable but large amount of hydrogen, and a constant amount of oxygen.

In case (a), the rate of formation of hydrochloric acid could be represented approximately by the equation

$$d[\text{HCl}]/dt = k_1[\text{H}_2][\text{Cl}_2] \quad \dots \quad (\text{i})$$

and in case (b) approximately by the equation

$$d[\text{HCl}]/dt = k_2[\text{Cl}]^2/[\text{H}_2]^{1-x} \quad \dots \quad (\text{ii})$$

in which x is a fraction less than $\frac{1}{2}$.

Now it will be seen that the equation

$$\frac{d[\text{HCl}]}{dt} = \frac{k_1[\text{H}_2][\text{Cl}_2]^2}{k_2[\text{H}_2]^{2-x} + [\text{Cl}_2]} \quad \dots \quad (\text{iii})$$

reduces to (i) when $[\text{H}_2]$ is made very small, and to (ii) when $[\text{Cl}_2]$ is made very small.

Moreover, if the concentration of the chlorine is kept constant, the value of $d[\text{HCl}]/dt$ reaches a maximum value at a definite value of $[\text{H}_2]$.

Adopting the formula (iii) provisionally as giving the rate of formation of hydrogen chloride when the concentration of the oxygen was constant, I next endeavoured to discover how the constants contained in it depended on the concentration of the oxygen. A clue to a means of obtaining information on this point quickly was furnished by an accidental observation made while conducting the previous experiments. In the determinations of the degrees of sensitiveness of mixtures which contained small proportions of hydrogen, it was noticed that the values for two mixtures which contained different quantities of oxygen, but the same quantities of chlorine and hydrogen, in unit volume, were not inversely proportional to the respective concentrations of the oxygen. The observed difference in the degrees of sensitiveness was much less than the calculated difference.

A further examination of this unexpected result led to the discovery that, as the proportion of hydrogen is reduced, the rate of photochemical combination tends to become independent of the concentration of the oxygen, whereas whenever the concentration of the hydrogen is moderately large, the sensitiveness is almost inversely proportional to the concentration of the oxygen. These and the other experimental results can be represented by a formula derived from (iii) by the substitution of $k_3[\text{O}_2]$ for k_1/k_2 , that is, by the formula

$$\frac{d[\text{HCl}]}{dt} = \frac{k_1[\text{H}_2][\text{Cl}_2]^2}{k_3[\text{H}_2]^2 + [\text{O}_2] + [\text{Cl}_2]} \quad \cdot \quad \cdot \quad \cdot \quad (\text{iv})$$

The most important results of this investigation are those which demonstrate that oxygen is not an inhibitor unless appreciable quantities of hydrogen are present in the mixture, a fact which makes it probable that the forms of energy which cause the union of the chlorine and the hydrogen are removed from the system, or degraded, by the joint agency of the hydrogen and oxygen molecules.

EXPERIMENTAL.

It is essential that the apparatus and materials used in the experiments should be almost entirely free from inhibitive impurities. Unless the utmost care is taken to ensure that this is the case, the results are untrustworthy.

In the experiments to be described the pure water used in the actinometer was obtained in the following manner: ordinary distilled water in which chlorine had been dissolved was redistilled

from a glass retort and then boiled for several hours in a flask on to which a reflux condenser had been fused. It was then syphoned out into a glass vessel which was only open to the air through two narrow tubes, one of which was graduated in c.c. By means of this apparatus a measured quantity of purified water which had only been in contact with a small volume of enclosed air could be introduced into the actinometer.

Water prepared as above was almost free from inhibitors and these could generally be completely removed in the following manner.

The insolation vessel, after the desired quantity of water had been introduced, was filled with sensitive electrolytic gas. It was illuminated for two minutes and then shaken until the index remained stationary. This was repeated until the amount of hydrochloric acid formed during the two minutes' illumination was constant, and, in order to be quite certain that all the inhibitors had thus been removed from the solution, another reading was taken after the insolation vessel had been kept in the dark for twelve hours. A fall in the degree of sensitiveness after this period was seldom observed. It may be remarked that even in the freshly filled insolation vessel combination started instantly on exposure to light.

In the experiments to be described, whenever possible, each important measurement was made twice over in order to test for destructible inhibitive impurities, the presence of which would have been indicated by the second measure of the sensitiveness being greater than the first.* This test is the only trustworthy method of detecting a small "induction period," for since in a Bunsen and Roscoe actinometer the formation of hydrochloric acid reduces, for the time, the pressure of the water vapour in the actinometer, the apparent rate of combination is at first rapid and then falls off gradually, and it is therefore not possible to detect a slight increase in sensitiveness during a single observation.

An expansion when the mixture is first exposed to light does not prove the absence of any "induction period"; it only shows that combination commences immediately, that is, that the "induction period" is not pronounced.

The experiments of which the results are given below, under series I, were conducted in a similar manner to those of Chapman and Whiston, and the apparatus used did not differ essentially from theirs.

* In the few exceptional cases in which the above test for purity was not satisfactory, mention will be made of the fact in recording the results of the experiments.

The rate of combination of electrolytic gas to which a little oxygen had been added was measured at pressures of one atmosphere and of half an atmosphere.

A source of error in the investigation of Chapman and Whiston was the presence of 5 c.c. of water in the insolation vessel, for since the concentration of a saturated aqueous solution of chlorine increases with the partial pressure of the gas, a small error was occasioned by chlorine being withdrawn from solution when the pressure was reduced.

In order to diminish this error in my experiments, only 2 c.c. of water were introduced into the insolation vessel. The volume of the latter was 120 c.c. and its diameter 2.8 cm. It was fixed in a vertical position. Owing to its length, its vertical position, and to the amount of liquid contained in it being small, its contents could not be rapidly brought into equilibrium by shaking. In fact, at each measurement twenty-four hours had to elapse before the final reading could be taken.

The rate of combination was measured by a vertical capillary manometer filled with water, as in the subsequent experiments. In some of the experiments a light filter was used. This was a glass globe, about 18 cm. in diameter, filled with chlorine. The same light filter was used in most of the subsequent experiments.

The results obtained are tabulated below. It will be seen that they are in substantial agreement with those of Chapman and Whiston, and indicate that, when the correction is made for the change in pressure of the oxygen, the order of the reaction approximates very much more closely to the first than to the second.

Series (1).

(A) Experiments with white light.

No. of expt.	Percentage of oxygen.	Sensitiveness at one atmosphere.	Sensitiveness at half an atmosphere.	Light used.
1	1.00	89.5	78.5	Osram lamp.

(B) Experiments with filtered light.

No. of expt.	Percentage of oxygen.	Sensitiveness at one atmosphere.	Sensitiveness at half an atmosphere.
5 (a)	unknown	118	94
5 (b)	0.50	168	160
5 (c)	0.25	331	320

In these, and in all experiments subsequently described, the intensity of illumination was not necessarily the same if the numbers assigned to the experiments are different. When, however, care was taken to maintain the intensity of the light constant by keeping the lamp and light filter in exactly the same position during a series of experiments, the separate experiments of the series are designated by the same numeral with different index letters. Thus, in the experiments 5a, 5b, and 5c, of which the results are recorded above, the intensity of illumination was maintained as constant as the method of illumination permitted.

All subsequent experiments were conducted with the form of apparatus shown in the figure. The gases could be separately introduced into the actinometer and the effect of altering their relative concentrations could be investigated.

The hydrogen and chlorine were generated in the electrolytic cell, *C*, a U-tube filled with pure hydrochloric acid. Iridium electrodes were used. The gases passed separately through the wash-bottles, *E* and *F*, and entered two wide tubes, *a* and *b*, which had been tightly packed with glass wool. By means of a temporary furnace these tubes were kept at a temperature of 270°. Thus the gases were heated for some time before entering the actinometer. This was done in order to destroy any nitrogen chloride in the gases and to remove any chlorine which might be present in the hydrogen.* The tubes were fixed in a sloping position in order that they might be easily cleaned with chromic acid *in situ*.

The insolation vessel, *A*, immersed in the thermostat, *H*, was of such a design that its contents could rapidly be brought to equilibrium. It was fixed in a horizontal position by the long capillary tubes, through which the gases were introduced and withdrawn, and contained 6 c.c. of pure water, which was spread in a shallow layer over its lower surface. Owing to its mode of suspension (which admitted of its being shaken) and to its horizontal position, equilibrium could be attained with the desired rapidity.

Combination was indicated by the movement of the water in the tube, *K*, which was connected through the tap T_{15} to the water reservoir, *R*. The reservoir could be connected by the three-

* The sensitiveness of the gas, which had been heated as described above, was measured, and the percentage of oxygen contained in it estimated to be about 0.02. It was thus evident that no appreciable amount of oxygen was formed by the interaction of chlorine and water vapour in the hot tube. By allowing some of the hydrogen which escaped at the tap T_4 to pass through potassium iodide solution, a rough estimation was made of the chlorine which remained in it. The percentage of chlorine was found to be about 0.20.

way tap T_{14} , both with the bottle, B , immersed in the thermostat, which served to keep the pressure in the reservoir constant during an experiment, and with the large bottle, B' , outside the thermostat, in which the pressure could be adjusted to any desired value.

FIG. 1.

The pressure in the insulation vessel could be measured by bringing the reservoir into connexion with the bottle B' (the necessary adjustment of pressure in B' being, of course, made), and then reading the pressure in B' on a mercury manometer.

The fall of pressure due to combination, measured by the move-

ment of the water in *K*, was accompanied, of course, by a slight decrease in volume. In order to make a correction for this, a small U-tube, *G*, containing water was introduced between the reservoir and the bottle *B*. After equilibrium had been attained, the tap T_{12} was closed and the water index drawn down to its original position. The change of pressure at constant volume was then measured by the difference in level of the water on each side of the tap T_{12} .

None of the taps or ground glass joints with which the gases came into contact before entering the insulation vessel was lubricated. Taps lubricated with grease and with metaphosphoric acid were tried and had to be abandoned; the former because grease was liable to be washed into the insulation vessel and render its inner surface dirty, and the latter because metaphosphoric acid sometimes contains ammonia.

In order to prevent any leakage of gas through the taps T_9 and T_{10} when the pressure in the actinometer was low without resorting to the use of lubricants, the procedure described below was adopted. The long tube leading from the T-piece, *J*, was fitted into a rubber stopper on to which a glass pipe, *P*, fitted tightly. The pipe, *P*, was connected by a long tube, *L*, to the bottle *B'*. By reducing the pressure in *B'* to a value a little below that in the actinometer, and opening the taps T_9 , T_{10} , the water in the insulation vessel could be drawn up the capillary tube to any desired position, and kept there, after closing the taps, while an experiment was being made.

When the gas from the cell was not entering the actinometer, it was allowed to escape through the water in the cylinder, *D*. While the actinometer was being filled care was taken that the water in *D* should be only slightly sucked up the long tubes which dipped into it. It was thereby ensured that the pressure in the apparatus outside the actinometer never fell below that of the atmosphere. The actinometer could be exhausted with the pump through the tap T_{13} .

Before introducing any gas into the actinometer, the tubes immediately outside the tap T_9 up to the tap T_6 were evacuated and filled with the required gas several times in order to be certain that air which might have diffused through the tap T_7 had been removed.

Small measured quantities of gas were introduced in the following way. The three-way tap, T_{14} , was turned so that the actinometer was connected with the bottle *B*. Then the reading on the water index was taken and gas admitted until the index had fallen a previously estimated amount. Then the water in the insulation

vessel was drawn back to its previous position—generally to a fixed mark just beyond tap T_9 —and the final reading taken. This gave the partial pressure of the gas introduced (after corrections for the changes in volume occasioned by bringing the index liquid to the fixed reading on the scale had been made) in cm. of water. All readings of pressure on the mercury manometer were taken with the water in the insolation vessel drawn up to a fixed position, and with the water in K at a fixed reading on the scale.

In all the experiments recorded, the current of the lighting circuit was measured on an ammeter with a wide scale, and was kept constant with a variable resistance worked by hand.

The thermostat was heated by electrolysis of $N/4$ -sulphuric acid solution in the annular space between two glass tubes. This method of heating is very convenient for photochemical experiments, since no light is produced by it. The temperature of the thermostat was kept constant in the usual way by means of an electric thermo-regulator.

Series (2).—Experiments showing the effect of altering the concentration of the chlorine alone in mixtures in which the concentrations both of the chlorine and of the hydrogen were moderately great. Filtered light was used.

	24.2	39.5	„	630

Series (3).—Experiments showing the effect of altering the concentration of the chlorine alone, and also of altering the concentration of the hydrogen alone in mixtures in which the concentrations both of the chlorine and of the hydrogen were moderately great.

In the three following experiments the second mixture was obtained by adding chlorine to the first, after the sensitiveness of the latter had been measured. The third mixture was obtained by exposing the second mixture to light until the pressure of the chlorine had been reduced to approximately its original value, and the fourth mixture was obtained from this by adding hydrogen until the pressure of this gas also was at its original value.

Since the experiments were conducted in such a way that the composition of the final mixture was approximately the same as that of the original mixture, and as the degrees of sensitiveness of these two mixtures proved to be nearly the same, it is obvious that the marked fall in sensitiveness occasioned by the addition of

hydrogen was not due to the presence of oxygen (or other impurity) in the added gas. In this series of experiments filtered light was used.

	17.8	17.5	"	71
	35.6	17.3	"	51

* In this experiment, consecutive measurements of the degrees of sensitiveness were in bad agreement, indicating the presence of destructible inhibitive impurities in the insulation vessel of the actinometer. The figures in column 4 are therefore not entirely to be relied on. In the experiments 1 and 3, however, I obtained no indication of the presence of inhibitive impurities when the same test was applied.

† The light was filtered through a greater column of chlorine, its intensity being thereby reduced.

It will be seen from the experimental results included under series (2) and series (3) that doubling the concentration of the chlorine in mixtures in which the partial pressures of the chlorine and the hydrogen lie roughly between $\frac{1}{4}$ and $\frac{1}{2}$ an atmosphere causes the rate of combination to become about 3.2 times as great. The experimental results included under series (3) demonstrate, as we have already stated, the inhibitive effect of hydrogen.

Series (4).—Experiments showing the effect of altering the concentration of the chlorine in mixtures containing a small proportion of hydrogen. Filtered light was used.

No. of expt.	Pressure in cm. of mercury of			Relative degrees of sensitiveness.	Ratio of the two values of the sensitiveness.

(b)	0.78	54.47	"	56.5	2.15

It will be seen that as the pressure of the hydrogen is reduced the sensitiveness of the mixture becomes more nearly proportional to the concentration of the chlorine.

Series (5).—Experiments showing the effect of altering the concentration of the hydrogen in mixtures in which the concentration of the hydrogen is small and that of the chlorine appreciable.

The experiments were performed in the following way. The insolation vessel containing the given mixture was exposed to light for a definite period of time (generally ten minutes), and after its contents had been brought to equilibrium in the manner already described a reading of the fall in pressure was taken. From this reading the constant, k , in the last column of the following tables was calculated. The same operation was then performed successively until the pressure of the hydrogen had become so small that it was no longer practicable to make measurements of the amount of combination with a sufficient degree of accuracy to furnish trustworthy values of the constant k . After the last measurement had been made, the insolation vessel was exposed to an intense white light for at least twelve hours in order to remove the whole of the hydrogen. The final reading taken after this exposure was a check on the accuracy of the figures given for the hydrogen obtained in the insolation vessel towards the end of the experiment.

It is obvious that, owing to the necessarily small magnitude of the measurements taken at the end of each experiment, exceptional care had to be taken to perform all the operations involved with the utmost degree of accuracy.

In the tables of results which follow, the numbers in the column headed x are the observed falls in pressure during the successive exposures to light, and the numbers in the column headed t the total exposure to light in minutes. The "constant" k in the last column was calculated on the assumption that the reaction proceeded according to the differential equation

$$d[\text{HCl}]/dt = k[\text{H}_2][\text{Cl}_2],$$

or, more precisely, in accordance with the equation

$$k = -\frac{1}{t(c-h)} \log_{10} \frac{2h-x}{2c-x} \cdot \frac{c}{h},$$

which c and h are the respective pressures of the chlorine and hydrogen at the beginning of an exposure to light, x is the fall in pressure during that exposure, and t the time of exposure.

Pressure of oxygen throughout = 0-70 cm. of mercury.					

A comparison of the pressures of the hydrogen with the corresponding values of k will show that the order of the reaction with respect to the hydrogen lies between 1 and $\frac{1}{2}$. The order appears to approach 1 as the pressure of the hydrogen is reduced. It certainly falls, as the earlier experiments show, through zero to a negative value as the pressure of the hydrogen is increased.

Series (6).—Experiments showing the effect of varying the concentration of (a) the chlorine, (b) the hydrogen in mixtures containing a small proportion of chlorine.

Since the rate of combination of mixtures containing small proportions of chlorine is exceedingly small, the actinometer was illuminated with white light in order that a measurable rate of combination might be obtained. Since the pressure of the chlorine was very small, the amount of light absorbed in the actinometer must also have been very small and therefore the use of a light filter was unnecessary.

(a).

No. of expt.	Pressure in cm. of mercury of			Relative degrees of sensitiveness.	Ratio of the two values of the sensitiveness.
	Hydrogen.	Chlorine.	Oxygen.		
1	29.75	2.39	unknown	218	
	28.50	1.19	"	65	
				corrected value	
				58	3.93
2	60.04	1.68	0.13	13.0	
	59.94	3.44	0.13	58.0	4.41

The above experiments demonstrate that for mixtures containing small proportions of chlorine the rate of combination is proportional to the square of the pressure of the chlorine. In expt. 1, the rate of combination was measured in a mixture containing no added oxygen. Then the hydrogen and chlorine were combined until the pressure of the latter had reached half its original value and another measurement of the rate was then made. A correction was applied for the error due to the solubility of the chlorine.

In expt. 2, the rate of combination was measured in a mixture containing a little added oxygen. The concentration of the chlorine was doubled by the addition of chlorine evolved from the electrolytic cell when the hydrochloric acid in it was very concentrated, and another measurement of the rate made.

(b).

No. of expt.	Pressure in cm. of mercury of			Relative degrees of sensitiveness.	Ratio of the two values of the sensitiveness.
	Hydrogen.	Chlorine.	Oxygen.		
1	28.50	1.193	unknown	65.1	
	56.75	0.943	"	31.3	2.08
2	29.92	2.41	0.096	73.0	
	59.70	2.27	0.096	41.1	1.78
					5 K 2

The above experiments demonstrate clearly that hydrogen acts inhibitably and that, if an allowance is made for the small amount of chlorine contained in the hydrogen, its effect is such that the sensitiveness is inversely proportional to a power of its concentration which is a little less than one. The determinations of the rates of combination were difficult to make with accuracy on account of the extreme insensitiveness of the mixture.

Effect of Oxygen.

If the results of experiments 1(a) and 1(b) of series 5 are compared with the results of experiments 2(a), 2(b), 3(a), 3(b) of the same series, it will be seen that the rate of combination in mixtures in which the pressure of the oxygen was 0.30 cm. of mercury was less than twice the rate of combination in mixtures of the same composition with respect to hydrogen and chlorine in which the

pressure of the oxygen was 0.60 cm. and 0.70 cm. of mercury. Further, it will be seen that when the pressure of the hydrogen had been reduced to a very small value by combination, the rates in corresponding mixtures became practically equal, and the calculated constants k of nearly the same value. It thus appears that the rate of combination is independent of the concentration of the oxygen when the pressure of the hydrogen is very small. The conclusion is, however, not entirely legitimate, since, as we have already stated, no special precautions were taken to keep the intensity of illumination quite constant in experiments designated by different numbers.

Therefore, in order to test the conclusion more stringently, the rates in mixtures containing no added oxygen were compared with those in mixtures containing fairly large quantities of added oxygen. The results are recorded on p. 3076. Filtered light was used.

These experiments demonstrate that, in mixtures containing very small proportions of hydrogen and variable proportions of oxygen, the rate of combination is nearly independent of the concentration of the oxygen.

Series (8).—Experiments showing the effect of varying the concentration of the oxygen (*a*) in mixtures containing moderate proportions of hydrogen and chlorine, (*b*) in mixtures containing small proportions of chlorine.

No. of expt.	Pressure in cm. of mercury of			Relative degrees of sensitiveness.
	Cl ₂ .	H ₂ .	O ₂ .	
1 (<i>a</i>)	35.00	35.00	0.235	120.00
	34.75	34.75	0.470	58.00
	34.60	34.60	2.560	10.70
1 (<i>b</i>)	2.265	59.70	0.100	18.70
	2.107	59.54	0.192	10.65

These experiments demonstrate that both in case (*a*) and case (*b*) the ordinary relation holds, namely, the rate of combination is inversely proportional to the concentration of the oxygen.

Mixtures of Maximum Sensitiveness.

A rough determination was made of the quantity of hydrogen that must be added to a given quantity of chlorine in order to produce the maximum degree of sensitiveness. Hydrogen was added in small portions to a mixture in which the partial pressure of the chlorine was 60 cm. of mercury and that of the oxygen 0.4 cm. of mercury.

The mixture attained its maximum sensitiveness when the pressure of the hydrogen was between 11.0 cm. of mercury and 16.0 cm. of mercury.

Conclusions.

(1) The rate of combination of the hydrogen and chlorine in mixtures of electrolytic gas and oxygen is nearly independent of the pressure of the gas.

(2) In mixtures in which the concentrations of the hydrogen and the oxygen are kept constant the rate of combination is

- (a) proportional to the first power of the concentration of the chlorine when the proportion of hydrogen is small;
- (b) proportional to a power of the concentration of the chlorine between the first and the second when a moderate proportion of hydrogen is present;
- (c) proportional to the square of the concentration of the chlorine when the proportion of chlorine is small and that of the hydrogen large.

(3) In mixtures in which the concentrations of the chlorine and oxygen are kept constant the rate of combination is

- (a) proportional to the concentration of the hydrogen when the proportion of hydrogen is small;
- (b) inversely proportional to a power of the concentration of the hydrogen which is rather less than $\frac{1}{2}$ when the proportions of hydrogen and chlorine are moderate;
- (c) inversely proportional to a power of the concentration of the hydrogen which is rather less than 1 when the proportion of chlorine is small.

(4) The rate of combination is independent of the concentration of the oxygen in mixtures in which the concentration of the hydrogen is very small; for all other mixtures, it is inversely proportional to the concentration of the oxygen. The results can be summarised by the formula

$$\frac{d[\text{HCl}]}{dt} = \frac{k_1[\text{H}_2][\text{Cl}_2]^2}{k_2[\text{H}_2]^{2-\epsilon}[\text{O}_2] + [\text{Cl}_2]}$$

We are forced to the conclusion that the observed inhibitive effects of oxygen and of hydrogen are not—as has been hitherto assumed—due to the direct and independent action of these gases, but to the joint agency of both.

In conclusion, I wish to thank my husband for having suggested this investigation and for his advice during the course of the experiments, which were performed in the chemical laboratory of Jesus College, Oxford.

NOTE ON THE THEORY OF THE CHANGE.

(By D. L. CHAPMAN and M. C. C. CHAPMAN.)

It has already been stated that the discoveries announced in this paper cannot be explained by the unmodified working hypothesis of one of us and his collaborators. We will now indicate briefly what changes in the old hypothesis can, in our opinion, render it capable of explaining the facts recently discovered.

It has hitherto been assumed that when light is absorbed by chlorine unstable active chlorine molecules are formed, which by collision with oxygen molecules can lose their activating energy. Oxygen was, in fact, supposed to play the rôle of a deactivating catalyst. For the arguments, based on quantitative measurements and on analogy, in support of this view, previous papers must be consulted. It would, however, now appear to be probable that active chlorine is not deactivated by oxygen alone, but by the joint agency of oxygen and hydrogen. It seems to us that the simplest way of explaining this fact is on the supposition that the active energy is shared between the chlorine and oxygen, and the hydrogen can rapidly remove it from the oxygen. If we represent an active chlorine molecule by the symbol $\text{Cl}_2\epsilon$, in which ϵ is the active energy combined with the molecule of chlorine, then in a mixture of chlorine and oxygen the reversible change given by the equation

would take place, and in the steady state the proportion of active chlorine to active oxygen would be determined by the mass equation

$$k_2[\text{Cl}_2\epsilon][\text{O}_2] = k_3[\text{O}_2\epsilon][\text{Cl}_2].$$

We shall suppose that equilibrium is very rapidly established, that is, that the constants k_2 and k_3 are very large.

Now when a gaseous system in which only an infinitely small amount of chemical change can take place is absorbing light, the efficient energy absorbed by the molecules is degraded to heat with comparative rapidity. The process of degradation is sometimes accompanied by the phenomena of resonance and fluorescence, which admit of its being investigated; but as yet very little is known about the laws which control the change. In the present case we shall assume that the rate of degradation per unit volume is proportional to the concentration of the active chlorine, and is given by $k_4[\text{Cl}_2\epsilon]$, in which k_4 is a constant.

The usual assumption that the rate of formation of active chlorine is proportional to the rate of absorption of light energy will also

be made. It will now be seen that the rate of increase of concentration of active chlorine is given by the equation

$$d[\text{Cl}_2\epsilon]/dt = k_1 I[\text{Cl}_2] - k_2[\text{Cl}_2\epsilon][\text{O}_2] + k_3[\text{Cl}_2][\text{O}_2\epsilon] - k_4[\text{Cl}_2\epsilon] \quad (\text{i})$$

in which I is the intensity of illumination, and k_1 a constant. In the steady state, $d[\text{Cl}_2\epsilon]/dt$ is, of course, zero.

We have now to account for the removal of activating energy from molecules of oxygen by means of hydrogen. The simplest hypothesis is that the active oxygen combines with hydrogen to produce water, the active energy being simultaneously degraded. If the rate of formation of water is given by the normal mass equation, the rate of disappearance of active oxygen attributable to this cause would be given by the expression $k_5[\text{O}_2\epsilon][\text{H}_2]^2$, in which k_5 is a constant, and the total rate of increase of concentration of active oxygen would clearly be given by the equation

$$d[\text{O}_2\epsilon]/dt = k_2[\text{Cl}_2\epsilon][\text{O}_2] - k_3[\text{Cl}_2][\text{O}_2\epsilon] - k_5[\text{O}_2\epsilon][\text{H}_2]^2 \quad (\text{ii})$$

in which again $d[\text{O}_2\epsilon]/dt$ will become zero when the steady state is reached.

Putting $d[\text{Cl}_2\epsilon]/dt = 0$ and $d[\text{O}_2\epsilon]/dt = 0$ in equations (i) and (ii) and solving for $[\text{Cl}_2\epsilon]$, we obtain

$$[\text{Cl}_2\epsilon] = \frac{k_1 I[\text{Cl}_2][k_3[\text{Cl}_2] + k_5[\text{H}_2]^2]}{k_2 k_5[\text{H}_2]^2[\text{O}_2] + k_4[k_3[\text{Cl}_2] + k_5[\text{H}_2]^2]}$$

Remembering that by hypothesis k_2 and k_3 are large in comparison with k_4 and k_5 , we see that

$$[\text{Cl}_2\epsilon] = \frac{k_1 k_3 I[\text{Cl}_2]^2}{k_2 k_5[\text{H}_2]^2[\text{O}_2] + k_4 k_3[\text{Cl}_2]}$$

Whence

$$\frac{d[\text{HCl}]}{dt} = k_6[\text{H}_2][\text{Cl}_2\epsilon] = \frac{k_1 k_3 k_6 I[\text{Cl}_2]^2[\text{H}_2]}{k_2 k_5[\text{H}_2]^2[\text{O}_2] + k_4 k_3[\text{Cl}_2]} \quad (\text{iii})$$

in good agreement with the equation deduced from the experimental results.

It will, no doubt, have been observed that this hypothesis (as well as the older one) implies that the degradation of energy which occurs when hydrogen combines with active chlorine is negligible.*

* The most obvious method of justifying the implication is to assume that active chlorine can form with hydrogen a moderately stable molecular compound, the molecules of which break up on colliding with ordinary chlorine molecules in accordance with the equation

According to this view the active chlorine would function as a species of catalyst, and cause an increase in the velocity coefficient of both the action and the reverse action, but, owing to its instability, not necessarily in the same ratio as would be the case with a normal stable catalyst. One would, in fact, expect such a catalyst to shift the thermal equilibrium in the sense which is accompanied by the absorption of energy. It is also possible that the energy required to activate a molecule of chlorine is small.

On this point, the reader should consult Nernst (*Z. Elektrochem.*, 1918, **24**, 335), whose theory, with the aid of assumptions similar to those made above, will explain the facts which are known about the photochemical union of hydrogen and chlorine. The assumption that water is formed when a mixture of chlorine, hydrogen, and oxygen is exposed to light under the conditions of these experiments needs confirmation. It is certain that the oxygen disappears very slowly (if at all). Baly and Barker (*loc. cit.*) assert that oxygen is produced during the illumination. On the other hand, Weigert (*Ann. Physik*, 1907, **24**, 253) has shown that water is formed when mixtures of hydrogen, oxygen, and chlorine, in which the proportion of oxygen is large, are exposed in a glass tube, to the light from a mercury arc lamp.

[Received, September 17th, 1923.]

CCCLXIV.—*The Interaction of Bromine with Acetic Anhydride.*

By KENNEDY JOSEPH PREVITÉ ORTON, HERBERT BEN WATSON,
and (the late) JOHN EDWIN BAYLISS.

It was first shown by Urech (*Ber.*, 1880, **13**, 1687) that acetyl bromide and monobromoacetic acid could be isolated by fractional distillation from the product of the action of bromine on acetic anhydride at a somewhat elevated temperature. At the ordinary temperature, Lapworth (*T.*, 1904, **85**, 30) found that acetic anhydride is only very slowly affected, but that after saturation with hydrogen chloride or addition of a few drops of sulphuric acid the action is so vigorous that the temperature rises. In the course of researches on the halogenation and nitration of anilines and anilides, it was discovered (Orton and M. Jones, *T.*, 1912, **101**, 1720) that solutions of chlorine and bromine in acetic anhydride remained unchanged in the dark, but exposure to light was followed by a reaction. Moreover, the addition of small quantities of sulphuric or perchloric acid or ferric chloride always led to reaction. It was found that the rate of disappearance of bromine was not dependent on the concentration of the bromine, and that the presence of water retarded the reaction.

Our fuller examination of the interaction of bromine and acetic anhydride has shown that sulphuric acid, ferric chloride and bromide, stannic chloride and bromide, and hydrogen bromide are good catalysts, and that acetyl chloride and hydrogen chloride are poorer catalysts, but that iodine, nitric acid, and water are without effect.

With all the catalysts, except hydrogen bromide, the reaction follows the same course. There is an initial period of small velocity (or period of acceleration), followed by the attainment of a constant maximum velocity which is independent of the concentration of bromine (see Fig. 1). This latter characteristic is similar to Lapworth's (*loc. cit.*) original observation on the action of bromine on aqueous acetone, and to Dawson's (Dawson and Leslie, T., 1909, 95, 1860; Dawson and Wheatley, T., 1910, 97, 2048) on the action of iodine on ketones, and on aliphatic aldehydes (Dawson, Burton, and Ark, T., 1914, 105, 1275). The rate is independent of the concentration of the halogen. This peculiarity was satisfactorily explained by Lapworth (*loc. cit.*) by assuming an interaction—practically instantaneous—between bromine and an enolic tautomeride of acetone, which is formed only slowly from the predominant ketonic form. The velocity measured is the rate of change of ketone to enol. Meyer (*Ber.*, 1912, 45, 2864) finds that bromination of malonic acid and ketonic acids and esters is similar, and Aschan (*Ber.*, 1912, 45, 1913) has adopted Lapworth's suggestion to explain the α -bromination of carboxylic acids, which he formulates as follows when acetyl chloride is brominated :

It may be suggested that the interaction of acetic anhydride and bromine follows a similar course. The catalyst hastens the formation of the reactive form (enol) from the inactive, or perhaps forms a complex which is itself reactive. On the first supposition, the series of changes may be represented thus,

Of these transformations, the change to the enolic form proceeds with measurable velocity, the action of bromine thereon being too fast for measurement. It is possible that the hydrogen bromide is not "free," but at stage IV remains in some sort of combination.

If a compound of the type III reacts like free bromine and can

be titrated, as is indicated, the fall in bromine concentration is determined by the conversion of III into IV, which is not improbably a reversible change.

The maximum velocity and the duration of the period of low velocity vary with different catalysts and with different concentrations of the same catalyst. Fig. 1 shows curves obtained with sulphuric acid as catalyst, and these are typical of those got with each of the seven catalysts. The actual course of the reaction

FIG. 1.

is represented by ACB . The net result is obviously equivalent to that of a period of zero velocity (period of induction) followed by the immediate attainment of the maximum velocity, as represented by ADB . The reaction was regarded from this point of view, and the value of the maximum velocity and the duration of the period of induction were calculated as follows. Extrapolation of the straight line to the time axis (point B in figure) gives the time after which the bromine concentration is zero, that is, the time after which the reaction is complete. Let this time be T . Then if x

5 K* 2

be the concentration of bromine after a time t , the maximum velocity (represented by BD) will be given by

$$K = x/(T - t).$$

Moreover, the equation of the straight line is of the form

$$t = -x/K + T.$$

The equation of a parallel line will be

$$t = -x/K + T',$$

and if this passes through the point $x = a$; $t = 0$ (a being the initial concentration of bromine), then $T - T'$ measures the period of induction, P . Therefore

$$P = T - T' = T - a/K.$$

Table I gives the values obtained for the maximum velocity and the duration of the period of induction under the influence of different catalysts at varying concentrations. In all cases, increase in the concentration of the catalyst shortens the period of induction, and in some cases increases the velocity subsequently attained. There is no obvious mathematical relation between the concentration of catalyst and the velocity of the reaction or the length of the period of induction. Of the seven catalysts used, ferric chloride, ferric bromide, and sulphuric acid are the most effective, giving the shortest induction periods and the highest velocities. Acetyl chloride and hydrogen chloride give the longest induction periods, that in the case of hydrogen chloride being extraordinarily long (which is possibly due to a direct reaction with the anhydride, $\text{CH}_3\cdot\text{CO}_2\text{H} + \text{CH}_3\cdot\text{COCl}$).

The general form of the velocity curves recalls the observations of Hell (*Ber.*, 1880, **13**, 531) on the bromination of aliphatic acids. He observed first a period of feeble action lasting until from 10 to 20 per cent. of the bromine had reacted, then a period of rapid substitution, and finally, after some 60 per cent. of the bromine had disappeared, a diminution in the rate of substitution. Dawson and his co-workers (*loc. cit.*) found that the velocity of absorption of iodine by ketones decreased towards the end of the reaction; they considered it to be due to the reversibility of the reaction. In the present series of experiments, the reaction continued to completion, that is, until all the bromine had disappeared, but at least with acetyl chloride as catalyst, the reaction appeared to slow down towards the end.

Hydrogen bromide is a good catalyst of the reaction, but the velocity curves are very markedly different from those given by other catalysts. In the first place, no period of low velocity was

observed, and, secondly, the velocity was found to vary directly but not proportionately as the concentration of the bromine. Experiments with different concentrations of catalyst showed that the velocity of bromine absorption was roughly proportional to the square root of the concentration of hydrogen bromide. It may be suggested that the unusual behaviour in presence of hydrogen bromide is connected with the formation of an additive compound similar to the additive compounds of acetic acid, bromine, and hydrogen bromide described by Steiner (*Ber.*, 1874, 7, 184) and by Hell and Mühlhäuser (*Ber.*, 1877, 10, 2102; 1879, 12, 727), and mentioned by Michael (*Amer. Chem. J.*, 1884, 5, 202) and Ward (*T.*, 1922, 121, 1161). Hell and Mühlhäuser give the formula of the most stable of these compounds as $(C_2H_4O_2Br_2)_4HBr$, and consider that the formation of such compounds is responsible for the catalytic effect of hydrogen bromide on the bromination of aliphatic acids. The formation of hydrogen perbromide, HBr_3 , takes place to a considerable extent in glacial acetic acid solutions containing hydrogen bromide and bromine (W. J. Jones, *T.*, 1911, 99, 392); its formation here is highly probable, and it may be also an important cause of the peculiar behaviour of hydrogen bromide; but a fuller investigation of this point is necessary.

Pure dry iodine has no catalytic effect on the interaction of bromine and acetic anhydride, but in presence of small quantities of water it is a good catalyst. For a given concentration of iodine and of water the velocity curve is of the usual type. The value of the maximum velocity attained decreases somewhat with increase of water concentration, but the main effect of variation of water concentration is to change the duration of the period of induction. With constant iodine concentration, this period decreases with increase of water concentration up to 1.8 per cent. of water, but beyond 1.8 per cent. it increases. The effect of water is not due to the reaction $Br_2 + H_2O \rightleftharpoons HBr + HBrO$, for water alone does not catalyse the reaction, and, further, water increases the period of induction and reduces the velocity when ferric chloride is the catalyst. The effect was not likely to be due to hydrogen iodide produced by hydrolysis of the iodine, for the equilibrium constants of the reactions $Br_2 + H_2O \rightleftharpoons HBr + HBrO$ and $I_2 + H_2O \rightleftharpoons HI + HIO$ at 25° are $[H][Br][HBrO]/[Br_2] = 2.4 \times 10^{-8}$ and $[H][I][HIO]/[I_2] = 0.6 \times 10^{-12}$, respectively (Bray, *J. Amer. Chem. Soc.*, 1910, 32, 932). The period of induction, moreover, was not reduced by keeping the acetic anhydride, iodine, and water in contact at 25° for nine hours before adding bromine. On substituting as catalyst iodine bromide, IBr , for the iodine, a velocity curve identical with that given by iodine was obtained when the

concentrations of iodine and water were the same in both cases. This result seems undoubtedly to point to the conclusion that catalysis by iodine and water in conjunction is due to the hydrogen bromide liberated by hydrolysis of iodine bromide first formed.

The effect of dilution of the system with glacial acetic acid was studied, sulphuric acid being used as catalyst. The velocity curves obtained were of the normal type, but the dilution was found to increase very greatly the period of induction, and to lower considerably the subsequent velocity. Table II shows a comparison of the experiments in pure acetic anhydride with those in acetic anhydride diluted with glacial acetic acid.

Inactivity of Nitric Acid.—W. H. Gray (*Rep. Brit. Assoc.*; Thesis, University of Wales, 1913) found that a solution of bromine in acetic anhydride, in presence of nitric acid at a concentration of $0.0028M$, showed no fall in thiosulphate titre in forty and a half hours. Dilution with glacial acetic acid had no effect: in mixtures containing 60, 40, or 20 per cent. of acetic anhydride, and nitric acid at $0.0018M$, no fall in the thiosulphate titre was found after fifty hours. It is clear that nitric acid occupies a unique position here, as it does also in its effect on the hydrolysis of acetic anhydride (Orton and M. Jones, T., 1912, **101**, 1708), and in its peculiar reaction with anilines in acetic acid solution in presence of acetic anhydride (Orton, T., 1902, **81**, 495; Smith and Orton, T., 1908, **93**, 1242). This inactivity of nitric acid is most probably due to the formation of the compound diacetylnitric acid, $(\text{CH}_3\text{CO}\cdot\text{O})_2\text{N}(\text{OH})_2$, described by Pictet and Genequand (*Ber.*, 1902, **35**, 2526), or of acetyl nitrate, $\text{CH}_3\text{CO}\cdot\text{O}\cdot\text{NO}_2$ (Pictet and Khotinsky, *Ber.*, 1907, **40**, 1163).

redistillation, as described by Orton and Jones (T., 1912, 101, 1720). The bromine was shaken with an equal quantity of water, separated, and then shaken with concentrated sulphuric acid, and allowed to stand for three hours. Finally it was separated and distilled.

Method of Velocity Measurements.—0.33 C.c. of the purified bromine was added to the required quantity of a solution of the catalyst in pure acetic anhydride, and the whole made up to 25 c.c. at 25° with pure acetic anhydride. This gave, approximately, moles Br_2 : moles $\text{Ac}_2\text{O} = 1:40$. Two c.c. were at once withdrawn and added to excess of potassium iodide, and the iodine liberated was titrated against $N/10$ -sodium thiosulphate. The titration was repeated at intervals.

Sulphuric Acid as Catalyst.—A standard solution of sulphuric acid "pure for analysis" was prepared and used as described above. Table III gives the figures obtained with sulphuric acid as catalyst.

Ferric Chloride as Catalyst.—A specimen of anhydrous ferric chloride was distilled into a glass bottle from a bulb tube. The bottle had previously been cleaned, dried, and kept in a vacuum desiccator for a week. After sublimation, the sample was placed in a vacuum desiccator over potash to remove traces of hydrogen chloride. A standard solution of the pure ferric chloride in acetic anhydride was prepared by weighing. Table IV gives figures obtained with ferric chloride as catalyst.

Effect of Water on Catalysis by Ferric Chloride.—The ferric chloride concentration was kept constant (0.0012*M*) and varying small amounts of water, previously distilled from permanganate and potash, were added. Table V gives the results obtained.

It might be noted here that solutions of ferric chloride in acetic anhydride of the strengths used have a violet colour, and on addition of water the colour changes to yellow.

Ferric Bromide as Catalyst.—The ferric bromide was prepared from iron wire and bromine. Clean dry iron wire and 5 c.c. of bromine were kept in a stoppered bottle for twenty-four hours. The excess of bromine was then removed by means of a slow stream of dry carbon dioxide; and a solution of the ferric bromide in acetic anhydride was prepared and estimated gravimetrically. The figures obtained with ferric bromide as catalyst are given in Table VI.

driving off the excess bromine by warming. The bromide was then distilled into a dry vessel. It came over at 201° as a light yellow liquid which, on standing, completely solidified to a hard, white, crystalline mass. A standard solution in acetic anhydride was made by weighing. Table VIII gives figures obtained with stannic bromide as catalyst.

Acetyl Chloride as Catalyst.—The acetyl chloride was purified by bubbling dried air through it and then distilling into a clean, dry, specially constructed, pipette-stoppered bottle of about 180 c.c. capacity (Fig. 3). A standard solution was made rapidly in another similar bottle. The figures obtained with acetyl chloride as catalyst are given in Table IX.

Hydrogen Chloride as Catalyst.—Pure concentrated hydrochloric acid was run into pure concentrated sulphuric acid, and the hydrogen chloride gas liberated passed over calcium chloride and then into

Hydrogen Bromide as Catalyst.—A small distilling flask was half filled with phosphorus pentoxide, and Kahlbaum's hydrobromic acid dropped in slowly. The evolved hydrogen bromide gas was passed into pure acetic anhydride contained in the pipette-stoppered bottle, and the concentration of the solution determined gravimetrically. The velocity curves obtained with hydrogen bromide as catalyst are shown in Fig. 2. Table XI shows the figures obtained.

Catalysis by Iodine and Water in Conjunction.—A quantity of Kahlbaum's resublimed iodine was ground up in a mortar with some previously ignited barium oxide, sublimed over a small flame, and dried in a desiccator over calcium nitrate. This pure dry iodine was found to have no catalytic effect, and experiments were therefore carried out keeping the iodine concentration constant (0.0047N) and adding varying small quantities of water, previously distilled from permanganate and potash. Table XII (p. 3091) gives the figures obtained with iodine and water as catalyst.

The curve connecting period of induction with water concentration shows a minimum period of induction at 1.8 per cent. of water.

Iodine Bromide as Catalyst.—A mixture of pure iodine with excess of pure bromine was kept for half an hour in a current of dry carbon dioxide at a temperature of 40° to 60°. The carbon dioxide drove off the excess of bromine, and iodine

bromide solidified, on cooling, to a black solid. It was dissolved in acetic anhydride, and the concentration of the solution determined by adding 2 c.c. to potassium iodide solution and titrating the liberated iodine: $\text{HI} + \text{IBr} = \text{HBr} + \text{I}_2$.

An experiment was carried out with iodine bromide and water as catalyst, the concentration of iodine (as IBr) being 0.0051N and that of water 2 per cent. Table XIII (p. 3096) shows a comparison of the results with results got when iodine (as such) and water were used as catalyst, at similar concentrations.

Effect of Dilution with Glacial Acetic Acid (H_2SO_4 as catalyst).—0.33 C.c. of pure bromine, a measured quantity of the solution of sulphuric acid in acetic anhydride, and a further measured quantity of acetic anhydride were made up to 25 c.c. at 25° with glacial acetic acid. The amount of acetic anhydride added in each case gave a concentration of 5.6*M*, instead of the 10*M* in the experiments with acetic anhydride alone. Table XIV (p. 3095) gives the figures obtained by the velocity measurements.

Summary.

1. Bromine and acetic anhydride do not perceptibly react in the dark at the ordinary temperature. Illumination induces reaction.
 2. Sulphuric acid, ferric chloride and bromide, stannic chloride and bromide, and hydrogen bromide are good catalysts of the reaction. Acetyl chloride and hydrogen chloride are less effective. Iodine, nitric acid, and water are without effect, but iodine in conjunction with a small quantity of water is a good catalyst.
 3. A period of slow velocity precedes the attainment of a maximum velocity, which is independent of the concentration of the bromine. With hydrogen bromide, there is no period of slow velocity, and the velocity curves have a different character.
- Work on this subject is being continued.

The expense of this research was in part defrayed by grants from the Royal Society and the Council of the British Association, to whom the authors tender their thanks.

CCCLXV.—*The Bromine Compounds of Phenanthrene.*
Part II.

By HERBERT HENSTOCK.

THE bromination of phenanthrene at temperatures between 0° and 76° has been carried out systematically with varying quantities of bromine at each temperature. With one and with one and a half molecules of bromine, the only substances isolated in any quantity at these temperatures were 10-bromophenanthrene, m. p. 63° , and unchanged hydrocarbon. None of the remaining possible monobromo-compounds was found, the most probable reason for this being the fact that the bridge is the weakest spot with respect to the attack of bromine. With two or three molecules of bromine, the dibromophenanthrenes isolated were 10 : 4-, m. p. 113° (Werner, *Annalen*, 1902, **321**, 331); 10 : 2-, m. p. 161° (T., 1921, **119**, 55); 10 : 6-, m. p. 143.5° (Schmidt and Ladner, *Ber.*, 1904, **37**, 3571; compare Sandqvist, *Ber.*, 1920, **53**, 168); 10 : 8-, m. p. 123° (Sandqvist, *Ber.*, 1915, **48**, 1146); and 2 : 7-, m. p. $199-200^{\circ}$ (Hayduck, *Annalen*, 1873, **167**, 181; Schmidt and Mezger, *Ber.*, 1907, **40**, 4562). 9 : 10-Dibromophenanthrene (Hayduck, *loc. cit.*) was not formed in these reactions, but a minute yield of a dibromo-compound melting at 203° , also described by Hayduck, was obtained.

The reaction temperature may have influenced the orientation in some cases. In general it may be stated that at low temperatures a small quantity of bromine seems to favour the production of the monobromo-compound, whilst a large quantity tends to produce dibromo-compounds having one bromine atom in the bridge. At high temperatures, with a large quantity of bromine, 2 : 7-dibromophenanthrene is produced.

The same compounds were repeatedly formed in these reactions, and therefore they are the most stable and the most easily formed of all the bromophenanthrenes. In examining the reasons for the production of these particular compounds, recourse may be had to Lapworth's theory of induced alternate polarities of atoms (*Mem. Manchester Phil. Soc.*, 1920, **64**, 1; T., 1922, **121**, 416; compare also Kermack and Robinson, T., 1922, **121**, 427). In the formation of 10-bromophenanthrene, bromine adds on at the 9 : 10-positions, as though -CH:CH- were an ethylenic group, forming phenanthrene 9 : 10-dibromide, which on elimination of hydrogen bromide yields 10-bromophenanthrene.

A second bromine atom would attack the molecule in those positions where the negative carbon atoms are situated and thus the 10:2-, 10:4-, 10:6-, 10:8- and 10:9- dibromo-compounds would form. These are indeed the substances actually produced. Compounds having one bromine atom in the bridge would be more difficult to prepare and would probably be unstable. 2:7-Dibromophenanthrene would be formed in an analogous fashion, but it is not clear why the 2:1-, 2:3-, and 2:5-compounds also should not be produced in the same reaction; all that can be stated is that, when the bridge is vacant, bromine enters the molecule in positions as far apart as possible.

EXPERIMENTAL.

Experiments were carried out by adding the calculated quantity of bromine, in 50 grams of the solvent, to 10 grams of phenanthrene dissolved in such an amount of solvent that no crystallisation of phenanthrene occurred at the chosen temperature. Every precaution was adopted to ensure thorough drying of the materials, and the additions were made in such a way as to ensure the reactions taking place at constant temperature.

In the experiments at 0° and 15°, after the solid phenanthrene 9:10-dibromide had been removed, the mother-liquor (Q) was treated with about one-tenth of its volume of alcohol and well shaken; two layers formed, which, on separation and evaporation of the solvents, yielded mixtures of solids that were separated by repeated recrystallisation, first from suitably dilute alcohol and afterwards from solvents appropriate to each substance.

Where two and three molecules of bromine were used, in the reactions at 30° and 45°, the mother-liquor (Q) was evaporated, yielding a dark brown oil, which was distilled under a pressure of about 40 mm., when a nearly colourless oil came over between 270° and 280°, and a smaller fraction, b. p. 280—290°, both of which soon solidified. Their constituents were extracted as described above, dilute acetone taking the place of dilute alcohol. The chief part of the dibromo-compounds occurred in the higher boiling fraction. Brominations at the boiling points of chloroform and carbon tetrachloride were conducted on the water-bath for twelve hours. The resulting oil solidified, on standing at about 0°, and the mass was extracted twice with cold light petroleum, leaving 2:7-dibromophenanthrene (yield 55 per cent.). This procedure gives a better yield, and obviates most of the difficulties met with in the method given by Schmidt and Mezger (*loc. cit.*). The melting points of the substances isolated at each temperature are given on p. 3099.

REACTIVITY OF THE HALOGENS IN AROMATIC COMPOUNDS. 3099

Temp. of reaction.	Solvent.	Molecules of bromine used and m. p.'s of compounds produced.			
		1.	1½.	2.	3.
0°	CCl ₄	63°	63° 113	63° 113 123	63° 113 123
15	CCl ₄ CHCl ₃	—	63 —	— 63 162	— 63 162
30	CCl ₄	63	63	63 143·5	63 143·5
45	CCl ₄	—	—	63	63
61·5	CHCl ₃	—	—	199—200	199—200
76	CCl ₄	—	—	63 199—200	63 199—200

The yields were generally low; those of the dibromo-compounds were as follows: 10:2-, 8·3; 10:4-, 4·4; 10:6-, 7·2; 10:8-, 3·0 per cent. of that theoretically possible. The best yield of monobromophenanthrene was 21·75 grams, obtained from 32 grams of the hydrocarbon, which compares favourably with the 20 grams obtained by Austin (T., 1908, 94, 1760).

The author's thanks are due to the Research Fund Committee of the Chemical Society and to the Government Grant Committee of the Royal Society for grants in aid of the work.

CCCLXVI.—Quantitative Measurements of the Reactivity of the Halogens in Aromatic Compounds.

By ARTHUR HENRY RHEINLANDER.

THE enhanced reactivity conferred on a halogen atom in the benzene ring by the presence of nitro-groups in the nucleus was first noticed by Pisani in 1854. The problems arising from inquiries into the causes of this, and the wider study of reactivity in general, have since attracted a large number of chemical workers. Many recent investigators have assumed that substitution in these compounds is preceded by addition (compare Flürscheim, *J. pr. Chem.*, 1907, [ii], 76, 165), and in certain cases intermediate additive compounds have been isolated (*vide* Picton and Sudborough, T., 1906, 89, 583; Giua, Marcellino, and Curti, *Gazzetta*, 1920, 50, ii, 300).

Kenner and his co-workers, in recent papers (T., 1914, 105, 2717; 1920, 117, 852; 1921, 119, 1047, 1053), have directed attention to the important interrelation between certain groupings and

their orientation in the nucleus in problems concerning reactivity. They also adopt the addition theory of chemical reaction.

On the other hand, the quantitative measurements of the reactions between organic halogen compounds and various bases made by Lulofs (*Rec. trav. chim.*, 1901, **20**, 292), Segaller (T., 1913, **103**, 1154), Senter and Ward (T., 1912, **101**, 253), Senter and Wood (T., 1915, **107**, 1070), etc., clearly point to typical bimolecular reactions and preclude the existence of additive compounds in large proportion.

In view of the conflicting results and of the various theories briefly referred to above, it is clear that more quantitative work from the kinetic point of view is desirable to elucidate the problem. So far as concerns the actual determination of the velocity coefficients of reactions between halogenated nitrobenzenes and various bases, Lulofs's work (*loc. cit.*) appears to be the only contribution; some comparative tests on the relative reactivity of these substances were, however, recently published by Franzen and Bockhacker (*Ber.*, 1920, **53**, 1174). The present investigation was originally undertaken to obtain quantitative measurements of the reactivity of 1-bromo-2:4-dinitrobenzene with aniline and methylaniline, with the special object of ascertaining whether the reactions were unimolecular or bimolecular, and so to obtain evidence of the existence or non-existence in appreciable quantity of intermediate additive compounds. The work was subsequently extended to embrace the mono- and tri-nitrobromo-derivatives with the same object in view, and then further extended to obtain data on the order of the reactivities of chlorine, bromine, and iodine in the analogous compounds.

EXPERIMENTAL.

The ethyl alcohol used as solvent in these experiments was commercial "absolute" alcohol, d_{4}^{20} 0.79784 (99.16 per cent. by volume). In the examination of the reactivity of the mononitro-compounds with sodium ethoxide the effect of even 0.84 per cent. of water might be important, and in these cases the above-mentioned alcohol was dehydrated by Merriman's method (T., 1913, **103**, 628), giving after one treatment a density of 0.79390, corresponding to 99.94 per cent. by volume.

The sodium ethoxide used was prepared by adding the calculated weight of metallic sodium to a known volume of absolute alcohol, and the exact normality subsequently determined by titration against standard sulphuric acid. The calculated volume equivalent to 10 c.c. of 0.2N-solution was delivered direct into the reaction tube.

The aniline was prepared by the hydrolysis of pure acetanilide with subsequent extraction and fractionation.

The methylaniline was prepared by converting technical monomethylaniline into the phenylmethylnitrosoamine, which was then reduced, and the regenerated methylaniline separated and purified by fractionation.

The three aniline hydrogen halides were prepared by adding the calculated quantity of pure concentrated halogen acid to the pure base. The white salt that separated on cooling (and evaporating where necessary) was filtered with the aid of the pump, washed twice with a small quantity of a mixture of ether and alcohol to remove any uncombined acid or base, and then dried. By this means pure white aniline salts were readily obtained.

With the exception of *o*- and *m*-bromonitrobenzenes, which were obtained from Kahlbaum, the whole of the nitro-compounds used were prepared specially for this work. The mono- and dinitro-derivatives were obtained by nitration of the appropriate benzene halogen compound with the usual nitrating mixtures and subsequent repeated recrystallisation until the correct melting point was obtained. The nitration was done in two stages, as by this method it proceeded more easily and obviated the formation of any of the 2 : 6-isomeride.

As regards the trinitro-series, the method described by Frankland and Garner (*J. Soc. Chem. Ind.*, 1920, **39**, 257*r*) for picryl chloride gave good yields and also worked well for the preparation of picryl bromide from 2 : 4-dinitrobromobenzene, this process being a great improvement as regards yield on the method described by Jackson and Earle (*Amer. Chem. J.*, 1903, **29**, 212). The application to picryl iodide, however, was not successful, a considerable quantity of free iodine from the di-iodo-compound being liberated. Picryl iodide was therefore prepared from picryl chloride by treatment with excess of powdered potassium iodide in alcoholic solution (Hepp, *Annalen*, 1882, **215**, 361). The small solubility of this compound in absolute alcohol rendered difficult the use of concentrations higher than *N*/20 without alteration of the general experimental conditions.

The picryl bromide and iodide melted respectively at 121—122° and 165° (uncorr.).

The thermostat was controlled at first by an ordinary mercury thermo-regulator, but later a toluene-filled bulb was attached. This was found to be very efficient and maintained a temperature of 50.0° constant to within 0.1° for months.

The determinations of the velocity coefficients were carried out as follows :

The reactions were carried out in hard glass tubes of about 30 c.c. capacity. A weighed quantity of the nitro-compound was dissolved in 10 c.c. of alcohol by shaking and, if necessary, warming in the well-stoppered tube. An alcoholic solution of the base of the required normality was separately prepared, and 10 c.c. were transferred to the reaction tube. The contents were well mixed by shaking and the tube was immediately immersed to the top of the neck in the thermostat.

From time to time tubes were removed from the thermostat and the contents transferred with alcohol to a separator containing water, 10 c.c. of 0.1*N*-silver nitrate, and about 30 c.c. of benzene. The whole was vigorously shaken until the lower layer became colourless on standing, the unchanged base, the nitro-compound, and the condensation product being dissolved in the upper benzene layer. The excess of silver nitrate remaining in the aqueous portion was estimated by the Volhard method with approximately *N*/20-ammonium thiocyanate. The benzene was twice washed with water and the washing added to the titration flask. It was observed that the silver halide remained entirely in the upper layer or at the junction of the layers; a fact rendering unnecessary the filtration which would otherwise have been required in the case of the chloro-compounds.

In the case of the reaction of the mononitro-compounds with sodium ethoxide, the titration was modified by adding sufficient nitric acid to the contents of the separator to prevent the formation of silver oxide. It was ascertained that under the conditions of experiment the halogen compounds did not react with the silver nitrate solution used for the precipitation of the displaced halogen (see Table VI).

Calculation of the Experimental Data.—The coefficients were first calculated by the ordinary unimolecular and bimolecular formulæ, but (except where the base concerned was sodium ethoxide) neither expression gave satisfactory values. It was, however, observed (see Table I) that even after twenty-four hours less than half of the available halogen had been eliminated and that the slowing down had become very marked. It seemed probable, therefore, that the hydrogen bromide formed during the reaction united with the unchanged aniline to form aniline hydrobromide and that this undissociated salt no longer reacted with the halogen, reducing in effect the concentration of the reacting base. Thus,

The velocity equation expressing this hypothesis is $dx/dt = k(a - 2x)(b - x)$. Three cases had to be considered, namely,

$a > 2b$, $a = 2b$, and $a < 2b$. The solution gave rise to three special bimolecular expressions :

$$\begin{aligned} \text{When } a = 2b, k &= \frac{1}{2t} \frac{x}{b(b-x)} \cdot \\ \text{,, } a > 2b, k &= \frac{1}{(a-2b)t} \log_e \frac{b}{a} \frac{a-2x}{b-x} \cdot \\ \text{,, } a < 2b, k &= \frac{1}{(2b-a)t} \log_e \frac{a}{b} \frac{b-x}{a-2x} \cdot \end{aligned}$$

The recalculation of the coefficients with these expressions gave satisfactory values. As a justification of this hypothesis, it was found on investigation that the reaction velocity of 1-bromo-2:4-dinitrobenzene with aniline hydrobromide was about one hundred times slower than with the free base, and it is probable that even this velocity is due, to some extent, to the trace of water known to be present in the alcohol used as solvent.

Discussion of Results.

Records of a few of the actual measurements made are annexed by way of illustration, and a concise summary of all the experimental results is given at the end of this paper.

As regards the effect of varying the relative concentrations of base and halogen compound, it will be observed that when the concentration of bromo-dinitrobenzene was kept constant and that of the base increased, the value of k diminished. When that of the bromo-compound was increased, the value of k also diminished, but more slowly. Thus when the concentration of the base was eight times that of the bromo-compound the velocity coefficient had fallen to 0.00383, whereas when the concentration of the bromo-compound was eight times that of the base the velocity coefficient was still 0.00444. In general, throughout the whole range of the experiments, k was diminished by an increase in the concentration of the reactants, and in particular the effect of a variation of the base was more important than that of the halogen compound. This supports the observation of Segaller (*loc. cit.*).

On mixing the reacting solutions, a colour immediately developed; a fact which is generally taken as indicative of the formation of an intermediate compound. This coloration was most noticeable with methylaniline, but with the dilutions used was not so strong as would be expected from the remarks on this subject found in the literature. In this connexion, Hibbert and Sudborough (T., 1903, 83, 1336), in a paper on the "Additive Compounds of *s*-Trinitrobenzene and Alkylated Arylamines," remark "that when solutions of the coloured compounds were considerably diluted, the depth

of colour diminished considerably and the determinations of the molecular weights of some of the additive compounds in moderately dilute benzene solution have proved that these substances are almost completely dissociated into their two components, even although the solution still retains an appreciable amount of colour."

Were any additive intermediate compound formed in large proportion as a preliminary to the final condensation product, the values of k deduced from such large variations in the concentration of the two reactants would differ very widely and approximate to that for the unimolecular reaction. In no instance is this the case, and these experiments indicate that additive compounds are not formed to more than a very small extent. That is to say that, at 50° and at the concentrations shown, the course of the reaction between the halogenonitrobenzenes and sodium ethoxide, and aniline, and methylaniline in ethyl-alcoholic solution, is approximately bimolecular.

It may be noted in passing that in the cases previously cited, where an intermediate compound has been isolated, the nitro-compound has contained three nitro-groups, although the presence of certain additional substituents may even then inhibit the formation of additive compounds (see Sudborough and Picton, *loc. cit.*). With fewer nitro-groups present in the nucleus, the intermediate compound, if formed, appears to be less stable, and, when detected, the reactants have been originally in the solid phase, no solvent being present. In these cases, the criteria of the presence of the additive compound lie in physical observations and in examination of eutectic mixtures; no proof is offered of its existence at high temperatures and in dilute solutions.

The reaction between the picryl halides and aniline was found in every case to be too rapid for measurement. Even at room temperature, within three minutes of mixing 0.1N-solutions of aniline and picryl bromide, the reaction had proceeded beyond the half-way point; much more was this the case at 50°, that is to say, the point had been reached where (on the previous hypothesis) all the aniline remaining had combined with the hydrogen bromide liberated to form the aniline salt, and therefore the bromo-compound was presumably reacting with the aniline hydrobromide. The reaction therefore probably proceeds in two stages: first, the reaction with free aniline, which is very fast, and then the reaction with the aniline salt, which is slower. As a consequence of this, in these three cases measurements were taken of the reaction between the picryl halide and the corresponding aniline salt, with the hope that, whilst not strictly comparable, the figures obtained would be roughly indicative of the speed of reaction. Even so,

the velocity was so considerable as to render the effects of initial disturbances of great importance, and in order to eliminate these as far as possible the first reading in each of the series of reactions was used as a blank. The values of k so determined are still somewhat erratic, especially in the case of picryl chloride and aniline hydrochloride. This, no doubt, is to be accounted for in part by the displacement of chlorine in picryl chloride heated in alcoholic solution at 50° (see Table VI). This fact necessitated a slight correction in the amount of halogen acid as determined by titration (see col. 5 of Table IV).

The reaction velocities of the picryl halides with methylaniline were considerably slower, but the correction just alluded to was made in the case of picryl chloride.

The reaction velocity of the mononitro-compounds with aniline was too slow for convenient measurement, and the base used in these cases was sodium ethoxide. It will be observed that the *p*-bromo-compound is about twice as reactive as the *ortho*-, whilst the rate of reaction of the *m*-bromo-compound is so very slow as almost to be negligible. This is consistent with the suggestion referred to above (Kenner, *loc. cit.*), that a meta-directive group, such as the nitro-group in the meta-position to a substituent x , would strengthen its attachment to the nucleus and so render it less mobile.

Rough experiments on the effect of water on the reaction velocity showed that in 90 per cent. alcohol the speed of reaction of the *ortho*-compound was diminished from 6.38×10^{-5} to 2.71×10^{-5} or was 2.35 times slower than in absolute alcohol. For the *para*-compound, the figures were 1.23×10^{-4} and 0.82×10^{-4} , or 1.5 times slower. These experiments were made under exactly comparable conditions as regards concentration, temperature, and strength of alcohol, and it is not easy to account for the considerable difference in the effect of the same quantity of water on the reaction velocity of the two compounds (compare Lobry de Bruyn and Steger, *Rec. trav. chim.*, 1899, **18**, 311, and Lulofs, *loc. cit.*, who found that, in the reaction with sodium ethoxide, the influence of dilution was more marked with chloro- than with bromo- or iodo-dinitrobenzene).

A comparison of the velocity coefficients of the various nitro-compounds with aniline and methylaniline shows in every case that the former reacts more rapidly than the latter. In view of the fact that methylaniline is a stronger base than aniline, this effect is doubtless due to steric hindrance. The actual ratios, however, are by no means uniform; as regards the dinitro-halogen derivatives, the ratio of the reaction velocity of methylaniline

to aniline is 1 : 9.3 for the chloro-, 1 : 4.8 for the bromo-, and 1 : 5.8 for the iodo-compound. For the trinitro-halogen derivatives the corresponding ratios are 1 : 38.5 for the chloro-, 1 : 12.3 for the bromo-, and 1 : 2.6 for the iodo-compound.

The experimental results of the investigations do, however, enable comparisons to be made as to the order of the reactivities of chlorine, bromine, and iodine in similar nitro-compounds. In the reaction of the dinitro- and trinitro-derivatives with aniline, the order is iodine, chlorine, bromine; the iodo-compound being the least reactive. The actual numbers representing the ratios of the velocity coefficients are given at the end of the paper, from which it will be seen that the behaviour of picryl iodide with methyl-aniline is abnormal, and that the general order of halogen reactivity is remarkable, chlorine reacting more rapidly than iodine and less rapidly than bromine, with the one exception just noted. There is, however, no uniformity in the increase of speed of reaction of chlorine and bromine over that of iodine with the various substances used.

Preston and Jones (T., 1912, **401**, 1932) refer to an anomaly in the behaviour of methyl iodide, this substance reacting very much more quickly with triisobutylamine than would be expected. Menshutkin (Z. physikal. Chem., 1890, **5**, 589) also noticed an unusually great velocity in the reaction of methyl iodide with triethylamine. It is not quite easy to relate these observations with the abnormality of picryl iodide and methylaniline, but a connexion between the two seems likely, especially in view of the acidic character possessed by picryl compounds as compared with the mono- and di-nitro-derivatives, with which methylaniline reacts normally.

As regards the order of halogen reactivity, Lulofs (*loc. cit.*), working with the halogenodinitrobenzenes and sodium ethoxide, found the order to be chlorine > bromine > iodine. The changing of the reacting base from sodium ethoxide to aromatic amine has therefore been accompanied by an important change in the order.

An interesting case of unusual order of halogen reactivity has also been observed by Drushel and Simpson (J. Amer. Chem. Soc., 1917, **39**, 2453), who investigated the velocity of hydroxylation of the halogen-substituted aliphatic acids in water solution, and found the order to be bromine > iodine > chlorine.

The order found by Franzen and Bockhacker (*loc. cit.*) confirms both that of Lulofs with sodium ethoxide and that found in the present work with aniline. Franzen and Bockhacker did not use methylaniline, so no comparison can be made for that substance. The very different conditions under which Franzen's work was

carried out prevents any quantitative comparison, but it may be noted that they found *o*-bromonitrobenzene more reactive than the para-compound with sodium ethoxide. This is contrary to the results of the present investigation. As their experiments with these substances were carried out at 100°, it would appear probable that some very interesting and remarkable changes take place in the temperature coefficients in these reactions, and further work in this connexion is most desirable.

Results of Typical Measurements.

In the following specimen tables the concentrations refer to the total volume after mixture of the reacting substances. Column 2, headed "C.c. of *N*/20-thiocyanate," gives the burette readings for the back titrations of the unchanged silver nitrate with ammonium thiocyanate. In general, 20.0 c.c. of *N*/20-silver nitrate were added before titration; therefore the figures in this column subtracted from 20.0 give the c.c. of *N*/20-halogen acid eliminated during the *t* hours that reaction has proceeded.

" " " methylaniline ...	1	0.074	0.40

1. The reaction between the halogenonitrobenzenes and (a) sodium ethoxide, (b) the aniline bases in ethyl-alcoholic solution is a bimolecular one of a somewhat special type, in that the velocity coefficient varies slightly with the initial concentration. No evidence of the presence of additive compounds in appreciable proportion was obtained.

2. An increase in the concentration of the base or of the halogeno-compounds diminishes the velocity coefficient, the effect of the former being the more marked.

3. The mononitrohalogenobenzenes react very slowly with aniline. The 2:4-dinitrohalogenobenzenes react very slowly with aniline salts, but fairly rapidly with free aniline at 50°. The 2:4:6-trinitrohalogenobenzenes react with extreme speed with aniline and rapidly with aniline salts at 50°.

4. In the reaction between the three mononitrobromobenzenes and sodium ethoxide at 50.0°, the meta-compound reacts too slowly for accurate measurement, the reactivities of the ortho- and para-compounds are measurable, the latter reacting twice as fast as the former.

5. In all cases, methylaniline reacts more slowly than aniline, but there is no uniformity in the ratios.

6. The order of halogen reactivity with the aniline bases is bromine > chlorine > iodine.

7. The speed of reaction between methylaniline and picryl iodide is abnormal, as in this instance the iodide reacts more rapidly than either the bromide or chloride.

In conclusion, I desire to thank Dr. G. Senter, Principal of this College, for valuable suggestions and advice in the conduct of this research.

CCCLXVII.—*Studies in Nitration. Part I. The Velocity of Nitration of Phenol.*

By FRANCIS ARNALL.

In those few instances in which the velocity of a nitration has been measured, it has been found that the reaction is approximately bimolecular. Thus in the nitration of nitrobenzene three bimolecular side reactions occur (Holleman and de Bruyn, *Rec. trav. chim.*, 1900, **19**, 79, 188, 364; 1901, **20**, 206, 352) and in the nitration of nitrobenzoic acid, using a large excess of the nitrating acid, three unimolecular side reactions take place (Holleman, *Z. physikal. Chem.*, 1899, **31**, 79). Also in the nitration of phenol in ethereal solution at 25°, the reaction is approximately bimolecular (Klemenc, *Monatsh.*, 1914, **35**, 85), whilst Wibaut (*Rec. trav. chim.*, 1915, **34**, 241) found that although this was the case with benzene and chlorobenzene, yet with bromobenzene the value of the velocity coefficient increased as the nitration proceeded, and no satisfactory value could be obtained for the velocity coefficient in the case of toluene.

It is improbable that the nitration of phenol can be expressed as the sum of three bimolecular side reactions, because in general there is a marked period of induction before nitration commences; thereafter it is apparently accelerated auto-catalytically and the reaction proceeds readily. This is especially the case if one employs nitric acid which has been boiled with carbamide to free it from nitrous acid, or which has been treated with a small quantity of hydrogen peroxide. The following experiments were therefore carried out.

EXPERIMENTAL.

The experiments were performed at 25.5°. The solvent was absolute alcohol, which retarded the reaction so appreciably that there was no difficulty in maintaining the mixture at a constant temperature. The thermostat employed was heated electrically, and the temperature remained constant to within 0.02° throughout the experiments. It was found convenient to use solutions containing 10 per cent. of phenol and an equivalent quantity of nitric acid. The progress of the reaction was followed by measuring the amount of free acid at the end of definite time intervals. This can be done by direct titration with a solution of alcoholic potash, the nitrophenol itself acting as an indicator. But it is difficult to determine the end-point with accuracy, as the solution becomes coloured. The free acid was therefore estimated by adding an excess of potassium iodide and potassium iodate and titrating the

liberated iodine with *N*/5-sodium thiosulphate in the presence of starch (compare Klemenc, *loc. cit.*).

Equivalent quantities of phenol and nitric acid reacted somewhat slowly.

Time (mins.).	Thio. used (c.c.).	% Nitrated.	Time (mins.).	Thio. used (c.c.).	% Nitrated.
0	25	0	330	24.0	4.0
120	24.75	1.0	420	23.4	6.4
180	24.6	1.6	540	22.5	10.0
240	24.5	2.0			

The amount of nitrous acid present was too small to vitiate the results obtained. From these figures it is seen that the reaction is accelerated auto-catalytically and that it is impossible to obtain a constant for the velocity of reaction. As it seemed most probable that the auto-acceleration was due to the presence of nitrous acid, formed by subsidiary reactions, the effect of adding a small quantity of this acid to the nitration mixture was determined.

Velocity coefficients, k , have been calculated from the simplest expression for a bimolecular equation in which equivalent quantities of the two reacting substances are used. The results are plotted in Fig. 1. The two curves are approximately parallel. For comparison, the curve for the reaction using pure nitric acid alone is given. In order to determine whether the nitration in alcohol was retarded by an excess of nitric acid, and accelerated by an excess of phenol, as would be expected from the results of Klemenc, the velocities of nitration, in the first place with an excess of acid, and secondly with an excess of phenol, were measured. When half the equivalent quantity of acid was used, the reaction was very slow at 25.5° , but took place readily at 50° . With an excess of nitric acid, the following results were obtained :

Expt. III. 100% Excess of HNO_3 .		Expt. IV. 50% Excess of HNO_3 and 0.02% of HNO_2 .	
Time.	% Nitrated.	Time.	% Nitrated.

		190	89.0
		220	96.5
		240	99.0

FIG. 1.

Effect of nitrous acid upon the nitration velocity of phenol. 10 Per cent. solution in absolute alcohol. Temperature 25.5°.

These results are plotted in Fig. 2. They are especially interesting in that they show that the reaction proceeds during the early stages more slowly and less regularly in the presence of a large excess of nitric acid alone than in the presence of a little nitrous acid and a smaller excess of nitric acid. The experiments indicate the marked auto-catalytic acceleration apparent in the formation of the nitrophenols, and suggest that the acceleration is due to the production of nitrous acid. If this is so, it would seem as if the latter

first attacks the phenol with the formation of nitrosophenol, which reacts subsequently with nitric acid:

This explanation is feasible when one considers the great readiness with which *p*-nitrosophenol is formed by the action of nascent nitrous acid even at low temperatures. But as the main product of the interaction of nitrous acid and phenol is the *p*-nitroso-compound, one would expect *p*-nitrophenol to be the principal

FIG. 2.

Effect of excess of HNO₂ upon velocity of nitration. 10 Per cent. phenol in absolute alcohol. Temperature 25.5°.

isomeride obtained by the nitration of phenol. To test this, the velocity of nitration of phenol in the presence of a small quantity (0.05 per cent.) of freshly prepared *p*-nitrosophenol was determined. It was found that the velocity of reaction was almost exactly the same as that of solutions of phenol and pure nitric acid alone. Therefore the reaction must proceed in some other way than by the intermediate formation of this compound. It is possible that the reaction might be expressed by the equations

It should be remembered that nitrations may be carried out with nitrogen tetroxide. Finally, in order to prove that the auto-acceleration of the reaction was caused by the formation of small quantities of nitrous acid, the velocity of the reaction was measured in the presence of carbamide, hydrazine sulphate, and phenylhydrazine hydrochloride. With carbamide (0.5 per cent.), the reaction was considerably retarded, but not inhibited entirely. The reaction was entirely prevented by the presence of 0.5 per cent. of hydrazine sulphate, although this is practically insoluble in alcohol, and by the presence of 0.5 per cent. of phenylhydrazine hydrochloride (primary hydrazines readily react with nascent nitrous acid to form unstable nitroso-derivatives).

Conclusion.

It would seem, therefore, to be beyond dispute that the nitration of phenol is auto-catalytic, and that this is due to the formation of nitrous acid by subsidiary reaction. The nitration may be prevented by the presence of small quantities of hydrazine and its derivatives in the same way that the dissolution of metals in nitric acid is inhibited by the addition of urea (Veley, *Proc. Roy. Soc.*, 1890, 46, 216).

The author wishes to acknowledge his indebtedness to Mr. J. B. Coleman and Dr. J. C. Crocker, who have afforded him every facility for carrying out this work.

CCCLXVIII.—Some Derivatives of the Vinyl-diacetonalkamines.

By FREDERIC STANLEY KIPPING.

DURING the war, in view of the deficient supply of mydriatics, the author undertook the preparation of euphtalmin and of related substances, which might be of physiological importance.

Euphtalmin is a mydriatic, prepared by methylating the labile form of vinyl-diacetonalkamine (4-hydroxy-2 : 2 : 6-trimethylpiperidine) and then converting the *N*-methyl base into its mandelic ester. Harries, who first obtained the compound, treated the labile piperidine base with methyl iodide (2 mols.) and isolated the *N*-methyl derivative in crystals melting at 70–72° (*Annalen*, 5 L* 2

1897, 296, 328). The yield, although not given, was evidently a poor one, owing to the formation of the quaternary iodide.

The investigation of this method showed that in warm methyl-alcoholic solution the labile base gives an almost immediate precipitate of the crystalline quaternary salt; at the ordinary temperature, also, the principal product is the methiodide of the *N*-methyl base. When one equivalent of methyl iodide is used a large proportion of the original substance remains unchanged and its separation from the *N*-methyl base is rather troublesome. Methyl sulphate, also, gives very little, if any, monomethyl derivative.

It was then found that the labile base could be converted into the desired product with the aid of formaldehyde, which, as Eschweiler has shown (*Ber.*, 1905, 38, 880), is a most useful methylating agent at high temperatures in presence of acids. In this case, however, methylation took place very easily and practically quantitatively when the base was merely heated with formalin on a water-bath and the pure methyl derivative was obtained with great facility (m. p. 78°).

The conversion of the *N*-methyl derivative into its mandelic ester was accomplished under the conditions used by Harries (Ladenburg's method); the euphtalmin thus obtained melted at 113°, but sintered at 108°, as observed by Harries, and seemed to be a mixture, which, in view of the asymmetric groups in the molecule, is not surprising. The *tropic* ester and the *benzilic* ester of the methyl base were also prepared, and the former, according to a report for which the author is indebted to Dr. Dale, F.R.S., was found to be superior to euphtalmin as a mydriatic in cats.

Since the labile base (m. p. 162°) could be so easily transformed into its *N*-methyl derivative, the stable isomeride (m. p. 138°) was also treated with formalin with the object of preparing from the product some *N*-methyl- β -eucaine. The reaction was carried out as before; the product in this case was an oil, but it gave a crystalline hydrochloride, which appeared to consist entirely of a single substance. The hydrochloride, heated with benzoyl chloride, gave a viscous oil which would not crystallise; the free base as well as the sulphate, oxalate, and other salts showed a similar behaviour, which contrasted very markedly with that of β -eucaine and its salts. The cinnamate, on the other hand, crystallised very readily and an examination of this salt proved that the benzoyl derivative was practically homogeneous and was that of the *N*-methyl base. The hydrochloride of this *N*-methyl- β -eucaine, prepared from the pure cinnamate, was then obtained in a crystalline form; its

action was kindly examined by Dr. Dale, but it was found to be definitely inferior to β -eucaine as a local anæsthetic.

Preparation of 4-Hydroxy-1:2:2:6-tetramethylpiperidine.—From the mixture of bases obtained by the reduction of vinyl diacetone-amine oxalate with sodium amalgam and water, the labile alkamine (m. p. 162°) can be easily isolated if, instead of adding acid during the process, some concentrated sodium hydroxide solution is used; the solubility of the labile base is thereby diminished to such an extent that it separates in crystals together with the sodium oxalate and can be extracted from the latter with boiling benzene. The extracts give a product melting at about 155° which after one recrystallisation usually affords a pure preparation; the stable base, and also a considerable proportion of the labile form, remain in the aqueous alkaline solution of the reduction product.

As stated above, the methylation of the labile base by the method described by Harries and also methylation with methyl sulphate give very unsatisfactory results. For the preparation of the *N*-methyl derivative, the base is heated on the water-bath with about twice its weight of a commercial 40 per cent. solution of formaldehyde; the base gradually dissolves and bubbles of gas escape slowly. At the end of about three hours, the solution is evaporated almost to dryness, the glue-like mass is treated with a little solid sodium hydroxide to decompose the formate present, and then extracted with boiling light petroleum; this extract gives an almost colourless deposit of practically pure *N*-methyl derivative and the yield is almost theoretical, the only by-product being an oily substance which does not dissolve readily in boiling light petroleum; after recrystallisation from ether, the base melts at 78–79°.

The mandelic ester of the methyl-base (euphtalmin) was prepared by the process used by Harries (*loc. cit.*); after recrystallisation from ether, it melted from 108–113°.

The tropic ester, $C_9NH_{18}O \cdot CO \cdot CHPh \cdot CH_2 \cdot OH$, was obtained by adding excess of tropic acid to a solution of the methyl base in excess of hydrochloric acid, evaporating on the water-bath, and heating the residue during some twelve hours with the occasional addition of a few drops of hydrochloric acid. When the product was stirred well with water and a little dilute acid, a thick oil separated, and the filtered acid solution gave with excess of sodium carbonate a crystalline precipitate of the tropic ester, but the yield was very poor. The ester was recrystallised, first from ether and then from aqueous methyl alcohol; it melted fairly sharply at 110–111° and was soluble in dilute hydrochloric acid; its behaviour towards organic solvents was similar to that of euph-

talmin. The oily by-product (see above) was not appreciably soluble in dilute hydrochloric acid or in sodium carbonate, but it was slowly hydrolysed by a concentrated solution of sodium hydr. oxide, giving basic vapours and apparently a solution of tropic acid; it was not examined further. This is possibly the substance described as tropyl-*N*-methylvinyl diacetonealkamine in a German patent (*Centralblatt*, 1898, I, 968) as an "erstarrendes Oel."

From the results of several experiments in which the mydriatic action of this tropate was directly compared with that of euph. talmin, Dr. Dale found that the former was superior to the latter in cats, both in the rapidity and in the extent of its action, but that its effect was altogether below that of atropine or even homatropine.

The benzilic ester of the *N*-methyl derivative was prepared by evaporating a solution of the base in excess of hydrochloric acid with benzilic acid and then heating the residue on a water-bath during some ten hours. The syrupy product, treated with an excess of a dilute solution of sodium carbonate, gave an oily precipitate, which gradually solidified and was then separated and washed. It was recrystallised from ethyl acetate, from which it separated in large, flat, very brittle prisms, melting sharply at 156–157° and rather sparingly soluble in cold alcohol, even less soluble in ether; it dissolved in hydrochloric acid and was reprecipitated by sodium carbonate solution as a fine, crystalline powder (Found: C = 74.3; H = 8.0. $C_{23}H_{29}O_3N$ requires C = 75.2; H = 7.9 per cent.). Five grams of the methyl base gave about 0.6 gram of the benzilic ester, but more could be obtained by working up the original alkaline filtrate.

4-Benzoyloxy-1:2:2:6-tetramethylpiperidine.—The methylation of the stable form of vinyl diacetonealkamine (m. p. 138°) with formalin was carried out as described in the case of the labile base, but the treatment was more prolonged. As the product was very readily soluble in light petroleum, from which it separated as an oil, the crude methyl derivative was repeatedly evaporated with hydrochloric acid, until free from formaldehyde, and the crystalline residue washed with alcoholic ether. The hydrochloride of the *N*-methyl derivative was thus obtained in crystals melting at about 208° and the yield was almost theoretical; the salt was very readily soluble in cold water, much less soluble in cold alcohol; from the latter it separated in large, pyramidal crystals and then melted at 213–214°.

The crude hydrochloride was heated with excess of benzoyl chloride; only a slow reaction occurred at about 130°, so the mixture was heated at about 160° during an hour, at the end of which time the evolution of hydrogen chloride had ceased. The

product, freed from unchanged benzoyl chloride by extraction with ether, was a glue-like mass readily soluble in cold water and did not crystallise when the solution was evaporated, although judging from the yield the salt could not have contained much, if any, unchanged methyl derivative. The base, liberated by alkali and extracted with ether, was an oil (*Centralblatt*, 1898, II, 693) which did not crystallise in the course of some weeks; it was transformed into its sulphate, oxalate, and other salts, but none of these showed any signs of crystallising from water.

The cinnamate, on the other hand, crystallised immediately, so the whole of the crude hydrochloride was converted into this salt by precipitation with a slightly alkaline solution of sodium cinnamate. The fractional crystallisation of this product from aqueous alcohol showed that it was homogeneous (except for traces of cinnamic acid) and a direct comparison of the salt with the cinnamate of β -eucaine (which crystallised in large tablets and melted at $160-161^\circ$) showed that the treatment with formalin had resulted in the complete conversion of the stable base into the *N*-methyl derivative.

4-Benzoyloxy-1:2:2:6-tetramethylpiperidine cinnamate separates from aqueous methyl alcohol in lustrous plates and needles melting at $83-84^\circ$, and is only very sparingly soluble in water, but dissolves freely in aqueous acetone and in moist ethyl acetate (Found: C = 73.3; H = 7.6. $C_{25}H_{31}O_4N$ requires C = 73.3; H = 7.6 per cent.). The base, prepared from the pure cinnamate, is a thick oil; its hydrochloride separates from a mixture of acetone and ethyl acetate in slender needles melting at about 195° , and although not hygroscopic, is extremely soluble in water and in methyl alcohol, and very readily soluble in acetone.

Dr. Dale's report on this preparation was as follows: "The substance, *N*-methyl- β -eucaine hydrochloride, was tested in comparison with β -eucaine lactate for its power of producing anaesthesia in the cornea of the rabbit, when locally applied. It was found to have a distinct local anaesthetic action, but definitely inferior to that of β -eucaine, especially by reason of the extreme evanescence of the effect. As regards the completeness of the anaesthesia, we found it necessary to employ a 2 per cent. solution to produce an effect of about the same depth as 0.5 per cent. β -eucaine."

UNIVERSITY COLLEGE, NOTTINGHAM. [Received, September 27th, 1923.]

CCCLXIX.—*The Constitution of the Disaccharides,
Part IX. Gentiobiose: Its Identity with
Amygdalin Biose.*

By WALTER NORMAN HAWORTH and BIRKETT WYLAM.

GENTIOBIOSE, one of the most rare of the natural disaccharides, has been synthesised by the action of emulsin on glucose, but its constitution has remained unknown (Bourquelot, Hérissé, and Coirre, *Compt. rend.*, 1913, 157, 732). For the purpose of the present research, the sugar was prepared by the lengthy process of fermenting the trisaccharide, gentianose, which had been extracted from gentian root. The best process hitherto available for this purpose, that of Hudson and Johnson (*J. Amer. Chem. Soc.*, 1917, 39, 1274), yielded only 1 per cent. of the octa-acetate of the biose. By a modification of their procedure we have been able to increase the yield to more than 3 per cent.

In Part VI of this series of researches on "The Constitution of the Biose of Amygdalin," it was stated that the structure of gentiobiose was under investigation in these laboratories with the intention of deciding whether its structure corresponded with that of maltose, and, if this were found to be the case, then gentiobiose, which is a glucose β -glucoside, would be the stereoisomeride of maltose, and identical with the biose of amygdalin. Although definite evidence was lacking that in the amygdalin biose the two hexose residues were united by a β -linking, it was apparent that, whilst maltose and the biose of amygdalin possessed the same structural arrangement, these two sugars could not be identical. Most of the known β -glucosides of maltose are dextrorotatory, but amygdalin and also amygdalinic acid are levorotatory glucosides, and the sign of rotation of the latter could not be greatly influenced by the aromatic residue, which, moreover, in the case of amygdalinic acid, is racemic.

Confirmation of this surmise has appeared in the interim. Kuhn (*Ber.*, 1923, 56, [B], 857) has studied the rotation changes undergone by amygdalin in the presence of emulsin, and has arrived at the conclusion that amygdalin biose is a glucose β -glucoside, having the structure which Haworth and Leitch have already formulated.

There was still wanting a solution to the problem as to the identity of amygdalin biose with some known disaccharide, and in the course of our work we have been able to establish the fact that the disaccharide which is present in amygdalin is, indeed, gentiobiose. The steps which have led to this decision may briefly be enumerated. Gentiobiose passes by methylation into heptamethyl

methylgentiobioside, a crystalline compound showing $[\alpha]_D = -33.9^\circ$ in water. Cleavage of this crystalline derivative with dilute mineral acid leads to the isolation of two methylated glucoses, one of them being recognisable as the usual form of 2:3:5:6-tetramethyl glucose (IV) and the other being 2:3:5-trimethyl glucose (III), which readily gives a crystalline glucoside melting at $92-95^\circ$. Both these methylated glucoses had previously been isolated on two occasions as cleavage products of methylated maltose and amygdalin biose, and to each of these disaccharides the structural formula I has already been allocated by determination of the constitution of the degradation products (Haworth and Leitch, T., 1919, 115, 809; 1922, 121, 1921). Since the latter sugar has been shown to be a glucose β -glucoside just as is gentiobiose, and as it follows from the present work that gentiobiose is also structurally identical with amygdalin biose, it is finally established that the latter sugar is in every way identical with gentiobiose. The following scheme illustrates the procedure adopted in the course of the experimental proof:

Amygdalin must therefore be represented as mandelonitrile β -gentiobioside, or mandelonitrile β -glucose-6- β -glucoside. We are at present engaged on the problem of the synthesis of amygdalin, and we have succeeded in establishing the identity of hepta-acetyl amygdalinic ethyl ester, prepared from amygdalin, with a synthetic compound obtained by condensing ethyl mandelate with hepta-acetyl β -gentiobiose. This work will form the subject of a later communication.

Invertase hydrolyses the trisaccharide gentianose to gentiobiose and fructose, but some emulsin preparations effect the cleavage in another part of the molecule, yielding sucrose and glucose. Since sucrose is then a constituent part of the molecule of gentianose, this latter sugar may be regarded as having the constitution shown below:

EXPERIMENTAL.

Preparation of Gentiobiose.

At the outset the procedure described by Hudson and Johnson (*loc. cit.*) leading to the isolation of gentiobiose was imitated. On the grounds of the expense involved in this process, due to the quantities of pure methyl and ethyl alcohols recommended by these workers, it was found essential to modify considerably the means of extraction. Not only have the modifications furnished a cheaper method of obtaining gentiobiose, but it is gratifying to observe that the yield of product has been increased to three times the amount which had previously been obtained by Hudson and Johnson.

The following is the procedure which was finally adopted in the course of this work. Finely powdered gentian root (*Gentiana lutea*) (200 grams) was placed in a large flask along with two litres of water. Fresh yeast (20 grams) was added in two portions during twenty-four hours and the mixture was maintained at 30° for two days. Following the addition of 100 c.c. of basic lead acetate solution ($d = 1.25$), the mixture was filtered and the dissolved lead precipitated with hydrogen sulphide, and excess of the latter reagent was removed by means of a current of air. Decoloration of the solution was effected by filtering through a column of charcoal and thereafter the solvent was removed under diminished pressure, whereupon a brown syrup was obtained. This was extracted with five separate quantities, each of 200 c.c., of dried and purified methylated spirits; the five extracts were united and yielded, after distillation of the solvent under diminished pressure, a brown gum weighing about 17 grams, which contained gentiobiose. This was now acetylated by digesting during four hours with 70 grams of

rectified acetic anhydride containing also 4 grams of freshly fused sodium acetate. When cooled and poured into water, the reaction mixture deposited after three days a pasty, crystalline mass. This was collected, roughly dried, and extracted with ether, which removed much impurity in the form of a dark gum, whilst the crystals remained undissolved. The latter were washed with ether, dissolved in hot 90 per cent. ethyl alcohol, and this solution was decolorised with charcoal. On cooling, 8–9 grams of colourless crystals of gentiobiose octa-acetate were collected, melting at 191–192°, and this weight represented the yield from 200 grams of gentian root as compared with a yield of 2.5 grams quoted by the previous workers (Found: C = 49.53; H = 5.74; $\text{CH}_3\cdot\text{CO} = 51.2$ per cent.).

Hydrolysis.—A process was developed for the removal of the acetyl residues from the octa-acetate and this was based upon the method described by Maquenne and Goodwin (*Bull. Soc. chim.*, 1904, [iii], **31**, 854) for the regeneration of cellobiose from its octa-acetate.●

Potassium hydroxide (12 grams) was dissolved in 40 c.c. of absolute alcohol under reflux. To the cooled solution, 10 grams of gentiobiose octa-acetate were added and the temperature was maintained below 35°. The mixture was kept for two hours, filtered, and the solid product, which was the potassium derivative of gentiobiose, was washed with absolute alcohol and weighed 15 grams. This hygroscopic, white solid, which contained some potassium hydroxide, was dissolved in a little tepid water and the solution exactly neutralised with perchloric acid. The precipitated potassium perchlorate was removed by filtration and the filtrate evaporated in a vacuum to a yellow syrup and repeatedly extracted under reflux with absolute ethyl alcohol. On removal of the solvent, 4½ grams of syrup were obtained which crystallised. Its identity with gentiobiose was verified by preparing the phenylosazone (Zemplén, *Ber.*, 1915, **48**, 237), and this was found to melt at 162–167° with decomposition.

Heptamethyl Methylgentiobioside.

The colourless, hygroscopic solid derived from gentiobiose octa-acetate as already described, and consisting chiefly of the potassium derivative of the sugar, was dissolved in water and methylated in the same manner as in the case of cellobiose (Haworth and Hirst, *T.*, 1921, **119**, 193). Two digestions were required with methyl sulphate and sodium hydroxide, followed by the use of Purdie's reagents. Immediately on evaporation of the ether employed as solvent after the final methylation, the whole of the product crystal-

lised in colourless needles, which were purified from light petroleum (b. p. 45–60°), and melted at 106° (Found : C = 52.88; H = 8.32; OMe = 54.0 per cent. $C_{20}H_{38}O_{11}$ requires C = 52.90; H = 8.37; OMe = 54.6 per cent.). The above figures corresponded with those required by a completely methylated biose, and the compound was therefore heptamethyl methylgentiobioside. It was devoid of action towards Fehling's solution. Polarimetric data were recorded :

$[\alpha]_D = -33.9^\circ$ in water, -29.9° in ethyl alcohol, -30.0° in methyl alcohol, and -27.0° in acetone ($c = 0.57$).

Isolation of the Hydrolysis Products of Heptamethyl Methylgentiobioside.

The conditions established for the hydrolysis of the bioside were as follows. Aqueous hydrochloric acid (5 per cent.) was mixed with the methylated gentiobiose in quantities which yielded a solution containing 0.7 per cent. of the sugar. This was maintained at 90–95°, and the rotation changes were charted.

Time (mins.) ...	10	75	105	135	170	200
$[\alpha]_D$	-22.9°	$+25.0^\circ$	$+40.3^\circ$	$+51.3^\circ$	$+61.5^\circ$	$+68.8^\circ$
Time (mins.) ...	230	260	290	350		
$[\alpha]_D$	$+72.5^\circ$	$+74.2^\circ$	$+75.4^\circ$	$+76.5^\circ$	(constant).	

A graph representing these specific rotation values plotted against the time period shows the usual logarithmic curve.

When hydrolysis was completed the solution was neutralised with barium carbonate, filtered, and concentrated under diminished pressure. The greater part of the inorganic material was removed by precipitation with alcohol and a yellow syrup was finally obtained. Traces of mineral matter were removed from the latter by solution in dry ether. On evaporation of the solvent the syrup partly crystallised, and repeated extraction with light petroleum separated the product into two approximately equal parts; needle-shaped crystals were deposited from the petroleum extract, whilst the residual portion was a yellow, viscid syrup.

The crystals were purified from light petroleum containing a trace of ethyl acetate and yielded colourless needles melting at 88.5°. The properties of this compound were in close agreement with those of crystalline tetramethyl glucose (IV), and a mixed melting-point determination confirmed this view (Found : C = 50.74; H = 8.42; OMe = 52.40 per cent.). Polarimetric determinations showed the specific rotation to be $+85.2^\circ$ in water ($c = 1.9$), falling after catalysis to the equilibrium value, $[\alpha]_D = +83.05^\circ$.

Attempts to crystallise the liquid portion having failed, it was decided to prepare from it the methylglucoside. With this end in

view, a 1 per cent. solution of the sugar was made in 0.5 per cent. methyl-alcoholic hydrogen chloride. This was sealed into a thick glass tube and heated for twelve hours at 110°. Thereafter the contents were neutralised with freshly prepared silver carbonate and filtered. Removal of the solvent yielded a yellow syrup which distilled at 108°/0.01 mm., and the distillate crystallised immediately on nucleation with a crystal of 2 : 3 : 5-trimethyl β -methylglucoside. This compound was recrystallised from light petroleum and showed a melting point of 92.5°, and a mixed melting-point determination with 2 : 3 : 5-trimethyl β -methylglucoside prepared from amygdalin showed no depression (Found: C = 51.27; H = 8.65; OMe = 51.6 per cent.).

$[\alpha]_D^{20} = -25.1^\circ$ in methyl alcohol.

There could therefore be no doubt that this second cleavage product was 2 : 3 : 5-trimethyl glucose (III), since this gives rise on oxidation to a trimethyl saccharolactone,

The authors are greatly indebted to the Department of Scientific and Industrial Research for a grant which has enabled one of them to participate in this work.

CCCLXX.—*The Constitution of Raffinose.*

By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and
DAVID ARTHUR RUELL.

RAFFINOSE is the most important of the trisaccharides, and its relationship to sucrose renders a determination of its constitution of peculiar interest in view of the new constitutional formula which has been assigned to sucrose by Haworth and his co-workers. It occurs in sugar beet and accumulates in the molasses, from which it is not removed by the strontium hydrate treatment. It is present, also, in eucalyptus manna, and in the leaves of the common yew (*Taxus baccata*), but the most fruitful source of raffinose is cotton seed. From decorticated cotton-seed meal it has been extracted for the purpose of the present work.

Raffinose yields on hydrolysis with dilute acids, melibiose and fructose; and with stronger acids, the hexoses galactose, glucose, and fructose are formed in equal proportions. With emulsin, it

changes into sucrose and galactose, whilst invertase converts the trisaccharide into melibiose and fructose.

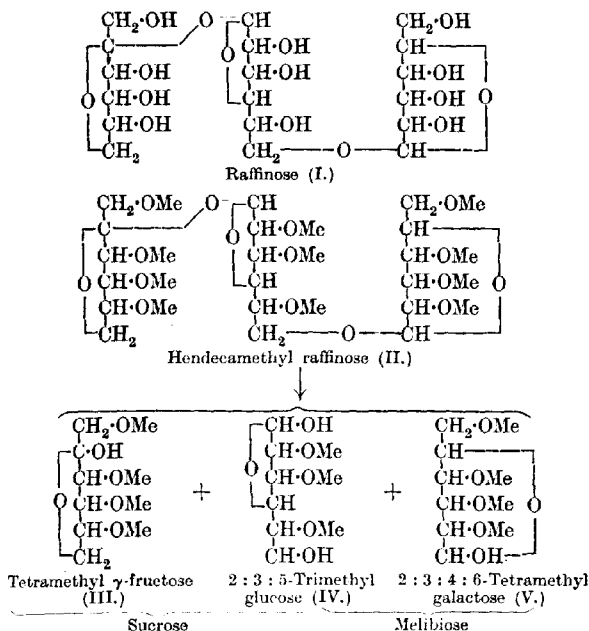

It will be clear from the above observations that raffinose is a complex containing galactose and fructose residues situated on either side of a glucose residue, and the linking between galactose and glucose must be of the β -type, since this is severed by emulsin. On the other hand, the linking which joins fructose to glucose must be similar to that in sucrose, since this union undergoes scission by means of invertase.

When raffinose was completely methylated, under the conditions described in this communication, eleven methoxyl groups were introduced, and the *hendecamethyl raffinose* was a viscid syrup distilling at 238–240°/0.02 mm., having n_D 1.4680, and $[\alpha]_D^{20} + 128.4^\circ$ in water. During the methylation with methyl sulphate, neutral conditions were observed as far as was possible, but owing to the development of local acidity, a small proportion only of the sugar was degraded to melibiose and fructose. With use of 1 per cent. aqueous hydrochloric acid, the methylated raffinose was hydrolysed, and yielded three methylated fragments which were recognised to be tetramethyl galactose, giving a crystalline anilide identical with that derived from methylated lactose; secondly, a trimethyl glucose, which gave a crystalline glucoside, identical with that isolated from methylated amygdalin and consequently having the structure of 2:3:5-trimethyl glucose (butylene oxide); thirdly, a tetramethyl fructose, which was dextrorotatory and identical with that obtained from methylated sucrose, so that this fructose fragment contained an amylen oxide ring structure. On the basis, therefore, of previous work with other sugars, it was easily possible to assign a structural formula to raffinose, since the degradation products could all be compared with other authentic specimens which were in our possession and for which the structural formulæ have been ascertained by oxidation methods.

The steps which have led to the allocation of the constitution I to raffinose are indicated on p. 3127.

The tetramethyl galactose formula (V) is represented as containing an amylen oxide ring, since its lactone is dextrorotatory, and must thus have its oxide ring engaging the hydroxyl group attached to the fifth carbon atom as shown by Pryde (this vol., p. 1808). It would be more correct to represent the Hudson rule as requiring that a lactone having its oxide ring on the right should show a greater dextrorotation than the acid from which it is formed, and it has been ascertained that this is the case. The usual form of tetramethyl galactose must therefore be represented as having methoxyl groups in the positions 2:3:4:6 and not 2:3:5:6

as was formerly thought to be the case, and the lactose and melibiose formulae should now be modified to conform with this view.

From this determination of the structure of raffinose, it may be inferred that the constitution of melibiose proposed by Haworth and Leitch (T., 1919, **115**, 809) receives substantial confirmation, but inasmuch as structural changes may occur in the resulting disaccharide when the fructose residue is eliminated from raffinose, it has been thought desirable to undertake a separate investigation of melibiose, which is now in progress.

EXPERIMENTAL.

Preparation of Raffinose.—The method of preparation adopted resembled that described by Hudson and Harding (*J. Amer. Chem. Soc.*, 1914, **36**, 2110), using decorticated cotton-seed meal as the source of the sugar. The yield of crystalline raffinose hydrate from 14.5 kilos. of cotton-seed meal was 341 grams, which melted at 77–78° and showed $[\alpha]_D + 101.5^\circ$. The ash content was 1.4 per cent. The figures for pure raffinose are m. p. 78°, $[\alpha]_D + 104^\circ$.

A sample of these crystals was purified by recrystallisation and gave pure anhydrous raffinose melting at 118° . This contained 0.41 per cent. of ash and showed $[\alpha]_D + 123^{\circ}$ ($c = 2$).

Methylation of Raffinose.—Raffinose hydrate, in quantities of 30 grams, was dissolved in a little water, and methyl sulphate (100 c.c.) was added very slowly, along with the equivalent quantity of alkali (100 grams of sodium hydroxide in 30 per cent. solution). During the procedure, which occupied about four hours, the temperature was maintained at 70° , and the mixture was thoroughly agitated by mechanical stirring. When the whole of the reagents had been added, the solution was heated for an hour at 100° . On cooling, sodium sulphate separated, and the supernatant liquor was decanted and extracted thrice with chloroform. The separated solid was also extracted with this solvent. The united chloroform extracts were dried and evaporated, and yielded only 20 grams of a syrup. The poor yield at this stage showed that much of the product remained in the aqueous solution and this was verified by a polarimetric reading. Consequently, the aqueous portion was evaporated and the residue, after powdering, was extracted with absolute alcohol under reflux. This treatment yielded a yellow syrup weighing 15.3 grams and containing only little mineral matter. The collected chloroform extracts were subjected to further methylation with methyl sulphate, and likewise also the syrup, extracted with alcohol, from the aqueous portions. In all, 105 grams of raffinose hydrate were methylated, corresponding to 94 grams of raffinose, and the total amount of syrup collected after two methylations was 80 grams. After one methylation with silver oxide, the product contained 46.7 per cent. of methoxyl. In order to ensure complete methylation, this material was again treated three times with Purdie's reagent.

Isolation of Hendecamethyl Raffinose.—The product arising from the repeated methylation of raffinose was purified by fractional distillation, and this operation was conducted several times with methylated products prepared on separate occasions. The following example serves to illustrate the general procedure. The distillate from 15 grams was collected in three fractions, which are indicated below along with their physical properties.

	Boiling point.	Weight.	n_D .
Fraction I.....	$76-150^{\circ}/0.15$ mm.	0.65 gram	1.4594
Fraction II.....	$179-226^{\circ}/0.1$ mm.	3.2 grams	1.4660
Fraction III.....	$238-240^{\circ}/0.02$ mm.	7.7 „	1.4680

The first two fractions distilled as colourless liquids from an oil-bath, but the third fraction required the use of a metal-bath, by the aid of which the distillation proceeded steadily, yielding

what proved to be the hendecamethyl raffinose which, on cooling, changed from a faintly coloured liquid to a viscid, amber syrup. There remained in the distilling flask a brown residue weighing about 3 grams and this was collected with other similar residues left from a corresponding distillation, when together they yielded a further quantity of the material represented by fraction III. Fraction I gave rise on further rectification to a mobile liquid distilling at $82^{\circ}/0.07$ mm. and having n_D 1.4628; it gave analytical figures agreeing with those of a tetramethyl hexose. Fraction II crystallised on keeping, and, after purification from light petroleum, melted at 78° with previous sintering at 72.5° . Analysis showed that this crystalline compound was a completely methylated disaccharide (melibiose).

A more detailed examination of the main fraction, III, was undertaken, and the analytical evidence indicated that this was a completely methylated specimen of raffinose containing eleven methoxyl groups (Found: C = 52.69; H = 8.18; OMe = 49.9. $C_{29}H_{54}O_{16}$ requires C = 52.9; H = 8.2; OMe = 51.8 per cent.). The optical rotations showed appreciable variation under different temperature and concentration conditions, a circumstance which is to be attributed to the presence of fructose and galactose residues in the compound.

$[\alpha]_D$.	Temp.	Solvent.	c.
+ 126.1°	18.5°	Water	1.838
128.4	16.5	Water	1.005
112.1	18	Ethyl alcohol	1.05
112.7	16	Ethyl alcohol	1.05

The completely methylated raffinose had no reducing action on Fehling's solution and showed no tendency to crystallise. It remained over a long period without darkening as an amber-yellow, viscid syrup. Its behaviour towards hydrolytic agents indicated that it was less sensitive than methylated sucrose. Hydrochloric acid of 0.5 per cent. concentration had little effect at 80° . On the other hand, it was hydrolysed with considerably greater ease than methylated reducing disaccharides like maltose or lactose. Using 1 per cent. hydrochloric acid, no change was observed in the polarimetric readings until a temperature of 85° was reached.

Isolation of the Cleavage Products of Hendecamethyl Raffinose.

After a series of preliminary experiments designed to effect complete hydrolysis of hendecamethyl raffinose under conditions of temperature and of acid concentration which would not impair the yield or purity of the cleavage products, the following conditions were finally adopted. The hydrolysing medium was 1 per cent. aqueous hydrochloric acid containing 2 per cent. of the

methylated sugar in solution. This mixture was heated under reflux on a water-bath at 90° , and polarimetric readings were taken during a period of twenty-two and a half hours. From these records, which are reproduced below, it appeared that the rotation reached a constant value after eighteen and a half hours, when the specific value showed a diminution from $+116^{\circ}$ to 82° . If the latter figure be corrected for the weight of hexoses generated, it appears as $+77.5^{\circ}$.

Hours	0	5	9	10	15½	16½	18½	20½	22½
$[\alpha]_D$	$+116.2^{\circ}$	102.8°	94.4°	93.0°	86.4°	84.2°	82.1°	82.1°	82.1°

On the completion of this hydrolysis, the solution was neutralised with barium carbonate, and the filtrate from the mineral matter was concentrated at low temperature and pressure until the barium chloride could be conveniently removed by the addition of alcohol. Repeated treatment with absolute alcohol produced a filtrate which was free from mineral salts, and evaporation of the alcohol left a syrup which was completely soluble in dry ether. Distillation of the latter solvent yielded a straw-yellow, mobile syrup which represented 80 per cent. of the original weight of methylated raffinose. This was divided into three fractions on distillation; the first of these was collected at $117-120^{\circ}/0.035$ mm. and showed n_D 1.4567; the second distilled at $132-135^{\circ}/0.4$ mm. and showed n_D 1.4676, and there remained as residue an approximately equal amount, which was not distilled but was purified by glucoside formation. Redistillation of the first fraction gave a pure, colourless liquid, boiling at $110^{\circ}/0.2$ mm., having n_D 1.4558, and a specific rotation of $+31.7^{\circ}$ (final value). The combined analytical data and general behaviour proved the identity of this cleavage product with tetramethyl γ -fructose (III) (Found: OMe = 49.0 per cent.). It reduced neutral permanganate freely, and behaved in other respects in exactly the same manner as a specimen of this compound prepared from methylated sucrose (Haworth, T., 1920, 117, 199).

The second fraction and the still residue, indicated above, evidently contained both the galactose and the glucose fragments and, although the fractional distillation led to a rough separation of these two products, the second fraction mentioned above was evidently not quite homogeneous. It consisted largely of a tetramethyl hexose, and on digesting for three hours with five times its weight of aniline and sufficient absolute alcohol to make a 5 per cent. solution of the sugar, a crystalline anilide separated as long, slender needles, which were purified from ethyl acetate. The anilide melted at 192° and showed $[\alpha]_D^{25} - 83.0^{\circ}$ in acetone ($c = 0.606$). After two hundred hours, the specific rotation had changed to the value $+40.0^{\circ}$. These data corresponded exactly with those

of the anilide of tetramethyl galactose (V) (Haworth and Leitch, T., 1918, **113**, 188), which had been prepared from lactose, and a mixed melting point determination with an authentic specimen of the anilide, prepared from galactose, showed no depression.

The still residue, remaining from the previous distillation, was a yellow, viscid syrup. This was dissolved in 50 c.c. of 0.5 per cent. methyl alcoholic hydrogen chloride and heated under pressure at 110° for ten hours. At the end of this time it no longer reduced Fehling's solution, and had been converted into a methyl glucoside. On neutralisation of the acid with silver carbonate and evaporation under diminished pressure, a liquid was obtained which distilled at 109°/0.05 mm. and showed n_D 1.4562, and this partly crystallised on keeping, yielding slender, colourless needles, which could be easily separated from the liquid portion. On purification from light petroleum, they melted at 74° and showed $[\alpha]_D^{25} - 24.8^\circ$ in methyl alcohol (Found: OMe = 51.5 per cent.). The crystalline product showed the behaviour of a trimethyl methylglucoside and resembled very closely the product isolated by Haworth and Leitch from methylated amygdalin. The specimen of 2 : 3 : 5-trimethyl β -methylglucoside obtained by these authors was mixed with a portion of the crystals isolated as described above and a melting-point determination showed no depression. It was therefore clear that the product consisted of a methyl derivative of 2 : 3 : 5-trimethyl glucose (IV), and consequently this sugar represents the glucose fragment from the original methylated raffinose. The uncrystallised portion of the glucoside was evidently the α -form of the glucoside of this sugar.

The authors are grateful to the Carnegie Trust for a scholarship and to the Armstrong College Council for a fellowship which enabled two of the authors to engage in this work.

CCCLXXI.—*Condensation of Aldehydes with Cyanoacetamide.*

By RONALD HAMILTON CURTIS, JAMES NELSON EDMUND DAY, and
LIONEL GEORGE KIMMINS.

It was shown by Thole and Thorpe (T., 1911, **99**, 422), Thorpe and Wood (T., 1913, **103**, 1586), and Kon and Thorpe (T., 1919, **115**, 686) that ketones condense with cyanoacetamide in presence of

piperidine to form the six-membered cyclic compounds (I) (95 per cent.) and (II) (5 per cent.) by *cis* and *trans* addition and subsequent ring closure. Guareschi has shown that ethyl cyanoacetate and ammonia react with ketones, yielding compounds of type (II) only, and with aldehydes to give substances of type (III) (or rather the ammonium salt) as the main product.

Day and Thorpe (T., 1920, 117, 1465) found that cyanoacetamide condensed with acetaldehyde, propaldehyde, and *n*-butaldehyde to form open-chain amides (IV) to the extent of about 99 per cent. of the total yield. The remaining 1 per cent. consisted of compounds (I) and (III). In the case of benzaldehyde, however, no trace of a compound (IV) could be obtained, the product being either the compound (V) or a mixture of (III) and (VI). There thus appears to be a very marked difference in the behaviour of aliphatic and aromatic aldehydes with cyanoacetamide. An intermediate position is occupied by phenylacetaldehyde, which gives a product consisting to the extent of 10 per cent. of a substance of type (IV), the remainder being of type (V) (Stevenson and Thorpe, T., 1922, 121, 1719).

The behaviour of heptaldehyde and cinnamaldehyde was investigated in 1920 by one of us (J.N.E.D.) in collaboration with Professor J. F. Thorpe. It was not possible, however, to finish the work at that time, and this author wishes to acknowledge Professor Thorpe's permission to continue the investigation.

*iso*Butaldehyde has been found to condense in the same way as *n*-butaldehyde. *iso*Valeraldehyde, however, gave only a 30 per cent. yield of the compound (I) together with a little of the Guareschi compound (III); no open-chain compound (IV) was obtained, although substances of this type appear to be characteristic of these condensations. The difference of behaviour in the two aldehydes is at present inexplicable.

Heptaldehyde proved by far the most interesting of the aldehydes investigated. The first condensation, carried out in aqueous solution, gave only the compound (VII). The next condensation (in alcoholic solution) gave a mixture of (VII) and (IX). Later condensations gave the compound (VIII), and after this had once been obtained it was found very difficult to get any quantity of (VII) or (IX), the condensations, in either aqueous or alcoholic solution, giving chiefly the compound (VIII). A possible explanation of this fact is that the laboratory became seeded with nuclei of the compound (VIII), and thus in the condensation this always tended to precipitate.

The structures of (VIII) and (IX) were proved by hydrolysing the substances to the imide (X) and the acid (XI); the latter was

identical with and confirmed the constitution of the β -*n*-hexylglutaric acid prepared by Blaise and Gault (*Bull. Soc. chim.*, 1907, [iv], 1, 94) from the dioxime of $\alpha\alpha'$ -diketo- β -*n*-hexylpimelic acid.

Cinnamaldehyde appears to react in a very similar manner to phenylacetaldehyde. Anisaldehyde, salicylaldehyde, vanillin, and piperonal have given only the compounds formed by condensation with cyanoacetamide in equimolecular proportions, no trace of substances of type (I) or (IV) being obtained. They therefore behave as benzaldehyde, and our hope that the influence of the side groups would be such that the aldehydes would condense with two molecular proportions of cyanoacetamide, and thus give (on hydrolysis) β -substituted glutaric acids, the preparation of which was the object of this research, has not been fulfilled.

EXPERIMENTAL.

The cyanoacetamide was recrystallised from alcohol and dried in the steam-oven for two to three hours. Liquid aldehydes were fractionated immediately before use. The condensations were carried out in glass-stoppered, wide-mouthed bottles. An aqueous solution of cyanoacetamide at about 15° was treated in succession with the aldehyde (and alcohol if any) and the condensing agent, which might be diethylamine, piperidine, or sodium or potassium hydroxide, all of which were equally effective.

isoButaldehyde.

$\alpha\alpha'$ -Dicyano- β -isopropylglutaramide (IV; R = Pr^s) was obtained in 79 per cent. yield from 7.2 grams of *isobutaldehyde*, 16.8 grams of cyanoacetamide, and 0.5 c.c. of diethylamine in 100 c.c. of water. The precipitate was collected after three hours and crystallised from a 50/50 mixture of alcohol and benzene, forming small, flat parallelograms, m. p. 151° (Found: C = 53.65; H = 6.65; N = 25.43. C₁₀H₁₄O₂N₄ requires C = 54.00; H = 6.40; N = 25.22 per cent.). The substance is insoluble in cold dilute 2*N*-hydrochloric acid, slightly soluble in benzene, and moderately soluble in alcohol. Prolonged boiling with alcohol or water decomposes it with formation of cyanoacetamide.

β -isopropylglutaric acid, CHPr^s(CH₂·CO₂H)₂, was obtained in 90 per cent. yield by boiling the above amide (27 grams) for four hours with 66 c.c. of concentrated hydrochloric acid diluted with 100 c.c. of water, and extracting the product with ether in the usual way. It crystallised from water or dilute hydrochloric acid in needles, m. p. 102° (Howles, Thorpe, and Udall, T., 1900, 77, 944; Crossley and Pratt, T., 1915, 107, 174) (Found: C = 54.86; H = 8.06. Calc., C = 55.16; H = 8.10 per cent. Found: for the silver salt, Ag = 55.70. Calc., Ag = 55.64 per cent.).

6-Imino-3-cyano-5-carbamyl-4-isopropyl-2-piperidone,

—The filtrate from the above glutaramide, on keeping, deposited a further small precipitate, which was soluble in cold dilute hydrochloric acid and reprecipitated unchanged by ammonia, and crystallised from alcohol as a microcrystalline, white powder which melted and decomposed at 224° (Found: N = 25.24. C₁₀H₁₄O₂N₄ requires N = 25.22 per cent.). On hydrolysis with hydrochloric acid, this substance yielded β -isopropylglutaric acid, which was identified by the method of mixed melting point.

When the condensation was carried out in aqueous solution, only a very small amount of the ring compound was obtained. The addition of alcohol to the solution resulted in a better yield of the ring compound (m. p. 224°) at the expense of the open-chain compound (m. p. 151°). Thus, if 90 c.c. of water and 90 c.c. of alcohol were used instead of 100 c.c. of water, a yield of 50 per cent. of the open-chain compound and 2.7 per cent. of the ring compound was obtained. When the quantity of alcohol was increased the maximum yield of the ring compound attained 4 per cent. of the theoretical, that of the open-chain compound declining to 25 per cent.

3 : 5-Dicyano-2 : 6-dihydroxy-4-isopropylpyridine (III; R = Pr^s).—When the filtrate from the above condensation was acidified with concentrated hydrochloric acid, a small precipitate formed (yield about 1 per cent.) which was very soluble in water, but could be crystallised from dilute hydrochloric acid in clusters of thick needles melting at 231° (Found : in material dried at 120°, N = 20.76. C₁₀H₉O₂N₃ requires N = 20.68 per cent.). The substance is evidently the above pyridine derivative, the *N*-ammonium salt of which was described by Guareschi (*Atti R. Accad. Sci. Torino*, 1902, **38**, 291).

*iso*Valeraldehyde.

*iso*Valeraldehyde obtained from two independent sources and having the correct boiling point was employed. The *p*-nitrophenyl-hydrazone melted at 110° (Found : N = 19.24. Calc., N = 19.00 per cent.) (Dakin, *J. Biol. Chem.*, 1908, **4**, 237, gives m. p. 109–110°, whilst Langheld, *Ber.*, 1909, **42**, 2369, gives 112°), and the semi-carbazone at 127° (Found : N = 29.53. Calc., N = 29.35 per cent.) (Semmler, *Ber.*, 1909, **42**, 2015, records m. p. 107°, but gives no analysis).

Several attempts were made to condense this aldehyde with cyanoacetamide in aqueous solution, but only a small yield of a sticky solid was obtained. This on crystallisation from alcohol gave a small amount of a compound melting and decomposing at 231°. No open-chain compound could be obtained either in aqueous or alcoholic solution.

6-Imino-3-cyano-5-carbamyl-4-isobutyl-2-piperidone,

was obtained in a 30 per cent. yield from 8 grams of the aldehyde in 40 c.c. of alcohol, 16 grams of cyanoacetamide in 75 c.c. of water, and 0.5 c.c. of diethylamine. The precipitate was collected after twelve hours, and obtained almost pure by washing twice with boiling alcohol. It was soluble in cold dilute hydrochloric acid and was reprecipitated unchanged by ammonia. It was only slightly soluble in hot alcohol, from which it crystallised as a fine, white powder melting and decomposing at 231° (Found : C = 56.31; H = 6.95; N = 23.78. C₁₁H₁₆O₂N₄ requires C = 55.89; H = 6.83; N = 23.72 per cent.).

3-Cyano-2 : 6-diketo-4-isobutylpiperidine-5-carboxylamide,

obtained as the first hydrolysis product of the above compound, crystallised from water in plates, m. p. 138° (Found : N = 18.09. C₁₁H₁₆O₃N₃ requires N = 17.72 per cent.).

β -isoButylglutaric acid was obtained in 60 per cent. yield by the hydrolysis of the above piperidone. 6.5 Grams of the substance were boiled for five hours with 30 c.c. of concentrated hydrochloric acid and 30 c.c. of water, the acid was extracted with ether after the solution had been saturated with sodium sulphate, and the ether was evaporated, the residue slowly solidifying when kept in a vacuum desiccator. It was crystallised with difficulty from dilute hydrochloric acid, when it formed short, thick needles, m. p. 47° (Knoevenagel, *Ber.*, 1898, **31**, 2590, gives the m. p. as 48°) (Found: for the silver salt, Ag = 53.27. Calc., Ag = 53.68 per cent.).

The anhydride, prepared by boiling the acid with acetyl chloride, was an oil insoluble in sodium hydrogen carbonate solution.

The semianilide, $(\text{CH}_3)_2\text{CH}\cdot\text{CH}_2\cdot\text{CH}(\text{CH}_2\cdot\text{CO}\cdot\text{NHPh})\cdot\text{CH}_2\cdot\text{CO}_2\text{H}$, prepared by boiling the anhydride with aniline in benzene solution for one minute, melted at 138° after being recrystallised from 50 per cent. alcohol, from which it crystallised in very fine needles (Found: N = 5.51. $\text{C}_{15}\text{H}_{21}\text{O}_3\text{N}$ requires N = 5.32 per cent.).

3 : 5-Dicyano-2 : 6-dihydroxy-4-isobutylpyridine (III; R = $\text{CH}_2\text{Pr}^{\beta}$).—The filtrate from the above piperidone derivative, m. p. 231° , was strongly acidified with hydrochloric acid; the white precipitate formed crystallised from water, on the addition of hydrochloric acid, in clusters of needles. The loss of weight at 120° of the air-dried crystals corresponded approximately to one molecule of water of crystallisation. The anhydrous crystals melted at 239° and were hygroscopic (Found: N = 19.49. $\text{C}_{11}\text{H}_{11}\text{O}_2\text{N}_3$ requires N = 19.35 per cent.). The *N*-ammonium derivative was described by Guareschi (*loc. cit.*, p. 294).

Heptaldehyde.

$\alpha\alpha'$ -Dicyano- β -hexylglutaramide (Formula VIII) is the main product of the condensation of heptaldehyde and cyanoacetamide.

11.4 Grams of the aldehyde in 125 c.c. of alcohol were mixed with 16.8 grams of cyanoacetamide in 75 c.c. of water, and 0.5 c.c. of piperidine was added. The precipitate which formed during the night was filtered off and washed with dilute alcohol (yield 87 per cent.). It crystallised from alcohol in small, flat plates which melted to a clear liquid at 147° (Found: C = 59.28; H = 7.76; N = 21.51. $\text{C}_{15}\text{H}_{20}\text{O}_2\text{N}_4$ requires C = 59.06; H = 7.63; N = 21.2 per cent.).

The small quantity of the piperidone derivative (described below) which is usually present in the crude amide can be removed by extraction with cold dilute hydrochloric acid.

β -Hexylglutaric Acid.—Ten grams of the above amide were boiled for five hours with 50 c.c. of concentrated hydrochloric acid and

50 c.c. of water, the solution, saturated with sodium sulphate, was shaken with ether, the ethereal extract (A) shaken with sodium carbonate solution, and the aqueous extract, acidified with hydrochloric acid, was shaken with ether (B). The ether solution (A) contained β -hexylglutarimide. The ether was distilled from solution (B) and the residue, which gradually solidified in a vacuum desiccator (yield 86 per cent.), was dissolved in boiling water and the solution treated with an equal volume of concentrated hydrochloric acid and cooled with ice. The acid which then crystallised out melted at 38° (Blaise and Gault, *loc. cit.*, give the m. p. as $37-38^\circ$) (Found: C = 61.02; H = 9.36. Calc., C = 61.05; H = 9.32 per cent. Found: for the silver salt, Ag = 50.18. Calc., Ag = 50.17 per cent.).

6-Imino-3-cyano-5-carbamyl-4-hexyl-2-piperidone (Formula IX).—The filtrate from the dicyanohexylglutaramide (above), on keeping, usually deposited a substance (yield 1–2 per cent.). This was dissolved in cold dilute hydrochloric acid, reprecipitated with ammonia, and recrystallised from a large volume of alcohol, when it separated in small plates which melted and decomposed at 225° (Found: C = 58.99; H = 7.73; N = 21.38. $C_{13}H_{20}O_2N_4$ requires C = 59.06; H = 7.63; N = 21.20 per cent.).

Hydrolysed in the same way as $\alpha\alpha'$ -dicyano- β -hexylglutarimide, 6-imino-3-cyano-5-carbamyl-4-hexyl-2-piperidone yielded the same two products, namely, β -hexylglutarimide (in ether solution A) and β -hexylglutaric acid (in ether solution B). The former crystallised from hot water in iridescent plates, m. p. 115° (Found: C = 66.79; H = 9.78; N = 7.15. $C_{11}H_{19}O_2N$ requires C = 66.94; H = 9.71; N = 7.10 per cent.) and on complete hydrolysis with hydrochloric acid gave β -hexylglutaric acid in almost quantitative yield.

α -Cyano- β -hexylacrylamide (Formula VII).—This compound was formed together with a certain amount of the compound (VIII) by the condensation of heptaldehyde and cyanoacetamide in aqueous solution. It was very soluble in alcohol, and was separated from the mixed precipitate by taking advantage of this fact. It crystallised from alcohol in clusters of flat plates which melted at 197° to a brown opaque liquid (Found: C = 66.53; H = 8.96; N = 15.70. $C_{10}H_{16}ON_2$ requires C = 66.61; H = 8.95. N = 15.55 per cent.).

α -Cyano- β -hexylacrylic Acid, $CH_3[CH_2]_5CH:C(CN)\cdot CO_2H$.—Three grams of the amide were boiled for three hours with 30 c.c. of dilute hydrochloric acid (1 : 1). A considerable amount of decomposition appeared to take place and the odour of the aldehyde was noticed. The solution was extracted with ether in the usual way. The residue, after evaporation of the ether, was recrystallised from

benzene and light petroleum, when it melted at 127° (Fiquet, *Bull. Soc. chim.*, 1892, [iii], 7, 770, gives m. p. $116-118^{\circ}$) (Found: N = 8.50. Calc., N = 7.73 per cent.).

Cinnamaldehyde.

Cinnamylidenecyanoacetamide, $C_6H_5 \cdot CH:CH \cdot CH:C(CN) \cdot CO \cdot NH_2$.—Condensation of this aldehyde with cyanoacetamide in 50 per cent. alcoholic solution yielded a viscous precipitate, from which no definite substance could be isolated.

Condensation in aqueous solution (6.6 grams of the aldehyde, 8.4 grams of cyanoacetamide, 50 c.c. of water, and 0.3 c.c. of 50 per cent. potassium hydroxide solution) gave *cinnamylidenecyanoacetamide* in 80 per cent. yield. The substance is moderately soluble in alcohol, very much less soluble in benzene, and crystallises from a mixture of these solvents in light yellow needles melting at 161° (Found: C = 72.97; H = 5.27; N = 14.08. $C_{12}H_{10}ON_2$ requires C = 72.71; H = 5.08; N = 14.15 per cent.).

The precipitate obtained by using one molecular proportion of cyanoacetamide was very viscous and appeared to contain some aldehyde.

Cinnamylidenecyanoacetic Acid, $C_6H_5 \cdot CH:CH \cdot CH:C(CN) \cdot CO_2H$.—Ten grams of the amide were hydrolysed by boiling for five hours with 50 c.c. of dilute hydrochloric acid (1:1). A considerable amount of decomposition took place and the liquid blackened. The product was extracted with ether, the extract shaken with sodium carbonate solution, and the aqueous extract nearly neutralised with hydrochloric acid, filtered from the black precipitate formed, and finally acidified. The precipitated acid (yield 50 per cent.) formed light yellow crystals, m. p. 210° , from benzene or benzene containing a little alcohol; it was very soluble in alcohol alone (Found: C = 72.47; H = 4.85; N = 7.26. Calc., C = 72.36; H = 4.55; N = 7.03 per cent. Found: for the silver salt, Ag = 34.9. Calc., Ag = 35.2 per cent.). Fiquet (*Ann. Chim.*, 1893, [vi], 29, 493) gives 212° as the m. p. of this acid.

$\alpha\alpha'$ -Dicyano- β -styrylglutaramide (?) (IV; R = $CHPh:CH$).—When kept, the filtrate from the cinnamylidenecyanoacetamide (above) usually deposited a small precipitate which was insoluble in benzene, but crystallised from alcohol as a fine, white powder, m. p. 230° (Found: C = 64.12; H = 5.16; N = 19.89. $C_{13}H_{14}O_2N_4$ requires C = 63.83; H = 5.00; N = 19.86 per cent.). Having once been obtained, this substance could be isolated in 10 per cent. yield by filtering the condensation mixture after two hours and seeding the filtrate. It was also prepared in 15–20 per cent. yield by seeding a mixture (in alcohol) of cinnamylidenecyanoacet-

amide and cyanoacetamide to which a few drops of diethylamine had been added. The products of hydrolysis of this compound are being investigated.

Anisaldehyde.

α -Cyano- β -4-methoxyphenylacrylamide (V; R = C₆H₄·OMe).—On the addition of a few drops of 2N-sodium hydroxide solution to 2.7 grams of the aldehyde and 3 grams of cyanoacetamide in 15 c.c. of water a precipitate formed at once, and in about five minutes the mixture appeared solid. The product crystallised from alcohol in clusters of small, very light lemon-yellow needles, m. p. 207° (Found: N = 14.19. C₁₁H₁₀O₂N₂ requires N = 13.87 per cent.). Condensation in aqueous alcohol (1 : 2) produced the same substance in 80 per cent. yield.

Salicylaldehyde.

α -Cyano- β -2-hydroxyphenylacrylamide (V; R = C₆H₄·OH).—Three grams of the aldehyde were added to the same weight (about 1.5 mols.) of cyanoacetamide in 20 c.c. of water. Sodium hydroxide was used as the condensing agent. A similar experiment was carried out in which sufficient alcohol was added to dissolve the aldehyde. Both experiments gave a compound which crystallised from alcohol in needles and melted and decomposed at 191° (Found: N = 14.99. C₁₀H₈O₂N₂ requires N = 14.89 per cent.).

Vanillin.

α -Cyano- β -4-hydroxy-3-methoxyphenylacrylamide (V; R = OMe·C₆H₃·OH).—Three grams of the aldehyde in 7 c.c. of alcohol were mixed with 3 grams of cyanoacetamide in 15 c.c. of water. In another experiment, 2 grams of cyanoacetamide in 10 c.c. of water were added to a saturated solution of the aldehyde (about 1 gram in 100 c.c. of water). In both cases a few drops of sodium hydroxide solution were added to the mixture. A precipitate formed during the night. It crystallised from alcohol in small, yellow prisms, m. p. 209° (Found: N = 12.99. Calc., N = 12.84 per cent.).

Piccinini (*Atti R. Accad. Sci. Torino*, 1903—1904, **39**, 1029) describes this compound, m. p. 210—210.5°, as one of the products of the reaction of the aldehyde with ethyl cyanoacetate and ammonia, or with cyanoacetamide and ammonia.

Piperonal.

α -Cyano- β -piperonylideneacetamide (V; R = C₆H₃·O₂CH₂).—Three grams of the aldehyde in 20 c.c. of alcohol were mixed with the same weight of cyanoacetamide in 15 c.c. of water, and a few

drops of sodium hydroxide solution added. In a few minutes crystals commenced to form, and in a very short time the mass appeared solid. The precipitate was filtered off (yield almost quantitative) and crystallised from alcohol, when it separated in light yellow needles, m. p. 210° (Found: N = 12.98. Calc., N = 12.96 per cent.).

The same compound was obtained when cyanoacetamide in water was mixed with a saturated solution of the aldehyde in water, and a little sodium hydroxide solution added.

Piccinini (*Atti R. Accad. Sci. Torino*, 1902—1903, **38**, 917) gives the melting point of this substance as 209°, but later (*ibid.*, 1904—1905, **40**, 472) he records m. p. 212—213° for the material prepared from cyanoacetamide and piperonal in glacial acetic acid or 15 per cent. ammonia solution.

CCCLXXII.—The Formation and Stability of spiro-Compounds. Part XI. Bridged spiro-Compounds from cyclopentane.

By CHRISTOPHER KELK INGOLD, ERIC WILLIAM LANFAR, and JOCELYN FIELD THORPE.

THE original hypothesis of Beesley, Ingold, and Thorpe (*T.*, 1915, **107**, 1080), that the strain inherent in a carbon ring is communicated through each carbon atom to the pair of valencies external to the ring, was suggested as a result of the comparative study of the structures (I) and (II).

Experiment showed that groups attached to the carbon atoms (1) and (2) interacted more readily when (3) participated in a cyclohexane ring, and that, in the derived cyclopropane structures (III) and (IV), the cyclohexane ring conferred enhanced stability on the cyclopropane ring, and especially on the spirocyclopropane bonds (1—3) and (2—3):

At a later date (T., 1919, 115, 320) the comparison was extended to the more complex ring structures (V) and (VI), and it was found that the principal influence exerted by the *cyclohexane* ring consisted in diminishing the stability of the *spirocyclopropane* bonds (1—5) and (4—5), whilst second-order effects appeared in the more remote parts of the molecule.

The (at first sight) curious fact that the *spirocyclopropane* bonds should be stabilised by the *cyclohexane* ring in (IV) but rendered less stable in (VI) received ready explanation on the lines of the original hypothesis, which also accounted in a natural manner for all the subsidiary effects; and in view of the agreement with theory, and the possibility which it opens of predicting the susceptibilities of complex systems of associated rings, it seemed desirable to carry out the obvious tests afforded by the group of compounds derived from the *cyclopentane* structure (VII). The angle of the *cyclopentane* ring is very close to that at which two valencies emerge from a carbon atom in the unstrained condition, and hence the structure (VII) should resemble the *gem*-dimethyl ring structure (V), rather than the *cyclohexane*-spiran structure (VI), in all the respects in which these latter differ from one another. Thus the bond (5—1) in (VII) should be as stable as it is in (V), and not singularly unstable as in the *cyclohexane* structure (VI); whilst, as regards the bonds (1—4) and (3—4), the second-order diminutions of stability, noticed in the case of the *cyclohexane* derivatives, should not appear.

It may be stated at once that each of the predictions of theory accords well with the facts which emerged in the course of the experimental investigation described in this paper.

The most remarkable contrast with the *cyclohexane* series was observed in experiments designed to test the susceptibility to fission of the bond (5—1). The fission of this bond was brought about with great ease in certain substances of the *cyclohexane* series by alkaline reagents which were without effect on corresponding compounds of the *gem*-dimethyl class. When the *cyclopentane* derivatives were examined, they were found to be just as stable as the *gem*-dimethyl compounds, and to resist the attack of reagents which completely decomposed their ring homologues of the *cyclohexane* series.

Evidence regarding the secondary influence on the bond (3 : 4) was also obtained. The expected effect is in the nature of a small increase in stability when comparison is made with the *cyclohexane* series, the *cyclopentane* structure closely resembling the *gem*-dimethyl structure. Owing to the smallness of the effect, and to

experimental difficulties arising from the instability of the bond (5 : 1) in the *cyclohexane* series, we have not succeeded in finding a reagent capable of bringing about the *fission* of the bond (3 : 4) in one series but not in the other. We have, however, examined the *establishment* of the bond (3 : 4), a process in which, as explained in the former paper, the influence of the *cyclohexane* ring, as transmitted through the bonds of the *cyclopropane* ring, is magnified sufficiently to render it capable of easy experimental detection. The result of a series of comparative experiments has been to show very clearly that the closure of the *cyclobutane* ring by the establishment of the bond (3 : 4) proceeds much more smoothly in the *cyclopentane* series than in the *cyclohexane* series, and that in this respect the *cyclopentane* derivatives closely resemble the compounds of the *gem*-dimethyl series.

The bond (1 : 4) undergoes fission in certain corresponding acids of all three series when these acids are treated with sodium amalgam, two atoms of hydrogen being added to the molecule. It is to be expected that in the *cyclopentane* series this reaction will proceed much as it does in the *gem*-dimethyl series, that is to say, considerably less easily than when *cyclohexane* derivatives are employed. Comparative experiments with acids of all three series have shown that this is the case, and that the reaction velocities are related to one another in the manner which the hypothesis of strain transmission requires.

Establishment of the Bond (3 : 4).

The bridged-ring compounds described in this paper* were synthesised by a method precisely similar to that employed in the former investigation; that is to say, *cyclopentane*-1 : 1-diacetic acid was brominated and the dibromo-ester (VIII) converted by treatment with ethyl sodiomalonate into a *cyclopentanespirocyclopropane* ester (IX), from which the bridged-ring sodio-ester (X) was prepared by the application of Dieckmann's reaction.

* As explained in former papers, the compounds of this series possess two distinct sets of properties, one referable to the bridged structure itself, and the other to a monocyclic tautomeric form. The present paper deals only with the chemistry of the bridged individual form. The reactions of the monocyclic individual and its relation to the bridged form will be made the subject of a future paper.

The compound (X) is plainly of type (VII), and the comparison of its derivatives with those of the analogous compounds (XI) and (XII) forms the basis of the experimental investigation on which the preceding considerations have been grounded.

Both the dimethyl and *cyclohexane* bridged-ring compounds can be prepared directly from the corresponding dibromo-esters (type

FIG. 1.

VIII) by treatment with ethyl sodiomalonate in the presence of sodium ethoxide. In the former case, the reaction proceeds fairly smoothly, the maximal yield of the compound (XI) being about 65 per cent. In the latter case, the second stage of the reaction is rather difficult to bring about and the yield of the bridged-ring compound (XII) is only about 25 per cent. Experiment has shown that in the *cyclopentane* series the reaction can also be brought about in one operation, and that it proceeds fairly smoothly, the yield of the compound (X) amounting to 63 per cent. of the theoretical, that is, practically the same as in the *gem*-dimethyl series.

In order to make the comparison more definite, the *cyclopentane*-*spirocyclopropane* ester (IX) was isolated, and then converted by treatment with sodium ethoxide into the bridged ester (X). The

corresponding reaction in the *gem*-dimethyl series leads to the formation of the bridged-ring compound (XI) in 70 per cent. yield after three hours at 75°, and in a maximal yield of 75 per cent. after five hours. In the *cyclohexane* series, the closure of the ring takes place with greater difficulty, the yield of the compound (XII) being only 23 per cent. and 29 per cent. respectively, after three and five hours' heating at 75°. In the *cyclopentane* series, a yield of 70 per cent. was obtained after two hours at 75°, and a yield of 73 per cent. after four hours, so that there can be no doubt that the *cyclopentane* series resembles the *gem*-dimethyl series rather than the *cyclohexane* series so far as concerns the establishment of the bond (3 : 4) in the bridged compound (X).

The progress of the reaction in the three series is shown by the curves of Fig. 1.

Stability of the Bond (4 : 5).

Evidence of a marked difference in stability between the bridged *spiro*-compounds of the *cyclopentane* and *cyclohexane* series was obtained in the course of experiments on the action of alkaline hydrolysing agents on the compound (X).

It will be recalled that in the *cyclohexane* series alkaline hydrolysis of the original sodio-ester (XII) proceeded in certain well-defined stages, the first product being a monobasic acid ester (XIII) and the next a basic acid ester (XIV), the further hydrolysis of which resulted in the scission of the bond (4 : 5), and the formation of an acid represented by formula (XV) :

On the other hand, when the *gem*-dimethyl acid ester (XVI), which corresponds with (XIV), was examined, it was found to be almost unaffected under conditions in which the *cyclohexane* analogue (XIV) underwent complete conversion into the fission product (XV). Even prolonged treatment with alkalis yielded no trace of a fission product, but only the monocarboxylic acid (XVII) formed by the elimination of the labile carboxyl groups :

The action of cold alcoholic potassium hydroxide on the *cyclopentane* sodio-ester (X) yields a well-defined dipotassium derivative of the acid ester (XVIII), analogous to (XIII). Further hydrolysis

leads to the dibasic acid ester (XIX), a singularly stable substance which yields no fission product, and, indeed, remains unattacked under conditions in which the corresponding compound of the cyclohexane series (XIV) is completely decomposed.

Both these acid esters are converted by mineral acids into the monobasic acid described below.

Stability of the Bond (1 : 4).

The first action of mineral acids on the sodium compound (X) is to convert it into the free enol-ester (XX). The further hydrolysis of this substance by mineral acids proceeds in a number of more or less definite stages, the isolable products being an acid ester (XXI or XXII), a dicarboxylic acid (XXIII), and a monocarboxylic acid (XXIV). The last two acids, which are produced side by side when the sodium compound (X), the enol-ester (XX), or any of their previously mentioned hydrolysis products are boiled for several hours with 20 per cent. hydrochloric acid, represent the ultimate products of acid hydrolysis, and they correspond exactly with the mono- and di-basic acids which form the ultimate acid hydrolysis products both in the *gem*-dimethyl and the cyclohexane series :

Further degradation of the structure can be brought about with the aid of reducing agents which readily effect the fission of the bond (1 : 4) in the monocarboxylic acid. The product is *cyclopentanespirocyclopentanonecarboxylic acid* (XXV), and its constitution follows from the fact that on oxidative degradation by nitric acid it yields a mixture of *cyclopentane-1 : 1-diacetic acid* (XXVI) and *cyclopentane-1-acetic-1-carboxylic acid* (XXVII).

It will be recalled that the reduction of the bridged monobasic acid of the *cyclohexane* series (type XXIV) to its unbridged derivative (type XXV) occurred with considerably greater ease than in the *gem*-dimethyl series. This was established by a series of comparative experiments which showed that, under the conditions employed, the reduction of the *cyclohexane* compound proceeded about 1.8 times as fast as that of the *gem*-dimethyl compound.

The comparison has now been extended to include the *cyclopentane* series, with results which are depicted in the accompanying diagram (Fig. 2). But at an early stage of the experimental work it was noticed that reductions carried out under conditions which,

in the *cyclohexane* series, led to a large yield of the reduced acid yielded much unchanged material in the *cyclopentane* case. Further experiment showed that the reduction takes place at only about half the rate at which it occurs in the *cyclohexane* series, and that the velocity is, in fact, very close to that which obtains for the *gem*-dimethyl compounds.

Thus in three separate instances of ring closure or ring fission, namely, the closure of the bond (3 : 4) and the fission of the bonds (4 : 5) and (1 : 4), the hypothesis of strain transmission has correctly predicted the susceptibilities of the structure under investigation.

It may be added that the constitution of the substances described in this paper were established by methods similar in many respects

to those employed in the former paper, and that the nature of the evidence can easily be gathered, without further explanation here, by co-reference to the introduction of that paper and the experimental portion of this one.

EXPERIMENTAL.

(A) Formation of the Bridged spiro-Sodio-ester (X).

cyclopentane-1:1-diacetic acid was prepared by condensing *cyclopentanone* with cyanoacetic ester and alcoholic ammonia (Guareschi's reaction), and hydrolysing the resulting imide with sulphuric acid. It was dibrominated by the Hell-Volhard-Zelinsky method and the neutral dibromo-ester, obtained by pouring the dibromo-acid chloride into ethyl alcohol, was purified by careful distillation under a low pressure.

Ethyl cyclopentanespiro-1-methylcyclopropane-1:2:ω:ω-tetracarboxylate (IX).—The dibromo-ester (20 grams) was added to a solution, in 30 grams of alcohol, of ethyl sodiomalonate prepared from 2.3 grams of sodium and 16 grams of ethyl malonate. The solution was heated until neutral, cooled, and poured into dilute hydrochloric acid. The oil was extracted with ether, washed with dilute sodium carbonate, dried, and distilled. It yielded as the principal fraction a colourless oil, b. p. 245–253°/11 mm. (Found: C = 60.1; H = 7.7. $C_{20}H_{30}O_8$ requires C = 60.3; H = 7.5 per cent.).

Ethyl Sodiocyclopentanespirodicyclopentan-3-one-1:2:4-tricarboxylate (X).—(a) From ethyl *cyclopentane-1:1*-dibromoacetate, ethyl malonate, and sodium ethoxide.* Five grams of sodium, dissolved in 90 grams of ethyl alcohol, were treated with 25 grams of ethyl malonate. The solution was cooled to 20° and carefully mixed with 15 grams of the dibromo-ester, the solution being kept below 25° by immersion in cold water. After half an hour the solution was heated for three hours on the water-bath, cooled, and filtered. The yellow solid substance was washed on the filter successively with alcohol, water, and alcohol and ether. It was crystallised for analysis from ethyl alcohol, from which it separated in bright yellow needles (Found: Na = 6.0. $C_{19}H_{23}O_7Na$ requires Na = 6.2 per cent.). The yield was usually 60–65 per cent. of the theoretical.

(b) From ethyl *cyclopentanespiro-1-methylcyclopropane-1:2:ω:ω-tetracarboxylate* and sodium ethoxide.—The ester (4 grams) was treated with 0.46 gram of sodium dissolved in 7 grams of ethyl alcohol, and the mixture heated at 75° for several hours, after which

* This experiment was first carried out by Mr. S. Sako, who made a careful study of the conditions necessary to secure a good yield.

the yellow sodium compound was collected and washed as described above. The yields obtained after heating for one, two, and three and a half hours were 55, 70, and 73 per cent., respectively, of the theoretical (see Fig. 1).

Ethyl cycloPentanespirodicyclopentan-3-one-1:2:4-tricarboxylate.—The yellow sodium compound was suspended in ether and shaken with dilute hydrochloric acid until no solid remained and the yellow colour had completely disappeared. The ether extract was dried with calcium chloride and evaporated. The ester was thus obtained as a colourless oil (Found: C = 60.9; H = 6.9. $C_{18}H_{24}O_7$ requires C = 61.3; H = 6.8 per cent.) which gave a deep wine-red colour with ferric chloride, and on treatment with dilute sodium hydroxide passed back into the original sodium compound.

(B) *Hydrolysis of the Bridged spiro-Ester.*

Diethyl Potassium Potassiocyclopentanespirodicyclopentan-3-one-1:2:4-tricarboxylate, $C_4H_8 > C \begin{matrix} \swarrow C(CO_2K) \\ \searrow C(CO_2Et) \end{matrix} \begin{matrix} -C-CO_2Et \\ | \\ C(CO_2Et)-C-OK \end{matrix}$ —The

yellow sodium compound (4 grams) was passed through a fine-meshed sieve and then suspended in 30 c.c. of 2.5 N-alcoholic potassium hydroxide. After a short time, it passed into solution, and a canary-yellow precipitate gradually separated, which was collected, washed with alcohol and ether, and dried. The yield was theoretical (Found: K = 19.7. $C_{16}H_{18}O_7K_2$ requires K = 19.5 per cent.). This substance gives a claret colour with ferric chloride.

Diethyl Hydrogen cycloPentanespirodicyclopentan-3-one-1:2:4-tricarboxylate.—The above potassium salt was suspended in ether and shaken with dilute hydrochloric acid until the colour had vanished. The ether layer was dried with sodium sulphate and evaporated. The acid ester, thus obtained as a mass of crystals melting at about 60°, was very soluble in the usual organic solvents and did not appear capable of being easily recrystallised. It was therefore converted into the *silver* salt (Found: Ag = 60.8. $C_{16}H_{18}O_7Ag_2$ requires Ag = 60.9 per cent.). The acid and its silver salt give a claret colour with aqueous-alcoholic ferric chloride.

Ethyl Dihydrogen cycloPentanespirodicyclopentan-3-one-1:2:4-tricarboxylate.—The yellow sodium compound (5 grams) was boiled with 40 c.c. of 3N-ethyl-alcoholic potassium hydroxide until the yellow colour was discharged. The precipitate was collected, washed with alcohol and ether, dried in a desiccator, and then dissolved in dilute hydrochloric acid. The acid, which was extracted from this solution by means of ether, melted at 124° after crystallisation from ether or water, and gave a violet colour with ferric chloride.

The silver salt was obtained as a white precipitate (Found : C = 32.7; H = 2.8; Ag = 42.6. $C_{14}H_{14}O_7Ag_2$ requires C = 32.9; H = 2.8; N = 42.3 per cent.).

The anhydro-ester, $C_4H_8 > C \begin{array}{c} \text{CO-O-CO} \\ \diagup \quad \diagdown \\ \text{C} \quad \text{CH} \\ | \quad | \\ \text{C(CO}_2\text{Et)} \quad \text{CO} \end{array}$, was prepared by heating the acid ester at 100° for one hour with acetyl chloride in a closed tube. The residue obtained on evaporation was an oil, which was insoluble in cold alkali and was converted into the original acid ester on boiling with water (Found : C = 60.0; H = 5.3. $C_{15}H_{14}O_6$ requires C = 60.4; H = 5.0 per cent.).

The acid ester is stable towards alcoholic potassium hydroxide under conditions in which the cyclohexane analogue is completely converted into products of ring-fission, and on prolonged boiling with 20 per cent. hydrochloric acid undergoes conversion into the monocarboxylic acid described below.

Ethyl Hydrogen cyclopentanespirodicyclopentan-3-one-1 : 2-dicarboxylate.—The yellow sodium compound or its ester was heated with ten times its weight of 20 per cent. hydrochloric acid for three hours, and the sparingly soluble oil washed with hot water and dried in a vacuum. Thus obtained, the acid ester forms a viscous gum, which gives a brown colour with ferric chloride, and behaves as a monobasic acid on titration (Found : C = 61.2; H = 6.6. $C_{13}H_{10}O_5$ requires C = 61.9; H = 6.35 per cent.).

cyclopentanespirodicyclopentan-3-one-1 : 2-dicarboxylic Acid.—The yellow sodium compound or its ester was heated with ten times its weight of 20 per cent. hydrochloric acid for five hours, and the solution cooled and filtered from the crystals of monocarboxylic acid (below). The filtrate was extracted six times with equal volumes of ether, and the residue obtained on drying and evaporating the ether was dissolved in ammonium hydroxide and treated with ammonium chloride and a strong solution of calcium chloride. After twenty-four hours, the completely precipitated calcium salt was collected (with the addition of any similar calcium precipitate obtained in the purification of the monocarboxylic acid), decomposed with hydrochloric acid, and the free dicarboxylic acid extracted with ether. The residue obtained after drying and evaporating the ether was crystallised from a small amount of hot water, from which the dibasic acid separated in needles, m. p. 160° (Found : C = 58.6; H = 5.3. $C_{11}H_{12}O_5$ requires C = 58.9; H = 5.4 per cent.). The acid gives an insoluble calcium salt, and a brownish-red colour with ferric chloride.

The anhydride was obtained by heating the acid with acetyl chloride for one hour at 100° in a closed tube, and evaporating the

solution in an evacuated desiccator containing potassium hydroxide. The crystalline residue was recrystallised from benzene, from which prisms separated, m. p. 162° . (Found: C = 64.0; H = 4.9. $C_{11}H_{10}O_4$ requires C = 64.1; H = 4.8 per cent.). On boiling with water, the anhydride regenerates the acid from which it was prepared.

The *p*-xylydic acid, $C_4H_8 > C < \begin{array}{c} C(CO \cdot NH \cdot C_6H_3Me_2) \cdot CH \cdot CO_2H \\ CH \text{-----} CO \end{array}$ or $C_4H_8 > C < \begin{array}{c} C(CO_2H) \cdot CH \cdot CO \cdot NH \cdot C_6H_3Me_2 \\ CH \text{-----} CO \end{array}$, was prepared by mixing

a warm solution of the anhydride in benzene with one of *p*-xylydine in the same solvent. The crystalline product was purified by recrystallisation from alcohol and thus obtained in feathery needles, m. p. 173° (Found: C = 69.5; H = 6.5. $C_{19}H_{21}O_4N$ requires C = 69.7; H = 6.4 per cent.).

cyclopentanespirodi-cyclopentan-3-one-1-carboxylic Acid.—The sparingly soluble crystalline acid obtained in the hydrolysis by hydrochloric acid (above) was dissolved in ammonium hydroxide and treated with ammonium chloride and calcium chloride. Any calcium salt which separated in the course of twenty-four hours was collected (and worked up for the dibasic acid), and the filtrate acidified with hydrochloric acid. The precipitated monobasic acid was collected, dried, and crystallised from ether, from which it separated in needles, m. p. 217° (Found: C = 66.8; H = 6.7. $C_{10}H_{12}O_3$ requires C = 66.7; H = 6.7 per cent.). This acid does not give a colour with ferric chloride, and its calcium salt is soluble in water.

The *semicarbazone* was prepared from the free acid and aqueous semicarbazide acetate, and crystallised from glacial acetic acid, from which it separated in leaflets, m. p. 258° (decomp.) (Found: C = 55.3; H = 6.3. $C_{11}H_{15}O_3N_3$ requires C = 55.7; H = 6.3 per cent.).

(C) Reduction of the Bridged Monobasic Acid.

cyclopentanespirocyclopentan-3-one-1-carboxylic Acid (XXV).—Five grams of the bridged monobasic acid were neutralised with aqueous sodium carbonate and the whole made up to 400 c.c. This solution was surrounded by cold water and maintained in contact with carbon dioxide, while 10 grams of sieved 3 per cent. sodium amalgam were added every half-hour for twelve hours. The mercurial layer was removed, and the aqueous solution concentrated and acidified. The oily acid thus precipitated was extracted with ether, from which it was obtained by evaporation as a colourless syrup, which, on rubbing, set to a hard cake of crystals, m. p. $65-70^{\circ}$. The acid was crystallised from a mixture of ether and ligroin,

from which it separated in dense prisms, m. p. 73–74° (Found: C = 65.7; H = 7.7. $C_{10}H_{14}O_3$ requires C = 65.9; H = 7.7 per cent.).

The *oxime* crystallised in the course of twelve hours from a cold solution containing equivalent proportions of hydroxylamine acetate and the carboxylic acid. It separated from water in stout prisms, m. p. 176° (Found: C = 60.6; H = 7.9. $C_{10}H_{15}O_3N$ requires C = 60.9; H = 7.6 per cent.).

The *phenylhydrazone* quickly separated, as a yellow oil which rapidly solidified, from a solution containing the carboxylic acid and phenylhydrazine acetate. It was crystallised from dilute alcohol, from which it separated in buff rosettes of minute needles, m. p. 99° (Found: C = 70.3; H = 7.5. $C_{16}H_{20}O_2N_2$ requires C = 70.6; H = 7.3 per cent.).

The *semicarbazone* crystallised rapidly and quantitatively from a solution, in dilute alcohol, of the acid and semicarbazide acetate. It separated from hot glacial acetic acid in small needles, m. p. 217° (decomp.) (Found: C = 55.2; H = 7.1. $C_{11}H_{17}O_3N_3$ requires C = 55.2; H = 7.1 per cent.).

Oxidation of cyclopentanespirocyclopentan-3-one-1-carboxylic Acid: cyclopentane-1:1-diacetic Acid and 1-Carboxycyclopentane-1-acetic Acid.—The acid was boiled with dilute nitric acid until red fumes ceased to be evolved, and the resulting solution evaporated with the occasional addition of water. 1-Carboxycyclopentane-1-acetic acid, the main constituent of the crystalline residue, was identified by analysis (Found: C = 55.5; H = 7.3. Calc., C = 55.8; H = 7.0 per cent.), and by comparison with an authentic specimen, and cyclopentane-1:1-diacetic acid, obtained from the ultimate mother-liquors of the crystallisation, by direct comparison and a mixed melting-point determination.

Velocity of Reduction of the Bridged Monobasic Acid.—These experiments were carried out exactly as described in the former paper (*loc. cit.*), and the percentage conversion was determined for each experiment also in the same way. After treatment for one, three, and five hours, the number of atoms of hydrogen taken up per molecule of acid was 0.4, 0.8, and 1.1, respectively. The results of these experiments, and some additional ones on the corresponding reaction in the *gem*-dimethyl and cyclohexane series, are displayed on Fig. 2.

We wish to thank the Chemical and Royal Societies for grants in aid of this investigation.

CCCLXXIII.—*An X-Ray Investigation of Certain Organic Esters and Other Long-chain Compounds.*

By GEORGE SHEARER.

IN a recent paper, Müller (this vol., p. 2043) has given the results of an X-ray investigation of some of the higher fatty acids. He found that these compounds give excellent X-ray reflections from what are presumably their cleavage planes and that the size of the "spacing" of these planes increases uniformly with the number of carbon atoms in the molecule. Such results indicate that in this way X-ray measurements yield valuable information as to the lengths of the molecules themselves, even although the crystal structure is far from completely determined.

The work described here is a continuation of those experiments, dealing with the esters of palmitic and stearic acids and with certain other long-chain compounds which, in addition to the long CH_2 chains, contain in their structure a benzene ring.

EXPERIMENTAL.

The experimental method adopted was very similar to that employed by Müller and need not be described in detail again. One slight modification may, however, be mentioned. The substance to be examined is mounted in the form of a very thin layer on a strip of mica. This is oscillated on the X-ray spectrometer table through an angle of about 8° on either side of the direct X-ray beam. During this oscillation the cleavage plane of the mica passes through the reflecting angle ($5^\circ 30'$ for iron K radiation, which was used in these experiments), so that there appear on the photographic plate, not only the lines characteristic of the substance on the mica, but also the K_α and K_β first-order reflections from the mica. These give exceedingly sharp lines corresponding to a spacing of 10.1 \AA . and calibrate the plate automatically. If required, the second-order mica reflections also can be obtained by oscillating the crystal through a slightly greater angle.

Substances Investigated.—The substances here discussed are four esters of palmitic acid (methyl, ethyl, octyl, and cetyl), two esters of stearic acid (methyl and ethyl), and three chain compounds, which also possess a benzene or phenol group—octadecylbenzene, *p*-hexadecylphenol, and *p*-octadecylphenol. All these substances were pure specimens most kindly supplied by Mr. N. K. Adam, of Sheffield University. The author wishes to take this opportunity of expressing his indebtedness to Mr. Adam for providing these specimens.

Experimental Results.—As was found in the case of the fatty acids, these compounds gave very good reflections from what are probably their cleavage planes. Many different orders of reflection for these planes occur on the plates, and it is possible by combining the measurements of these various orders to obtain the fundamental spacing of these planes with considerable accuracy. The results of such measurements are given in the following table, where the cleavage spacing is denoted by d_1 .

TABLE I.

Substance.	Formula.	Spacing in Å.		
		d_1 .	d_2 .	d_3 .
Methyl palmitate	$C_{15}H_{31} \cdot CO \cdot O \cdot CH_3$	22.0	4.07	3.72
Ethyl "	$C_{15}H_{31} \cdot CO \cdot O \cdot C_2H_5$	23.2	4.07	3.67
Octyl "	$C_{15}H_{31} \cdot CO \cdot O \cdot C_8H_{17}$	30.4	4.16	3.72
Cetyl "	$C_{15}H_{31} \cdot CO \cdot O \cdot C_{16}H_{33}$	40.4	4.05	3.69
Methyl stearate	$C_{17}H_{35} \cdot CO \cdot O \cdot CH_3$	24.0	4.07	3.74
Ethyl "	$C_{17}H_{35} \cdot CO \cdot O \cdot C_2H_5$	25.2	4.14	3.69
Octadecylbenzene	$C_{18}H_{37} \cdot C_6H_5$	49.2	—	—
<i>p</i> -Hexadecylphenol	$C_{16}H_{33} \cdot C_6H_4 \cdot OH$	46.5	—	—
<i>p</i> -Octadecylphenol	$C_{18}H_{37} \cdot C_6H_4 \cdot OH$	51.3	—	—

In addition to the various order reflections of the cleavage plane, certain other lines corresponding to relatively small spacings occurred on the plates. In the case of the esters, two strong, rather diffuse lines appeared at about 4.1 and 3.7 Å. and these lines were very nearly the same for all the esters examined. They are given in the table in the columns headed d_2 and d_3 . Similar results were found by Müller for the fatty acids, and a suggestion as to their interpretation is given in his paper (*loc. cit.*).

Discussion of Results.

An examination of Table I immediately reveals the fact that the cleavage spacing of the esters increases with the number of carbon atoms in the ester chain. This variation is shown in Fig. 1, where the spacing is plotted against the number of carbon atoms on the ester side of the molecule in the case of the esters and against the number of carbon atoms in the chain in the case of the other compounds.

It is clear from this figure that the addition of a CH_2 group to the molecule results in an increase in the length of the cell. In the case of the palmitates, this increase is the same throughout the whole range examined. The number of stearates so far investigated is too small to show whether this is also true for the esters of stearic acid, but the fact that the two stearates lie on a line which is, within experimental error, parallel to the line on which the palmitates lie is a strong argument in favour of the assumption that this increase of length per CH_2 group is constant also for the stearates and has the same value in the two cases.

This increase of length per CH_2 group can be calculated with considerable accuracy in the case of the palmitates, as there is a variation of from one to sixteen carbon atoms in the ester chain with a corresponding increase of about 90 per cent. in the length of the cell. If this is done, we find

$$\Delta d_1/\Delta n = 1.22 \text{ \AA.},$$

where $\Delta d_1/\Delta n$ denotes the increase of spacing per CH_2 group in the chain.

A similar result to the above was found for the fatty acids by Müller, but the increase per CH_2 group was found to be 2.0 Å.

FIG. 1.

Müller points out that the length of the cell is probably that of two molecules and that therefore the increase in the length of the molecule per carbon atom is 1.0 and not 2.0. This difference, with some other points of interest, is discussed in a joint paper (this vol., p. 3156).

As is to be expected from their formulæ, the stearates are longer than the corresponding palmitates. The increase per carbon atom on the acid side of the molecule is 1.0, a value which is in agreement with Müller's results.

The accepted "diameter" of the carbon atom is 1.5 Å. It is clear, therefore, that either the general direction of the molecules is not even approximately perpendicular to the cleavage planes or the carbon atoms of the chain are arranged in some spiral or zig-zag fashion. If we calculate the angle, θ , between successive pairs of

carbon atoms on the assumption that the arrangement is a zig-zag one, we find

$$\sin \theta/2 = 1.5/4.22 \text{ or } \theta = 109^\circ 30'.$$

This is almost exactly the angle ($109^\circ 28'$) which the normals from the centre to the faces of a tetrahedron make with each other. The significance of this result is discussed in the paper referred to above.

If the results obtained with the compounds which contain a benzene ring are examined, it will be seen that the observed spacings are about twice as great as the measurements of the esters would lead us to expect, on the assumption that the length of the cell is also a measure of the length of the molecule. Also the increase of length per CH_2 group is about twice as great as for the esters. These facts would naturally suggest that in these cases, as in the fatty acids, we are measuring the length, not of a single molecule, but of two placed end to end, probably in opposite directions. On this assumption, we find for the lengths of the molecules the following values :

Octadecylbenzene	24.6
<i>p</i> -Hexadecylphenol	23.3
<i>p</i> -Octadecylphenol	25.6

Here again the increase corresponding to two CH_2 groups is 2.3, but the accuracy of the measurements is not sufficient to permit us definitely to decide which type of chain is present.

The difference in length between the octadecylbenzene and *p*-octadecylphenol molecules is 1.0 Å. This is about what is to be expected for the oxygen atom which forms the only difference between the two molecules.

From our knowledge of "atomic radii," it is possible to calculate the lengths of the molecules on the assumption that the acid chain increases 1.0 and the ester chain 1.22 per CH_2 group. The results of such a calculation are given in Table II. In these calculations the chain in the benzene compounds has been assumed to be the same as in the acids, and the dimensions of the ring are those suggested by Bragg (*Proc. Physical Soc.*, 1921, **34**, 33).

TABLE II.

Substance.	Calculated length.	Observed spacing.
Methyl palmitate	20.6	22.0
Ethyl "	21.8	23.2
Octyl "	29.1	30.4
Cetyl "	38.0	40.4
Methyl stearate	22.6	24.0
Ethyl "	23.8	25.2
Octadecylbenzene	23.5	24.6
<i>p</i> -Hexadecylphenol	22.8	23.3
<i>p</i> -Octadecylphenol	24.8	25.8

The agreement is as good as could be expected.

In conclusion, the author wishes to acknowledge his indebtedness to Professor Sir W. H. Bragg, F.R.S., in whose laboratory these experiments were carried out, for his continual kindness and helpful suggestions; also to the Department of Scientific and Industrial Research, whose financial help made the work possible. Reference has already been made to the assistance rendered by Mr. Adam in supplying the material.

CCCLXXIV. — *Further X-Ray Measurements of Long-chain Compounds and a Note on their Interpretation.*

By ALEX MÜLLER and GEORGE SHEARER.

IN two papers communicated to this Society, the authors (this vol. pp. 2043, 3152) have described the results of the measurements by X-ray methods of certain organic compounds which contain in their structure long carbon chains. It is proposed here to give some further results of such measurements and, in addition, to discuss all the results so far obtained.

In the papers referred to, it was shown that, in the case of the normal saturated fatty acids, and also in the case of the esters of these acids so far examined, the addition of a CH_2 group to the molecule resulted in an increase in the spacing of the cleavage plane as measured by the X-ray spectrometer. The fatty acids showed an increase of 2.0 Å. per CH_2 group added, whilst the esters increased by 1.22 Å. for a corresponding change in the molecular structure. Other compounds containing CH_2 chains showed similar phenomena.

On the other hand, in the case of the acids and the esters, there appeared on the plates two fairly strong lines the spacings of which (4.1 and 3.7 Å.) were, within narrow limits, the same for all these compounds. It was suggested that the planes giving rise to these reflections depended, not on the length, but merely on the cross-section of the molecules.

Before proceeding to a detailed discussion of these results, certain new data which are now available may be given.

Further Experimental Results.

In addition to the normal saturated fatty acids already described certain others whose total number of carbon atoms is odd have

now been measured; also certain unsaturated acids have been examined. For all the specimens used, the authors are once more indebted to the kindness of Mr. N. K. Adam. The results of these measurements are given in the following table :

Substance.	Formula.	d_1 .	d_2 .	d_3 .
Undecylic acid	$C_{11}H_{22}O_2$	25.8	—	—
Pentadecylic "	$C_{15}H_{32}O_2$	36.2	4.00	3.76
Margaric "	$C_{17}H_{34}O_2$	39.2	4.05	3.77
Oleic "	$C_{18}H_{34}O_2$	36.2 (?)	—	—
Elaidic "	$C_{18}H_{34}O_2$	48.3	4.03	3.65
isoOleic "	$C_{18}H_{34}O_2$	35.9	—	—
Erucic "	$C_{22}H_{44}O_2$	46.3	4.22	3.72
Brassicidic "	$C_{22}H_{44}O_2$	59.9	4.25	3.72

The bearing of these results on each other and on the previous results will be discussed later in this paper.

The Significance of X-Ray Measurements.

What is measured by the X-ray spectrometer is the perpendicular distance between two planes of the crystal which are identical with each other. It is clear, therefore, that, in general, the spacing of any one plane will have only a very indirect connexion with the dimensions of the molecule itself. It is only by a complete investigation of the crystal structure that the dimensions of the molecule can be determined. In the case of such complicated compounds as those under discussion, such a complete solution is, at present, out of the question.

However, it happens that in the case of these long-chain compounds there appears to be a very close connexion between the length of the molecule and the spacing of the cleavage plane. In both the acids and the esters it is found that the continued addition of CH_2 groups results in a uniform increase in the spacing of the cleavage planes, although the amount of this increase is different in the two series. The obvious conclusion is that in any one series the crystals are all of approximately the same type and that the molecules are arranged lengthwise between successive cleavage planes. The observed increase of spacing as the number of CH_2 groups in the chain is increased also shows that the purely chemical reasoning that the carbons are actually arranged in long chains is essentially correct.

It does not follow that the general direction of the length of the molecule is perpendicular to the cleavage plane, but, in order to explain the uniform increase of spacing of this plane per CH_2 group, it is necessary to conclude that for any one series the molecules are all inclined at the same angle to this plane.

A consideration of the spacings of the acids will show that there

is a strong probability that between two successive cleavage planes there must be not one molecule but two, probably arranged end to end in opposite directions. Such an arrangement is very common in crystal structure and is the result of the symmetry properties of the crystal (compare Bragg, T., 1922, **121**, 2766). This follows from our knowledge of the "diameter" of the carbon atom (1.5 Å.). Even if all the carbon atoms were placed one above the other, the length of the molecule would be considerably less than the observed spacing. This is even more clearly demonstrated if the spacings of the acids are compared with those of the esters. For an equal number of carbon atoms in the molecule the spacing of the esters is only a little larger than half that of the acids. For example, cetyl palmitate with 32 carbon atoms has a spacing only a little larger than that of stearic acid with 18 carbon atoms. Similar results were shown to hold for *p*-hexadecyl- and *p*-octadecylphenol and for octadecylbenzene.

It is therefore concluded that in the case of the acids we are dealing with two molecules placed end to end, and that the average increase per CH_2 group is 1.0 as compared with 1.22 in the ester series, where we are dealing with only one molecule between successive cleavage planes.*

The Structure of the Carbon Chains.

Let us, in the first place, assume that the molecules in all these compounds are, within narrow limits, arranged perpendicularly to the cleavage planes, and see whether the observed increase of length can be explained in terms of a reasonable arrangement of the carbon atoms in the chain.

It is well known that in the diamond structure each carbon atom is surrounded by four others and that the lines joining their centres make angles with each other which are the same as the angles between the normals from the centre of a regular tetrahedron on its faces ($109^\circ 28'$). Such a result might have been, and indeed was, anticipated by the quadrivalent property of the atom. It is therefore natural to assume that in these carbon chains the carbon atoms are so arranged that the lines joining the centres of adjacent atoms make this angle with each other. The question arises—What chains are possible which satisfy this condition and also have

* Langmuir (*Proc. Nat. Acad. Sci.*, 1917, **3**, 251), in his investigations of films on water, deduced for the lengths of the molecules values which for most of the acids are almost exactly half those found by the authors for the cleavage spacings, and values for the esters nearly equal to the X-ray spacings. These results are in agreement with the above hypothesis. He also showed that the carbon atoms in the chains must be arranged in some zig-zag fashion.

the property—observed experimentally—that the continued addition of a limited number of atoms to the chain always results in a uniform increase in the length of the chain?

There are several chain structures which satisfy these conditions.

(1) The longest possible chain is such that all the atoms are in one plane and are arranged in zig-zag fashion as in Fig. 1. If the diameter of the carbon atom is taken as 1.5 \AA. , this chain would show an increase of 1.22 \AA. per carbon atom.

FIG. 1.

FIG. 2.

FIG. 3.

(2) The second chain in order of length is obtained by arranging the carbon atoms in a spiral, the fourth being directly above the first, the seventh above the fourth and so on, as in Fig. 2. The increase per carbon is the same for each member of the chain and has the value 1.12 \AA.

(3) The third longest chain is shown in Fig. 3. In this the carbon atoms are arranged in sets of four, the fifth being directly above the first. Every two carbons contribute 2.0 to the length of the chain, but of this amount one of the pair contributes 1.5 and the other only 0.5 \AA. Each set of four lies in a plane, but the planes of successive sets are not necessarily the same.

These are the simplest possible chains which satisfy the conditions

laid down. Other arrangements are possible. For example, a chain may be made by combining the first and third of the above chains. Such a chain, however, although having a different arrangement in space, would show the same rate of increase of length as number (3). It is also possible to arrange the atoms in such a way that the sixth is above the first, the eleventh above the sixth, and so on, but in such a case the increase for the first set would be different from the increase for subsequent sets and such a chain would be inconsistent with the experimental results. It is interesting to note that the case of a closed ring of six atoms is the limiting case of a chain—a chain in which the average increase per carbon is zero.

In the diamond structure there are present, in addition to the closed rings, chains which show increases of 1.22 per carbon atom and 2.0 per two carbon atoms. The former is identical with that of Fig. 1; the arrangement of the latter is more complex than that of Fig. 3, although the increase in the direction of length is the same. The spiral arrangement is not shown by the diamond, although the silicon atoms in quartz form a spiral as in Fig. 2.

The two chains observed in these experiments show average increases of length per carbon of 1.22 and 1.0 for the esters and the acids respectively. These values agree extremely well with the first and third chains described above and it appears highly probable that the arrangements of the carbon atoms in these compounds are actually represented by Figs. 1 and 3. This striking agreement with experiment is in itself a very considerable argument in favour of the assumptions originally made, that the direction of length of the molecules is approximately perpendicular to the cleavage planes and that the carbon atoms tend to join together at the tetrahedral angle.

Other Possible Interpretations.

Certain other possibilities must also be considered. It is quite conceivable that, although the inclination of the molecules to the cleavage planes may be the same for any one series, it may not be the same for all the series. The observed difference between the acids and the esters may be due to a difference in the inclinations of the molecules in the two series.

There are certain experimental results which seem to indicate that this hypothesis is not valid and that there really exist two different chain arrangements. For example, the difference in spacing between methyl palmitate and methyl stearate is 2.0, and the difference between the ethyl esters of these acids has also this value. In this case, we have added two CH_2 groups to the

acid side of the molecule and the increase is the same as between palmitic and stearic acids and different from what would result from the addition of two groups to the ester side. If this could be shown to hold over a larger range, the argument would be a strong one in favour of the existence of two chains, but even with the limited observations so far available, considerations of the error limits of the experiments suggest that this test is of considerable value.

There is, however, still another possibility which might be suggested. The ester molecule may have a sharp bend at the $\text{CO}\cdot\text{O}\cdot$ group and thus, in itself, have two inclinations to the cleavage plane. If this were so, the argument in the previous paragraph would collapse. Such an arrangement appears improbable from the observations of the constancy of the spacings d_2 and d_3 .^{*} The constancy of these spacings in itself suggests that the inclination of the molecules to the cleavage plane is the same in the two series. If these spacings are taken as giving an indication of the other dimensions of the crystal cells—they might well be half the fundamental spacings of the other two planes—then the dog-legged molecule suggested above appears to be very improbable from a crystallographic point of view, as the projection of the molecule on the plane of d_2 and d_3 would be much greater than either side and therefore would extend over several cells. On the whole, therefore, this evidence supports the assumption of two different chains.

Again, if we consider Fig. 3, we see that, if this is an actual representation of the acid chain, an increase of two carbons results in an increase of 2.0 Å., but the two carbons do not contribute equally to this amount. If, therefore, the accuracy of the experiments were sufficient, there would be a difference between the acids containing an odd number of carbon atoms and those with an even number. This difference is almost within experimental error, but it is a significant fact that if the odd acids are plotted on a similar diagram to that used to represent the even-number acids the points representing them all lie just above the line showing the variation of the even-number acids. This evidence is directly in favour of such a chain as is shown in Fig. 3.

Let us now consider the unsaturated acids. There is, as is shown

^{*} In order to test the constancy of these spacings, which were represented in our photographs by somewhat diffuse lines, experiments with various acids were made by Dr. Piggott and Dr. Wark. A transmission method was used, and it was found that within the limits of experimental error d_2 and d_3 were the same for all the acids so examined. Our thanks are due to them for their assistance.

in the table, a very large difference between erucic and brassidic acid. Each contains twenty-two carbon atoms, the same number as behenic acid. Erucic acid shows a spacing just smaller than that of behenic acid, whilst the spacing of brassidic acid is 12 Å longer. The obvious suggestion would be that here we have two isomerides, the one with the one type of chain, the other with the other. The ratio of the spacings is 1.29, which certainly supports such a hypothesis. Again, the ratio of the spacings of elaidic and stearic acids is 1.25. These results in themselves might offer little support to the reality of the two chains, but, taken in conjunction with the other evidence, they are certainly suggestive.

On the whole, therefore, the balance of evidence appears to support the hypothesis of two different types of chain rather than the other possible explanations of the observed results which have been put forward here.

General Considerations.

It will have been noticed that, in what has preceded, sometimes it has been assumed that there is one molecule only between successive cleavage planes, and sometimes two have been postulated. This is more or less what is to be expected from chemical considerations. In the acids, we have at the ends of the molecule the active carboxyl group, and the presence of such a group may well tend to cause two of the molecules to join together end to end in the crystal cell. On the other hand, in the esters we have no such active group at the end of the molecule and in the case of these compounds there is no sign of the double spacing found in the acids. The presence of a benzene or phenol group also apparently facilitates the junction of two molecules end to end. Here again, this arrangement is probably due to the presence of the active group. Thus, so far as the experiments have gone, the general arrangements of the molecules in the cells are what might be expected from their chemical properties.

The difference between the acids containing an odd and an even number of carbon atoms is interesting. It is well known that similar differences are found in their melting points. Also the even-number acids are common in nature, whilst the odds are very rare. It would therefore appear that there is a stronger tendency to add two carbon atoms to the acid chain than only one.

It might appear at first sight that, if there are two different chains, we might expect to find a difference between the energy of the molecule according as it contains the one chain or the other. Measurements of the heat of decomposition show that practically the same increase takes place whether a CH_2 group is added to the

ester side or to the acid side. A consideration of the chains represented in Figs. 1 and 3 will show that the two chains are very approximately equally probable. They both involve the attachment of a fresh carbon atom to the existing chain at the tetrahedral angle. Thus, although the increase of length of the chain is different in the two cases, there would be little if any difference in the energy.

The unsaturated acids on the above hypothesis would have formulæ which might be represented as in Figs. 4 and 5, where the

arrangement of the carbons on either side of the unsaturated carbon atoms is shown. A comparison of these figures with the formulæ generally accepted for erucic and brassidic acids is interesting. These acids are usually written

the former as a "trans" the latter as a "cis" acid. A comparison of these formulæ with the arrangements represented in Figs. 4 and 5 shows a great similarity between the two, but they are interchanged, brassidic being the *trans*- and erucic the *cis*-acid. Similar results apply to elaidic acid. This appears to have the first type of chain and therefore would, on the above considerations, be a *trans*- and not a *cis*-compound. Whether this is compatible with the chemical evidence is a matter for the chemical expert.

The small difference between erucic and behenic acid—1.5 for two molecules—is probably to be associated with the so-called double-bonded carbon atoms. Some slight difference in the chain here from that of the normal saturated acids might explain the difference. Experiments are in progress with oleic acid, which is liquid at the ordinary temperature, and although the results are not yet conclusive, there is evidence that the length of this cell is 36.2, a value 2.5 less than that for the corresponding saturated acid—stearic acid. The difference of 2.8 Å. between *iso*oleic acid and stearic acid is of the same order of magnitude. *iso*Oleic acid,

however, does not show the same spacings d_2 and d_3 . It would appear, therefore, that there is some structural change, although the chain is essentially the same as in stearic acid.

If the interpretation of these experimental results is correct, we have fresh evidence that the tetrahedral angle is closely associated with the carbon atom, not only in such crystal structures as diamond, but also in actual molecular structures. It would appear that the tendency of one carbon atom to join to another is very strong in certain directions only and that these directions are closely connected with the directions of the normals from the centre of a regular tetrahedron on its four faces.

In conclusion, the authors wish to express their indebtedness to Professor Sir W. H. Bragg, F.R.S., for his many helpful suggestions during the course of the work.

CCCLXXV.—*The Influence of Dilution on the Hydrolytic Dissociation of some Oxime Hydrochlorides.*

By LEONARD BEAUMONT TANSLEY.

THE majority of the measurements of hydrolytic dissociation in the past have been made on salts which are hydrolysed only to a relatively small extent and Ostwald's dilution law, $K = x^2/(1-x)v$, holds for these within narrow limits. In certain cases weaker bases have been studied and in some instances good constants obtained at moderate dilutions (Walker and Aston, T., 1895, 67, 576; Walker and Wood, T., 1903, 83, 484; Farmer, T., 1904, 85, 1713; Arnall, T., 1920, 117, 835).

In the present paper, a study has been made of the hydrolysis of the hydrochlorides of a number of oximes, using the polarimetric method to determine the concentrations of free acid formed at dilutions ranging from $N/10$ to $N/160$ at 55.7°. With the exception of acetoxime hydrochloride in decinormal solution (Farmer, *Brit. Assoc. Reports*, 1901, 240), the salts formed by oximes with acids do not appear to have been previously studied.

On hydrolysis, these compounds yield products falling into two classes: (1) soluble oximes, (2) sparingly soluble oximes.

For substances in class 1 Ostwald's dilution law does not give a true constant when the salts are strongly hydrolysed, and deviations are obtained which are similar to those presented by the dissociation of strong electrolytes. Rudolphi's formula, $K = x^2/(1-x)\sqrt{v}$,

gave slightly better constancy. Several other empirical formulæ, proposed in the past, have been tried, but the best concordance is given by taking into account the possibility of some electrical action between the ions and the molecules of the solute (*a*) and between the ions themselves (*b*), Jahn's formula for this being $K = n_1^2 e^l / N - n_1$, where $l = -(aN/n) + n_1(2a - b)/n$ (*Z. physikal. Chem.*, 1902, **41**, 257). Goebel (*ibid.*, 1902, **42**, 59) put the constant in the form

$$K = \frac{C_2^2}{C - C_2} e^{2B_{12}C - 4(B_{12} - B_{22})C_1},$$

where B_{12} and B_{22} take the place of *a* and *b* above. For the present purpose this last formula has been used in the form

$$K = \frac{C_2^2}{C_1} e^{AC_1 + BC_2},$$

C_2 being the concentration value for the hydrolysed part of the molecule and C_1 that for the unhydrolysed portion, whilst *A* and *B* denote B_{12} and B_{22} respectively. To determine these constants, *A* and *B*, three sets of experimental values (marked * in Table III) of C_2 and C_1 were used for each substance. It is noteworthy that the constant values for *K* calculated by this method agree with those obtained by Ostwald's formula when this is applied at the highest dilutions only, as shown in the 3rd, 4th, and 5th columns of Table I. This is in accordance with the view that strong electrolytes in very dilute solutions do obey the law of mass action (Washburn, *J. Amer. Chem. Soc.*, 1918, **40**, 106). For purposes of comparison, urea nitrate was experimented with in the same way at higher dilutions than had been previously used for salts of this compound and gave results showing a similar divergence, from which, however, a dissociation constant could be calculated.

In the case (2) of sparingly soluble oximes, the old dilution law ceases to hold and calculation shows that the degree of hydrolysis is independent of the dilution; for, applying the law of mass action to the case of this simple hydrolytic dissociation of hydrochloride, we can write, denoting the concentration of oxime as base by [B], since no compound of the type B·OH is formed,

$$\frac{[B] \times [HA]}{[BA] \times [H \cdot OH]} = \text{constant.}$$

[B] itself, however, must be constant too, since the oxime is only sparingly soluble and the solution is always saturated with respect to it; also [H·OH] is constant, thus

$$\frac{\text{Concentration of hydrolysed salt}}{\text{Concentration of unhydrolysed salt}} = \frac{[HA]}{[BA]} = \frac{x}{v \cdot (1 - x)}$$

and therefore $x/(1 - x) = \text{constant}$.

TABLE I.

Hydrolytic Dissociation Constants of the Hydrochlorides of Oximes, Class I, and their Basic Constants.

Hydrochloride of the base (class I).	Vol. (v_2 litres) containing 1 equivalent of salt.	Hydrolytic dissociation constants.			Basic constants of the oximes. $K_b = K_w/K$.
		Ostwald.	Ostwald's extra-polated value.	Mean values. Goebel.	
Diethyl ketoxime	140	0.000632	0.000350	0.000349	2.95×10^{-10}
Methyl ethyl ketoxime .	160	0.00120	—	0.00126	8.13×10^{-11}
Methyl <i>n</i> -propyl ketoxime	120	0.00157	—	0.00156	6.57×10^{-11}
Acetoxime	120	0.00278	0.00200	0.00182	5.64×10^{-11}
Acetaldoxime	100	0.0461	0.0230	0.0211	4.86×10^{-12}
Diacetylmonoxime	100	0.293	—	0.2097	4.88×10^{-13}
		$(K_w = 1.025 \times 10^{-13})$			

This true value for K_w (= dissociation constant for water at 55.7°) was found by interpolation between those given by Lorenz and Böhi at intervals on the temperature scale, and its use is more satisfactory than that of the general value 1.2×10^{-14} often used.

This conclusion was exactly borne out by experimental results shown in Table IV and the values of the constants found are given in Table II.

TABLE II.

Degrees of Hydrolysis and Constants for Hydrochlorides of Sparingly Soluble Oximes.

EXPERIMENTAL.

In the determination of the degree of hydrolysis at each dilution, a freshly prepared 5 per cent. sucrose solution was mixed in a thermostat with the solution of the oxime hydrochloride, and the concentration of free acid found in the usual way by means of polarimetric readings. The polarimeter tube, fitted with false glass ends, was maintained at constant temperature by circulating water from the thermostat through a jacket surrounding it. The inversion velocity coefficients were calculated by two independent methods.

The degree of hydrolysis was found to be independent of the quantity of sucrose present, and titrations with caustic alkali and

congo-red, and with iodine, to detect any free hydroxylamine hydrochloride, proved that practically no decomposition of the oximes themselves occurred in the solutions during hydrolysis.

The following hydrochlorides were prepared in the pure solid state for the determinations: Benzophenoneoxime hydrochloride, m. p. 125°; acetophenoneoxime hydrochloride, m. p. 103°; benzylideneacetoxime hydrochloride, m. p. 146°; and the benzaldoxime hydrochloride, m. p. 63–65°, usually known as the *syn*-form, prepared by passage of carefully dried hydrogen chloride through a solution of the pure *anti*-oxime in dry ether. The last-mentioned hydrochloride has been shown to be a hydrate by Brady and Dunn (this vol., p. 1783). An *N*/5-suspension in water appears to be converted rapidly into the oily *anti*-oxime, but the *N*/20-suspension of the solid *syn*-oxime persists for eighteen hours, finally changing to the oil and partly dissolving at 56°. Both these specimens gave sensibly the same degrees of hydrolysis as were shown by the partly soluble *anti*-oxime in hydrochloric acid at various corresponding dilutions. In general, the results obtained with the solutions prepared from the solid hydrochlorides were almost identical with those found for solutions of the oximes in the equivalent quantities of hydrochloric acid. The determinations in the case of the aliphatic oximes were all made by the latter method.

As it could not be substantiated by the ordinary methods of titration that acetaldoxime does not decompose under the conditions employed, solutions of acetaldehyde and hydroxylamine hydrochloride were mixed and the extent of the reaction was followed in the polarimeter by measuring the increase in concentration of free acid until a stable condition was reached. This corresponded with the fullest formation of oxime hydrochloride, oxime and consequent free acid, and showed apparently no decomposition of the oxime itself. The concentration of free acid here was nearly thirty times greater than that given by an equivalent solution of hydroxylamine hydrochloride alone, which was confirmed as being practically non-hydrolysed under the conditions employed.

In the experimental results the product, for hydrochloric acid alone, of velocity coefficient and dilution, shown as k_1v_1 , which was found to be constant within very narrow limits for all concentrations up to *N*/100, has the value 0.442 in most cases, and at higher dilutions it is known to be constant (Fales and Morall, *J. Amer. Chem. Soc.*, 1922, 44, 2071).

Conductivity water was used throughout the experiments and also for making up the solution of hydrochloric acid used. Solid oxime suspensions were kept and shaken before being placed in the polarimeter tube, in which they settled, thus affording a clear view for accurate readings.

Summary.

(1) Ostwald's dilution law and the law of mass action are not followed by the hydrochlorides of the oximes examined, owing to the hydrolytic dissociation being, at the higher dilutions, far less than that required to satisfy the equation $K = x^2/(1-x)v$. This anomaly is not due to any appreciable decomposition of the oximes themselves and is precisely similar for the majority of them.

(2) The variations in the degrees of hydrolytic dissociation are analogous to those shown in the electrolytic dissociation of strong electrolytes. To the values obtained at various dilutions the application of a simplified formula based on those of Jahn and Nernst, $K = C_2^2 e^{A_1 + B_1 C_1} / C_1$, allows a true hydrolytic "dissociation constant," K , to be calculated in each case.

(3) The degrees of hydrolytic dissociation of the hydrochlorides of those oximes which are only partly soluble in water are independent of the concentration, owing to the presence of immiscible solid or liquid phase, and the formula $K = x/1-x$ is strictly borne out by experiment, the constant K including the solubility of the oxime.

The author wishes to express his gratitude to the Principal, Mr. S. Skinner, to the Head of the Chemical Department, Mr. J. B. Coleman, of this Institute, for the many facilities provided, and to Dr. J. C. Crocker for his unceasing interest. A grant from the Chemical Society for materials is also gratefully acknowledged.

CHELSEA POLYTECHNIC INSTITUTE, S.W. [Received, August 16th, 1923.]

CCCLXXVI.—*A Synthesis of m-Opianic Acid.*

By WILLIAM HENRY PERKIN, jun., and FRANCIS WILBERT STOYLE.

m-OPIANIC acid was first obtained as one of the products of the degradation of cryptopine in 1916 (T., 109, 928) and subsequently its synthesis was accomplished (T., 1921, 119, 1724) essentially in accordance with the scheme:

4:5-Dimethoxy-6-tolyl
methyl ketone.

4:5-Dimethoxyphthalonic acid.

m-Opianic acid.

During the course of experiments which had another object in view, we have worked out another synthesis of this interesting acid.

When *o*-veratric acid (I) is digested with strong aqueous hydrobromic acid, one only of the methoxy-groups is attacked and an acid is produced which may be represented either by formula (II) or (III).

Had the acid (III) been produced, then application of the Tiemann-Reimer reaction would have furnished an aldehydo-acid which should yield opianic acid on methylation and thus the synthesis of this important acid would have been accomplished. It was, however, more probable that the acid of formula (II), that is, *o*-vanillic acid (guaiacolicarboxylic acid), would result from the demethylation of *o*-veratric acid under the conditions employed and we have been able to show that this is what actually happens. In the first place, the acid resulting from this demethylation (m. p. 152°) gives a deep blue coloration with ferric chloride, which it would not do if it were a *m*-hydroxy-acid, and, secondly, the same acid (II) is obtained when *o*-vanillin is fused with potassium hydroxide.

On treatment with chloroform and potassium hydroxide, this acid is converted into 2-hydroxy-3-methoxy-5-aldehydobenzoic acid (IV) which, if it could be methylated, would give rise to a new isomeride (V) of the opianic acids.

Unfortunately the hydroxy-group in this acid resists methylation to such a remarkable degree that, with the small amount of material at our disposal, we have been unable, either with the aid of methyl sulphate or by employing methyl iodide and alkali, to obtain any of the dimethoxy-acid.

We next attempted to synthesise opianic acid from ordinary veratric acid (VI) by employing a process similar to that outlined above in the case of *o*-veratric acid. Tiemann (*Ber.*, 1875, 8, 514) has shown that veratric acid, when heated with dilute hydrochloric acid, yields a mixture of vanillic (VII) and *isovanillic* (VIII) acids.

We find, however, that, when the demethylation is carried out with the aid of hydrobromic acid, the sole product appears to be *isovanillic* acid.

It was hoped that the application of the Tiemann-Reimer reaction would convert *isovanillic* acid into the two isomeric aldehydo-acids (IX) and (X).

If this were the case, the acid (IX), on methylation with alkali and methyl sulphate, should yield *m*-opianic acid, whereas the acid (X) might be expected, in the same circumstances, to yield *ψ*-opianic acid (XI), an acid which, so far, has only been obtained by the degradation of berberal by means of dilute sulphuric acid (T., 1890, 57, 1064).

Experiment showed, unfortunately, that only one aldehydo-acid is produced when *o*-vanillic acid is digested with chloroform and potassium hydroxide, and that this acid is 5-hydroxy-4-methoxy-2-aldehydobenzonic acid (IX) is proved by the fact that, on methylation, it is converted into *m*-opianic acid. It is in this way that the second synthesis of *m*-opianic acid has been achieved.

The Action of Alcoholic Potassium Hydroxide on o-Veratraldehyde.

A method which gives a good yield of *o*-veratryl alcohol and *o*-veratric acid is the treatment of *o*-veratraldehyde with aqueous potassium hydroxide (Perkin and Robinson, T., 1914, 105, 2384). According to Douetteau (*Bull. Soc. chim.*, 1911, [iv], 9, 933), alcoholic potash gives the same products.

On repeating the latter process, a very unexpected result was obtained. When *o*-veratraldehyde was left for some hours at the ordinary temperature with strong ethyl alcoholic potassium hydroxide, an almost quantitative yield of *o*-veratryl alcohol was obtained. On acidifying the alkaline solution, instead of pure *o*-veratric acid, a mixture of acids was precipitated, and this, on fractional crystallisation, yielded *o*-veratric acid (m. p. 120°) and an acid, C₁₁H₁₂O₄, melting at 180°.

The detailed examination of the latter acid, described on p. 3174, has proved conclusively that it is 2:3-dimethoxycinnamic acid, C₆H₃(OMe)₂:CH:CH:CO₂H.

Not only is the formation of a cinnamic acid under these conditions remarkable, but the yield is considerable (4 grams from 20 grams of *o*-veratraldehyde). The probable explanation is that some of the ethyl alcohol is oxidised to aldehyde, which then,

under the alkaline conditions, condenses with the *o*-veratraldehyde to yield 2 : 3-dimethoxycinnamaldehyde,

and that this then suffers further oxidation with the formation of the cinnamic acid. We are engaged in determining whether this reaction is a general one, and a preliminary experiment seems to indicate that small quantities of cinnamic acid are produced when benzaldehyde is left in contact with ethyl-alcoholic potassium hydroxide.

EXPERIMENTAL.

Action of Alcoholic Potassium Hydroxide on o-Veratraldehyde. Formation of 2 : 3-Dimethoxycinnamic Acid.—In studying this change, *o*-veratraldehyde (20 grams), prepared by the methylation of pure *o*-vanillin in alkaline solution with methyl sulphate, was dissolved in ethyl alcohol (25 c.c. of 97 per cent.), added to a solution of potassium hydroxide (30 grams) in alcohol (75 c.c.), and kept at the ordinary temperature over-night. The yellow solution, mixed with an equal volume of water, was evaporated on the steam-bath until free from alcohol, the deep brown liquid extracted with benzene, and the extract dried and distilled, when *o*-veratryl alcohol (8.5 grams) passed over at 155–160°/17 mm. The hot aqueous alkaline layer gave, on acidifying with hydrochloric acid, a yellow precipitate, which was immediately collected by the aid of the pump; the hot filtrate deposited, on standing, a white, crystalline acid (3 grams) which proved to be almost pure *o*-veratric acid. The yellow precipitate was recrystallised from benzene, from which a colourless acid separated in glistening needles which melted at 180° (Found : C = 63.0; H = 6.0; *M*, by titration, = 205. $\text{C}_{11}\text{H}_{12}\text{O}_4$ requires C = 63.5; H = 5.8 per cent.; *M* = 208). The ethyl ester of this acid melted at 43° and the dibromide at 152° (compare Krannichfeldt, *Ber.*, 1913, 46, 4021) and, on oxidation with alkaline permanganate, the acid yielded *o*-veratric acid. There can therefore be no doubt that the acid of melting point 180° is 2 : 3-dimethoxycinnamic acid. The yield of the pure acid obtained in the above experiment was 4 grams.

o-Vanillic Acid and its Conversion into 2-Hydroxy-3-methoxy-5-aldehydobenzoic Acid.—The demethylation of *o*-veratric acid to *o*-vanillic acid (compare p. 3172) was brought about by boiling the former acid (20 grams) with hydrobromic acid (*d* 1.3; 20 c.c.) and water (20 c.c.) for three hours in a reflux apparatus. On diluting with water and allowing to stand for some hours, a colourless, crystalline mass was deposited which separated from benzene in needles melting at 152°. The aqueous solution gave, on the

addition of ferric chloride, a blue coloration, and the other properties showed that it is *o*-vanillic acid identical with the acid obtained by fusing *o*-vanillin with potassium hydroxide under the following conditions: Potassium hydroxide (200 grams), moistened with water (5 c.c.), was fused in a nickel crucible and to the just molten mass *o*-vanillin (20 grams) was gradually added during eight minutes with efficient stirring. The cold mass, dissolved in as little water as possible, was gradually acidified with hydrochloric acid, the whole being kept cold in a freezing mixture during the operation, as otherwise charring is apt to occur. The *o*-vanillic acid separated at first as an oil, but this rapidly crystallised and was collected; a further quantity was obtained by extracting the filtrate with ether. The whole was recrystallised from as little water as possible, from which the acid separated in needles containing 1 mol. of water (Found: C = 51.1; H = 5.3. $C_8H_8O_4 \cdot H_2O$ requires C = 51.5; H = 5.3 per cent.). The anhydrous acid separates from benzene in needles melting at 152°, which Fritzsche (*Annalen*, 1898, **301**, 354) also states is the melting point of *o*-vanillic acid (guaiacolcarboxylic acid).

2-Hydroxy-3-methoxy-5-aldehydobenzoic Acid (IV).—This acid is obtained in small yield when *o*-vanillic acid is subjected to the Tiemann-Reimer reaction. *o*-Vanillic acid (10 grams), chloroform (7.1 grams), and sodium hydroxide (11.9 grams) were heated together in a reflux apparatus on the steam-bath for five hours. The deep green liquid was rendered acid to Congo paper with hydrochloric acid, and the brown precipitate collected and washed with ether. It was then extracted with boiling water and the undissolved portion crystallised from acetone with the addition of animal charcoal. From the concentrated acetone solution crystals (1 gram) of *2-hydroxy-3-methoxy-5-aldehydobenzoic acid* separated, m. p. about 272° (Found: C = 54.8; H = 4.2. $C_9H_8O_5$ requires C = 55.1; H = 4.1 per cent.). The aqueous solution of the acid gives, with ferric chloride, a blue coloration and reduces ammoniacal silver solution. It is mentioned in the introduction that we were not successful with the small amount of material at our disposal, in converting the acid into *2:3*-dimethoxy-5-aldehydobenzoic acid.

5-Hydroxy-4-methoxy-2-aldehydobenzoic Acid and m-Opianic Acid.—The demethylation of veratric acid and its conversion into *iso*-vanillic acid were carried out under the following conditions.

Veratric acid (20 grams) was heated in a reflux apparatus with hydrobromic acid (*d* 1.3; 100 c.c.) and water (30 c.c.) for twenty-four hours, the product mixed with water, and the crystalline mass which separated was dried and extracted twice with boiling benzene,

which removed unchanged veratric acid and a little isovanillic acid. The residual isovanillic acid separated from water, in which it is sparingly soluble, in colourless plates melting at 250°. In order to convert the isovanillic acid into 5-hydroxy-4-methoxy-2-aldehydobenzoic acid, the pure acid (20 grams), dissolved in water (46 c.c.) and sodium hydroxide (23.8 grams), was boiled in a reflux apparatus, and chloroform (14.2 grams) gradually added. After five hours, the deep green liquid was made acid to Congo paper with hydrochloric acid, when a white precipitate separated which proved to be unchanged isovanillic acid. The filtrate from this was evaporated to dryness, the mass extracted with hot acetone, and the acetone extract evaporated, when an oil remained which solidified to a yellowish-green mass. After repeated recrystallisation from water, a colourless, sandy, crystalline powder was obtained which contained 1 mol. of water of crystallisation (Found: C = 51.1; H = 4.7. $C_9H_8O_5 \cdot H_2O$ requires C = 50.5; H = 4.7 per cent.). The water of crystallisation is lost at 100° and the anhydrous acid melts at about 178°.

m-Opianic Acid.—The methylation of 5-hydroxy-4-methoxy-2-aldehydobenzoic acid was carried out by adding the acid (1 mol.) to sodium methoxide (2 mols.) and heating with excess of methyl iodide at 100° in a bottle immersed in boiling water. Water was added, the methyl alcohol removed by evaporation, the solution acidified with hydrochloric acid, extracted several times with ether, and the ethereal solution washed with thiosulphate to remove iodine. After distilling off the ether, a brown syrup remained which only partly crystallised, but, after hydrolysis with methyl alcoholic potassium hydroxide and acidifying, a sandy powder separated which after crystallisation from water melted at 183–184° and proved to be *m*-opianic acid.

The identity was confirmed by conversion into the phenylhydrazone, which melted at 228° and had the characteristic properties observed by Fargher and Perkin (T., 1921, **119**, 1743).

One of us (F.W.S.) desires to thank the Advisory Council of the Department of Scientific and Industrial Research for a grant which has enabled him to take part in this research.

[Received, November 1st, 1923.]

CCCLXXVII.—*The Condensation of Aromatic Amino-sulphonic Acids with isocyanic Acid, Phenyl-carbimide, and Cyanamide.*

By JOHN RICHARD SCOTT and JULIUS BEREND COHEN.

IN the condensation of para-substituted aniline-*o*-sulphonic acids (I) with *isocyanic acid*, which was the subject of a previous communication (T., 1922, 121, 2034), it was shown that, when X = H, CH₃, or SO₃H, the product is a carbamido-acid (II), and when X = Cl, Br, or I, the product is a biuret derivative (III).

Since the formation of a biuret derivative by the condensation of an amino-acid with *isocyanic acid* has apparently not been observed previously, it was thought of interest to determine the conditions which bring about this reaction. The following influencing factors have been investigated:

(i) The nature of the atom or group X. In addition to the para-substituted aniline-*o*-sulphonic acids (I) previously investigated (*loc. cit.*), some other acids of this type have now been examined.

When X = CO₂H (*p*-amino-*m*-sulphobenzoic acid), the product is an apparently homogeneous substance, which, however, consists of the unchanged amino-acid mixed with a small amount of a condensation product the nature of which could not be determined, as it could not be isolated. *p*-Amino-*m*-sulphobenzoic acid was therefore converted into its ethyl ester (X = CO₂Et), but on treating this with *isocyanic acid*, no condensation appeared to take place, as the ester was recovered unchanged.

When X = NH₂ (*p*-phenylenediaminesulphonic acid), the product was a mono-carbamido-compound, which might be repre-

sented by formula IV or V. An attempt was made to determine the constitution by replacing the amino-group by bromine, and

identifying the resulting bromo-acid, since both isomerides of the latter have been prepared. Although a little bromo-acid was apparently formed, it could not be isolated in sufficient quantity for its identification.

(ii) The position of the atom or group X; as apparently the presence of a halogen atom is necessary in order to bring about condensation with two molecules of *isocyanic acid*, the succeeding experiments were confined to halogen derivatives.

5-Chloroaniline-*o*-sulphonic acid (VI) combines with one molecule of *isocyanic acid*, giving a carbamido-compound, whereas the corresponding *p*-chloro-acid (VII) gives a biuret derivative (Scott and Cohen, *loc. cit.*).

(iii) The position of the sulphonic acid group. *p*-Bromoaniline-*m*-sulphonic acid (VIII), unlike the *o*-acid (IX), gives a carbamido-compound; *o*-bromoaniline-*p*-sulphonic acid (X), however, gives a biuret derivative. It is therefore evident that if the ortho- and

para-positions to the amino-group are filled, a biuret compound will be formed by the action of *isocyanic acid*, irrespective of whether the halogen occupies the para-position and the sulphonic acid group the ortho-position, or *vice versa*; if, however, one of the substituents is moved to the meta-position, the condensation product will be a carbamido-compound.

(iv) The nature of the acid group. 5-Bromoanthranilic acid (XI) gives a carbamido-compound, whereas the corresponding sulphonic acid (IX) gives a biuret derivative.

Experiments were also made to determine whether those sulphonic acids which condense with 2 mols. of *isocyanic acid* would also condense with 2 mols. of its derivatives, phenylcarbimide and cyanamide. It was found that the latter do not resemble *isocyanic acid* in this respect, since the condensation of *p*-chloro- and *p*-bromo-aniline-*o*-sulphonic acids (and also of *p*-toluidine-*m*-sulphonic acid) with cyanamide gives derivatives of phenylguanidine (XII), and the potassium salts of *p*-bromoaniline-*o*-

sulphonic acid and *p*-toluidine-*m*-sulphonic acid give, by the action of phenylcarbimide, phenylcarbamido-derivatives (XIII).

Summarising the above results, we may say that, of the amino-acids so far examined, the only ones which condense with 2 mols. of isocyanic acid to give biuret derivatives are those of the type XIV, where A is a sulphonic acid group and B a halogen atom, or *vice versa*; these acids, however, do not condense with 2 mols. of cyanamide or of phenylcarbimide.

Incidentally, it has been found that the sulphonation of para-substituted acetanilides affords a more convenient means of preparing certain para-substituted aniline-*o*-sulphonic acids than the methods described in the literature. In the preparation of *p*-toluidine-*m*-sulphonic acid by the sulphonation of *p*-toluidine (von Pechmann, *Annalen*, 1874, 173, 195), a troublesome fractional crystallisation is necessary to separate the meta-acid from the accompanying ortho-acid, and the final yield is only 20 per cent. By the sulphonation of aceto-*p*-toluidide, however, only *p*-toluidine-*m*-sulphonic acid is formed, and the yield is about 50 per cent. Kreis (*Annalen*, 1895, 286, 381) obtained *p*-bromoaniline-*o*-sulphonic acid by the sulphonation of *p*-bromoacetanilide; *p*-chloroacetanilide has been found similarly to give a good yield of *p*-chloroaniline-*o*-sulphonic acid. *p*-Amino-*m*-sulphobenzoic acid, originally obtained by the action of ammonia on *p*-bromo-*m*-sulphobenzoic acid, is readily prepared by the sulphonation of *p*-acetylaminobenzoic acid. It is interesting to note that the action of sulphuric acid on *p*-aminobenzoic acid does not give the corresponding sulphonic acid, but the sulphone (XV) (Michael and Norton, *Ber.*, 1877, 10, 580). *o*-Bromoaniline-*p*-sulphonic acid (XVII) has also been prepared by the sulphonation of *o*-bromoacetanilide.

It will be noticed that in all these sulphonations of acetylaminocompounds, the product has the sulphonic acid group in the ortho-

or para-position to the amino-group, whereas in the sulphonation of the corresponding amino-compounds the sulphonic acid group enters mainly or entirely the ortho- or para-position to the halogen, and in the case of *p*-toluidine enters partly ortho to the methyl- and partly ortho to the amino-group (von Pechmann, *loc. cit.*); this is shown by the fact that *p*-chloro- and *p*-bromo-anilines give mainly the *m*-sulphonic acids (Armstrong and Briggs, P., 1892, 8, 40; Claus and Mann, *Annalen*, 1891, 265, 94), whilst *o*-bromo-aniline gives 6-bromoaniline-*m*-sulphonic acid (XVII) (Augustin and Post, *Ber.*, 1875, 8, 1560; Andrews, *Ber.*, 1880, 13, 2126). These facts suggest that the acetylamino-group has a more powerful ortho-para-directing influence than the amino-group.

EXPERIMENTAL.

p-Amino-*m*-sulphobenzoic Acid.—This acid has apparently only been prepared previously by heating *p*-bromo-*m*-sulphobenzoic acid with ammonia in a sealed tube (Fischer, *Ber.*, 1891, 24, 3801; van Dorssen, *Rec. trav. chim.*, 1910, 29, 374); as this method is inconvenient for preparing the acid in quantity, the sulphonation of *p*-acetylaminobenzoic acid was investigated, and found to be a satisfactory method for preparing *p*-amino-*m*-sulphobenzoic acid.

p-Acetylaminobenzoic acid was obtained in 65 per cent. yield by the method of Kaiser (*Ber.*, 1885, 18, 2942), who, however, gives the yield as 50 per cent. Forty grams of the acid were mixed with 35 grams of fuming sulphuric acid (*d* 1.880, containing 10 per cent. of SO₃) and the resulting mass was heated in a basin on a sand-bath. At 140°, effervescence (due to the evolution of acetic acid) commenced, and proceeded rapidly at 170°; after keeping at this temperature for a short time, the mass became almost solid, and, to avoid charring, the heating was continued in an oven (170°) until the mass was quite dry. It was then dissolved in 1500 c.c. of hot water, neutralised with barium carbonate, filtered, and the barium precipitated from the filtrate by sulphuric acid. The solution of the free acid, after decoloration with animal charcoal, was cooled, when a portion of the sulphonic acid separated in small, glistening plates; the greater part of the acid was obtained by concentrating the mother-liquors. The first crop evidently contained a little *p*-acetylaminobenzoic acid, as it softened at 250° (the melting point of the latter compound); it was therefore recrystallised from hot water. The total yield was 26 grams (= 55 per cent. of the theoretical); the purity of the product was proved by analysis [Found: 0.1512 gram neutralised 11.52 c.c. of 0.119*N* sodium hydroxide. Calc. for C₇H₅O₃NS (dibasic), 11.65 c.c.]

The position of the sulphonic acid group follows from the rules of substitution, as both the carboxyl and acetyl-amino- (or amino-) groups tend to produce substitution in the meta-position to the carboxyl group; it is confirmed by the fact that the acid, like that obtained by Fischer and van Dorssen, crystallises in anhydrous, glistening plates, whereas *p*-amino-*o*-sulphobenzoic acid forms monohydrated needles.

The aniline salt of *p*-amino-*m*-sulphobenzoic acid is prepared by adding aniline to a suspension of the acid in a little hot alcohol; on cooling the clear solution thus formed, the salt separates in colourless, prismatic needles. After recrystallisation from alcohol, in which it is readily soluble, it melts with vigorous effervescence at 228–229°, at the same time turning yellow.

Action of Potassium Cyanate on p-Amino-m-sulphobenzoic Acid.—By the action of 2 or 4 mols. of potassium cyanate on *p*-amino-*m*-sulphobenzoic acid, the former is decomposed, yielding the potassium salt of the sulphonic acid and possibly a small amount of a carbamido- or biuret derivative, which was difficult to isolate and too small in amount to investigate further.

Ethyl p-Amino-m-sulphobenzoate.—Seven grams of *p*-amino-*m*-sulphobenzoic acid were boiled under reflux for ten hours with 150 c.c. of alcohol (dried over sodium) containing 6 grams of hydrogen chloride; the sulphonic acid did not pass into solution, as the ester, like the free acid, is practically insoluble in alcohol. After the reaction mixture had been cooled, the crude ester was filtered off and recrystallised from hot water. The yield of pure ester was 4 grams (= 50 per cent. of the theoretical). It crystallises from water, in which it is sparingly soluble, in anhydrous, thin, glistening plates, which turn orange-red and decompose with vigorous effervescence at 263° (Found: N = 5.95. $C_9H_{11}O_5NS$ requires N = 5.71 per cent. 0.2130 Gram neutralised 7.47 c.c. of 0.1196N-sodium hydroxide. Calc. for monobasic acid, 7.27 c.c.). It was assumed to be a carboxylic ester by analogy with the sulphobenzoic acids, all three of which give carboxylic esters on esterification by the Fischer-Speier method. By the action of potassium cyanate in the usual way, the ester was recovered unchanged.

Condensation of p-Phenylenediaminesulphonic Acid with isocyanic Acid.—Forty-nine grams (1 mol.) of *p*-phenylenediaminesulphonic acid (D.R.-P. 64908), 42 grams of potassium cyanate (2 mols.), and 26 c.c. of hydrochloric acid (1 mol.) were mixed with 390 c.c. of water and the solution was evaporated as far as possible on the water-bath. The residue consisted of a purple, viscous mass which showed no tendency to crystallise on cooling; it could not be crystallised from water, and on adding alcohol to an aqueous

solution the substance separated as a viscous liquid. The whole was therefore heated with 170 c.c. of hydrochloric acid, when it mostly dissolved, but after a short time a solid began to separate. The heating was continued for thirty minutes and the mixture then kept over-night. The resulting pasty mass was filtered and the solid recrystallised from 160 c.c. of boiling water, with the addition of animal charcoal. Crude *p*-aminophenylcarbamide-*m*-(or *o*)-sulphonic acid was thus obtained as minute, pale violet plates; for analysis, it was recrystallised from water. *p*-Amino-phenylcarbamide-*m*-(or *o*)-sulphonic acid forms minute plates having a slightly violet colour, probably due to impurity. It is anhydrous, and decomposes at about 274° to a bulky froth which gradually acquires a deep purple colour (Found: N = 17.82. $C_7H_9O_4N_2S$ requires N = 18.18 per cent. 0.2035 Gram neutralised 10.45 c.c. of 0.0856*N*-sodium hydroxide. Calc. for monobasic acid, 10.30 c.c.). Unlike all the other carbamidodisulphonic acids yet examined, it is rather sparingly soluble in water.

To examine the action of nitrous acid on this substance, it was dissolved in dilute sodium hydroxide solution, and sodium nitrite (1 mol.) added. On acidifying the solution with hydrochloric acid, a yellow coloration was produced, and soon crystals began to separate, but there was no evolution of nitrogen. After standing for fifteen minutes, the crystals were filtered off, washed, and dried. This substance forms yellow, thin, glistening flakes, practically insoluble in water, and decomposing, without melting, to a dark brown mass at 171—173°. As it gives a red azo-colour with alkaline β -naphthol, it is presumably a diazo-compound; it is quite different in crystalline form from the diazo-compound produced from *p*-phenylenediaminesulphonic acid.

In order to replace the diazonium group by bromine, the substance was suspended in warm water and added to warm cuprous bromide solution. Nitrogen was evolved and the substance soon passed into solution. The liquid was acidified with hydrochloric acid, and the copper precipitated by hydrogen sulphide. The filtered solution was evaporated to small bulk and treated with an equal volume of hydrochloric acid. The crystals which separated consisted of sodium bromide and contained no organic matter. The filtrate from this, on further evaporation, gave a little solid substance which decomposed to a violet, frothy mass at about 260°. This may therefore have contained a *p*-bromophenylcarbamidesulphonic acid, but the amount was too small to permit of its separation from the inorganic matter.

Action of Aniline on p-Aminophenylcarbamide-*m* (or *o*)-sulphonic Acid.—A mixture of 1 gram of the acid and 1 gram of aniline was

heated to 160° , when it liquefied, and then, after about five minutes, resolidified to a stiff paste. After heating for a further ten minutes, the mass was cooled, ground with ether to remove excess of aniline, and the solid boiled with 50 c.c. of dilute sodium hydroxide solution. The insoluble residue was recrystallised from alcohol, with the addition of animal charcoal. It then formed small, colourless prisms and was identified as *s*-diphenylcarbamide; it melted at 236.0 – 236.5° , and at 236 – 237° when mixed with an authentic specimen (m. p. 237.0 – 237.5°). The presence of a carbamido-group in the product of condensation of *p*-phenylenediamine-sulphonic acid and isocyanic acid is thus proved, since it has been shown (T., 1922, 121, 2035) that carbamido-sulphonic acids give *s*-diphenylcarbamide by heating with excess of aniline, whereas biuret derivatives give *s*-diphenylbiuret.

When the crude *p*-aminophenylcarbamide-*m* (or *o*)-sulphonic acid was added to boiling 60 per cent. hydrochloric acid it dissolved, but almost immediately a crystalline solid began to separate. After cooling, this was filtered off and dried in air. This substance forms thick, square plates, decomposing at 270° to a dark mass; it is apparently a hydrochloride of the carbamido-acid, since by the action of silver nitrate in dilute nitric acid solution, silver chloride is precipitated (the chlorine was estimated in this way) (Found: Cl = 7.32. $2C_7H_5O_4N_3S \cdot HCl$ requires Cl = 7.12 per cent. 0.3266 Gram neutralised 16.62 c.c. of 0.1184*N*-sodium hydroxide. Calc. for tribasic acid, 16.60 c.c.).

Condensation of 5-Chloroaniline-o-sulphonic Acid with isoCyanic Acid.—Eight grams (1 mol.) of 5-chloroaniline-*o*-sulphonic acid (Claus and Bopp, *Annalen*, 1891, 265, 105) and 4.8 grams of potassium cyanate (1.5 mols.) were mixed with 70 c.c. of water; 2 c.c. of hydrochloric acid (0.5 mol.) were added and the mixture was evaporated to dryness. The residue was recrystallised by boiling with 30 c.c. of alcohol and adding hot water until solution was complete. The filtered liquid, on standing over-night, deposited a little solid matter, and a further quantity was obtained by concentrating the mother-liquors. The whole of the solid was dissolved in 10 c.c. of hot water and after the addition of 20 c.c. of hydrochloric acid the mixture was evaporated to a pasty consistency and then cooled and filtered. The solid, after drying on a porous plate, was heated with 15 c.c. of water; some insoluble matter was filtered off and the filtrate cooled, when a little amorphous solid separated. The filtered solution was treated with an equal volume of hydrochloric acid; the crystals of potassium chloride, which separated on standing, were filtered off and the filtrate was concentrated and allowed to stand in an open vessel,

when minute nodules, mixed with potassium chloride, slowly separated. This mixture was dissolved in 3 c.c. of boiling water and the solution filtered and cooled, when a mass of minute plates separated; these were filtered off and dried in air. As this product contained potassium and was neutral to litmus, it was evidently the potassium salt of the condensation product. *Potassium 5-chlorophenylcarbamide-o-sulphonate* was thus obtained as minute, colourless plates, decomposing at 285° (Found: in air-dried material, $H_2O = 5.32$; in material dried at 130° , $N = 9.52$. $C_7H_6O_4N_2ClSK \cdot H_2O$ requires $H_2O = 5.87$. $C_7H_6O_4N_2ClSK$ requires $N = 9.71$ per cent.). It is readily soluble in water, and when treated with sodium nitrite in acid solution gives nitrogen and a diazonium salt.

Condensation of p-Bromoaniline-m-sulphonic Acid with isoCyanic Acid.—Five grams (1 mol.) of *p*-bromoaniline-*m*-sulphonic acid (Kreis, *Annalen*, 1895, **286**, 377), 2.4 grams of potassium cyanate (1.5 mols.), and 1 c.c. of hydrochloric acid (0.5 mol.) were dissolved in 40 c.c. of water and the solution was evaporated to dryness. The residue was dissolved in a little boiling water, and the pasty solid, which separated on cooling and standing, filtered off, dried on a porous plate, and dissolved in a little hot water. The filtered solution was treated with twice its volume of hydrochloric acid, boiled for a minute, and cooled, when *p*-bromophenylcarbamide-*m*-sulphonic acid separated in granular crystals. It was recrystallised twice by dissolving in hot water, adding an equal volume of hydrochloric acid, and cooling. *p-Bromophenylcarbamide-m-sulphonic acid* then separated in anhydrous, colourless, rhombic plates, decomposing at 265 – 268° (Found: $N = 9.16$. $C_7H_6O_4N_2BrS$ requires $N = 9.49$ per cent. 0.3015 Gram neutralised 12.15 c.c. of 0.0856*N*-sodium hydroxide. Calc. for monobasic acid, 11.95 c.c.). It is very soluble in water, and is decomposed by nitrous acid, giving nitrogen and a diazonium salt.

o-Bromoaniline-p-sulphonic Acid.—This acid, which has not been previously described, was obtained by the sulphonation of *o*-bromoacetanilide. *o*-Nitrobromobenzene (Ullmann, *Ber.*, 1896, **29**, 1880) was reduced to *o*-bromoaniline according to Dobbie and Marsden (*T.*, 1898, **73**, 254), and the product acetylated with acetic anhydride. Twenty-two grams of *o*-bromoacetanilide were sulphonated with 11 grams of fuming sulphuric acid (*d* 1.880), the same method being used as in the preparation of *p*-toluidine-*m*-sulphonic acid from aceto-*p*-toluidide (p. 3190). The sulphonation took place more rapidly than with the latter substance, and after completing the reaction in an air-oven, the resulting dark-coloured, hard mass was broken up and dissolved in a hot solution of 12 grams of

anhydrous sodium carbonate in 150 c.c. of water. The solution was boiled with animal charcoal, filtered, and acidified with 35 c.c. of hydrochloric acid. On cooling, the sulphonic acid separated as a thick mass of hair-like needles; a further quantity was obtained by concentrating the mother-liquors. The yield (after drying in a vacuum) was 19 grams (= 74 per cent. of the theoretical); for analysis, a portion was recrystallised from hot water.

o-Bromoaniline-*p*-sulphonic acid crystallises in felted masses of colourless, hair-like needles, which are anhydrous [Found: 0.3362 gram neutralised 11.21 c.c. of 0.1184*N*-sodium hydroxide. Calc. for $C_6H_4O_3NBrS$ (monobasic), 11.25 c.c.]. It is sparingly soluble in cold and moderately soluble in hot water, and does not melt or decompose below 300°.

The position of the sulphonic acid group was determined by boiling 0.5 gram of the acid with 0.75 gram of zinc dust and 10 c.c. of 5 per cent. sodium hydroxide solution for twelve hours. The solution was then filtered and acidified with hydrochloric acid. The sulphanilic acid that separated on cooling was identified by comparison with an authentic specimen (efflorescent, rhombic plates: colour reaction with dilute sulphuric acid and manganese dioxide, reddish-violet, changing to violet-brown on boiling; metanilic acid gave a purplish-brown colour changing to dull brown on boiling, and aniline-*o*-sulphonic acid gave a yellowish-green colour changing to brown).

The aniline salt of *o*-bromoaniline-*p*-sulphonic acid was prepared by heating the acid with aniline and alcohol; on cooling the clear solution thus obtained, the salt separated in prisms which, after recrystallisation from alcohol, melted at 221° to a brown liquid which gradually acquired a purple colour.

Condensation of o-Bromoaniline-*p*-sulphonic Acid with *isocyanic* Acid.—Sixteen grams of the sulphonic acid (1 mol.), 7.6 grams of potassium cyanate (1.5 mols.), and 3.2 c.c. of hydrochloric acid (0.5 mol.) were together dissolved in 120 c.c. of water, and the resulting clear solution was evaporated to dryness. The residue was dissolved in sufficient boiling water to make 30 c.c. of solution, which was filtered hot and kept over-night. The white, pasty substance which separated was filtered off, dried on a porous plate, and dissolved in 25 c.c. of hot water. After the addition of 50 c.c. of hydrochloric acid and bringing to the boiling point, the mixture was allowed to cool, when glistening plates of *o*-bromophenylbiuret-*p*-sulphonic acid first separated (A). These were filtered off while the liquid was still hot, and on further cooling the filtrate, a mass of very fine needles separated. The latter was filtered off, dried in a vacuum to remove hydrochloric acid, and recrystallised from

40 c.c. of hot water. The product then formed hair-like needles and was identified as *o*-bromoaniline-*p*-sulphonic acid by means of its aniline salt, which formed colourless prisms, m. p. 222°, and melting at 221° when mixed with an authentic specimen. On treating the mother-liquor from this acid with an equal volume of hydrochloric acid and keeping it over-night, a further quantity of *o*-bromophenyl-biuret-*p*-sulphonic acid separated; this, however, was not mixed with the main fraction, as it contained some of the amino-acid, which could not be removed by recrystallisation.

The first crop of the biuret derivative (A) weighed 1.7 grams; it dissolved readily in 10 c.c. of cold water, and on adding 10 c.c. of hydrochloric acid the substance again separated in thin, glistening plates, which were recrystallised twice from boiling, dilute hydrochloric acid (2 vols. of acid to 1 of water).

o-Bromophenylbiuret-*p*-sulphonic acid was thus obtained in glistening, elongated laminae, decomposing to a frothy mass at 229–231°. The product purified as described above still showed a rather high nitrogen content, but the amount of substance remaining was insufficient to permit of further purification (Found: in material dried over sulphuric acid, $H_2O = 10.07$; in material dried at 140°, $N = 13.05$. $C_9H_5O_5N_3BrS \cdot 2H_2O$ requires $H_2O = 9.63$. $C_9H_5O_5N_3BrS$ requires $N = 12.43$ per cent. 0.1476 Gram of the hydrated substance neutralised 3.33 c.c. of 0.1184*N*-sodium hydroxide. Calc. for monobasic acid, 3.33 c.c.). This acid is readily soluble in cold water, and shows the characteristic behaviour of a biuret derivative towards nitrous acid. The latter reagent produces no evolution of nitrogen, and the subsequent addition of alkaline β -naphthol gave only a pale orange-yellow coloration (compare the action of nitrous acid on potassium *p*-bromophenylbiuret-*o*-sulphonate, and on *as*-phenylbiuret, Scott and Cohen, T., 1922, 121, 2045, 2051).

On adding aniline to a hot, concentrated, alcoholic solution of the acid and cooling, no crystals separated, but on adding excess of chloroform, an amorphous solid was precipitated. This was filtered off, washed with chloroform, and dried in a vacuum. The product, which was presumably the aniline salt, was a white powder, melting with decomposition at 184–186°.

Condensation of 5-Bromoanthranilic Acid with isoCyanic Acid.—Two grams (1 mol.) of 5-bromoanthranilic acid (Alt, Ber., 1889, 22, 1645) were dissolved in a hot mixture of 25 c.c. of water and 4 c.c. of hydrochloric acid (4 mols.). On adding 3.2 grams of solid potassium cyanate (4 mols.) a vigorous effervescence took place, and a little amorphous solid matter separated. The filtered solution was cooled and acidified with hydrochloric acid, which threw

down a yellow precipitate of 5-bromo-*o*-carbamidobenzoic acid mixed with some unchanged amino-acid. To remove the latter, the precipitate was dissolved in a little warm, aqueous sodium carbonate, and the solution, after filtering, acidified with excess of dilute hydrochloric acid; the carbamido-acid was reprecipitated, while the amino-acid remained in solution as the hydrochloride. The precipitated acid was dissolved in hot, dilute alcohol; on cooling the solution, a small quantity of flocculent crystals first separated. These were filtered off and, on further cooling the filtrate, the pure carbamido-acid separated in clusters of small prisms.

5-Bromo-*o*-carbamidobenzoic acid forms small, pale buff prisms, which are anhydrous (Found: N = 10.92. $C_8H_5O_3N_2Br$ requires N = 10.81 per cent.). It is sparingly soluble in water, but readily soluble in alcohol, and decomposes at 182.5°. The *hydantoin* was prepared by evaporating to dryness on the water-bath a mixture of 1 gram of the carbamido-acid, 14 c.c. of hydrochloric acid, and 6 c.c. of water. The residue was heated with 20 c.c. of 50 per cent. alcohol to remove any unchanged acid, and the insoluble *hydantoin* filtered off and dried in a vacuum (Found: N = 11.58. $C_8H_5O_3N_2Br$ requires N = 11.62 per cent.). It is a cream-coloured powder, insoluble in water and sparingly soluble in alcohol.

Condensation of p-Bromoaniline-o-sulphonic Acid with Cyanamide.—A mixture of 20 grams (1 mol.) of *p*-bromoaniline-*o*-sulphonic acid (I., 1922, 121, 2043), 13.75 grams of sodium cyanamide (2 mols.), 24 c.c. of hydrochloric acid (3 mols.), and 200 c.c. of water was heated on the water-bath, when a clear solution was soon obtained; after a short time, a bulky mass of fine needles separated and the mixture acquired a pale green colour. It was evaporated to dryness, the residue boiled with 500 c.c. of water, and filtered hot. The greater part of the product remained undissolved and consisted of crude *p*-bromophenylguanidine-*o*-sulphonic acid. A portion of it was recrystallised from a very large volume of boiling water with the addition of animal charcoal; on cooling, the pure acid separated in fine, colourless needles.

p-Bromophenylguanidine-*o*-sulphonic acid forms colourless, long, hair-like needles, which do not melt or decompose below 300° (Found: in material dried over sulphuric acid, H_2O = 5.77, 5.79; in material dried at 140°, C = 28.39; H = 2.79; N = 14.35. $C_8H_5O_3N_3BrS \cdot H_2O$ requires H_2O = 5.77. $C_8H_5O_3N_3BrS$ requires C = 28.57; H = 2.72; N = 14.28 per cent.). This acid is sparingly soluble in water (giving a neutral solution) and in glacial acetic acid, but practically insoluble in alcohol or acetone; it dissolves in sodium hydroxide, but not in sodium carbonate solution.

The *potassium* salt was prepared by treating the acid with sufficient boiling, aqueous potassium hydroxide (8 per cent.) to give a clear solution; on cooling, the salt separated in glistening, flattened needles or elongated plates. It was filtered off, washed with alcohol, and dried over sulphuric acid (Found: K = 11.44, $C_7H_7O_3N_3BrSK$ requires K = 11.75 per cent.). Except in the presence of excess of alkali, this salt is hydrolysed by water, the free acid being precipitated in fine needles.

Condensation of p-Chloroaniline-o-sulphonic Acid with Cyanamide.

—This was carried out in the same way as for the bromo-acid (see above), using 4.4 grams of *p*-chloroaniline-*o*-sulphonic acid (prepared as described on p. 3190), 3.4 grams of sodium cyanamide, 6 c.c. of hydrochloric acid, and 40 c.c. of water. The product obtained by recrystallisation from water, however, proved to be impure (Found: in material dried at 135°, N = 18.05, 18.11 per cent.). It was therefore converted into the potassium salt (as in the preparation of potassium *p*-bromophenylguanidine-*o*-sulphonate described above), which was dissolved in a large volume of hot water, and the solution acidified with dilute hydrochloric acid. On cooling, the pure sulphonic acid crystallised out.

p-Chlorophenylguanidine-*o*-sulphonic acid was thus obtained as fine, colourless needles, remaining unchanged below 300° (Found: in material dried over sulphuric acid, H_2O = 6.64, 6.78; in material dried at 135°, N = 16.46. $C_7H_8O_3N_3ClS \cdot H_2O$ requires H_2O = 6.73. $C_7H_8O_3N_3ClS$ requires N = 16.83 per cent.). Its properties resemble those of the corresponding bromo-acid, but it is more soluble in water than the latter. The *potassium* salt forms rectangular or octagonal plates, and is dissociated by water with liberation of the free acid.

Condensation of p-Toluidine-m-sulphonic Acid with Cyanamide.

—A mixture of 9.75 grams (1 mol.) of *p*-toluidine-*m*-sulphonic acid (p. 3190), 8.6 grams of sodium cyanamide (2 mols.), 15 c.c. of hydrochloric acid (3 mols.), and 100 c.c. of water was evaporated to dryness and the pale green residue recrystallised from 400 c.c. of boiling water, with the addition of animal charcoal to decolorise the solution. On cooling the filtered solution, *p*-guanidinotoluene-*m*-sulphonic acid separated in fine, colourless needles. This product, however, was shown by analysis to be impure (Found: in material dried at 145°, C = 41.27; H = 4.87; N = 19.36. $C_8H_{11}O_3N_3S$ requires C = 41.92; H = 4.80; N = 18.34 per cent.). Repeated crystallisations from water or dilute hydrochloric acid did not yield a pure product. The substance was therefore dissolved in a little warm sodium hydroxide solution; on cooling, the sodium salt separated as a mass of needles, which was filtered off and

dissolved in a large volume of boiling water. The solution was acidified with hydrochloric acid and cooled, when the pure sulphonic acid crystallised out in fine needles, which were dried for several days over sulphuric acid.

p-Guanidinotoluene-m-sulphonic acid forms colourless, long, fine, silky needles, which do not melt below 300° (Found: in material dried over sulphuric acid, $H_2O = 7.48$; in material dried at 145° , $N = 18.54$. $C_8H_{11}O_3N_3S \cdot H_2O$ requires $H_2O = 7.29$. $C_8H_{11}O_3N_3S$ requires $N = 18.34$ per cent.). Its properties are similar to those of *p*-bromo- and *p*-chloro-phenylguanidine-*o*-sulphonic acids, but it is more soluble in water and in alcohol. The sodium salt forms fine, colourless needles, and is dissociated by water with formation of the free acid.

Condensation of p-Bromoaniline-o-sulphonic Acid with Phenylcarbimide.—*p*-Bromoaniline-*o*-sulphonic acid was prepared by the method previously described (T., 1922, **121**, 2043); 2.7 grams of this acid (1 mol.), and 0.56 gram of potassium hydroxide (1 mol.) were dissolved in 35 c.c. of water, 2.4 grams of phenylcarbimide (2 mols.) were added, and the mixture was shaken, when a curdy, white solid soon separated. After an hour, the mixture was heated to decompose excess of phenylcarbimide, diluted to 120 c.c., boiled, and filtered. The insoluble residue consisted of *s*-diphenylcarbamide (m. p. $234-235^{\circ}$). The filtrate, on cooling, deposited a little more of the latter substance; after removing this by filtration, the liquid was concentrated and allowed to crystallise.

Potassium 4-bromo-s-diphenylcarbamide-2-sulphonate was thus obtained as colourless needles, which sintered to a thin core at $126-128^{\circ}$ and then melted with decomposition at $218-223^{\circ}$ (Found: in material dried in a vacuum over sulphuric acid, $H_2O = 7.65$, 8.09 ; in material dried at 130° , $N = 6.88$. $C_{13}H_{10}O_4N_2BrSK \cdot 2H_2O$ requires $H_2O = 8.09$. $C_{13}H_{10}O_4N_2BrSK$ requires $N = 6.85$ per cent.). This salt is moderately soluble in hot water, but sparingly soluble in cold water.

Condensation of p-Toluidine-m-sulphonic Acid with Phenylcarbimide.—This was carried out exactly as for *p*-bromoaniline-*o*-sulphonic acid (see above), using 1.95 grams of *p*-toluidine-*m*-sulphonic acid in place of the former. On shaking with phenylcarbimide, a slight, flocculent precipitate was first formed, but soon the condensation product separated in long, silky needles. It was isolated in the manner described above.

Potassium s-phenyl-p-tolylcarbamide-2'-sulphonate crystallises from hot water, in which it is moderately soluble, in long, colourless, silky needles; it sinters at $175-185^{\circ}$ and, after partially melting at $210-215^{\circ}$, resolidifies (Found: in material dried over sulphuric

3190 CONDENSATION OF AROMATIC AMINO-SULPHONIC ACIDS, ETC.

acid, $\text{H}_2\text{O} = 7.15, 7.26$; in material dried at 135° , $\text{N} = 8.26$. $\text{C}_{14}\text{H}_{13}\text{O}_4\text{N}_2\text{SK} \cdot 1.5\text{H}_2\text{O}$ requires $\text{H}_2\text{O} = 7.28$. $\text{C}_{14}\text{H}_{13}\text{O}_4\text{N}_2\text{SK}$ requires $\text{N} = 8.14$ per cent.).

Preparation of p-Toluidine-m-sulphonic Acid from Aceto-p-toluidide.—Aceto-*p*-toluidide (25 grams) was mixed with fuming sulphuric acid (19 grams, containing 10 per cent. of SO_3) and the resulting hot, brown, viscid mass heated on a sand-bath. At about 140° , the mass liquefied and the reaction commenced, acetic acid vapour being given off. The temperature was then raised to, and maintained at, 170° until, after about forty-five minutes, the mixture was converted into a pasty solid. This was broken up and the heating continued at 170° in an air-oven until a portion was completely soluble in sodium carbonate solution. The hard mass was ground up with 40 c.c. of water, and the solid filtered off and recrystallised from 600 c.c. of boiling water, with the addition of animal charcoal. On cooling, *p*-toluidine-*m*-sulphonic acid separated in small, faintly yellow needles, a further quantity being obtained by concentrating the mother-liquors. The yield was 17 grams (= 51 per cent. of the theoretical) and the product was shown by microscopic examination to be entirely free from *p*-toluidine-*o*-sulphonic acid (the characteristic rhombic plates of the latter substance can readily be detected in a mixture of the *m*-acid with a small quantity of the *o*-acid). Its purity was confirmed by analysis (0.4054 gram neutralised 17.35 c.c. of 0.1184*N*-sodium hydroxide. Calc. for $\text{C}_7\text{H}_8\text{N} \cdot \text{S}_3\text{H} \cdot 0.5\text{H}_2\text{O}$, 17.46 c.c.).

Preparation of p-Chloroaniline-o-sulphonic Acid from p-Chloroacetanilide.—*p*-Chloroacetanilide (32.5 grams) was sulphonated with 20 grams of fuming sulphuric acid (10 per cent. of SO_3), the process being similar to that used in preparing *p*-toluidine-*m*-sulphonic acid (see above). Instead of recrystallising the crude product from water, however, it was dissolved in a hot solution of 25 grams of anhydrous sodium carbonate in 500 c.c. of water, the solution decolorised with animal charcoal, filtered hot, and acidified with 115 c.c. of hydrochloric acid, when the sulphonic acid was precipitated in small, oblong plates (33 grams = 83 per cent. of the theoretical). By recrystallisation from hot water, the acid was obtained as fine, colourless needles; its identity with *p*-chloroaniline-*o*-sulphonic acid obtained from *p*-chloroaniline and amidosulphonic acid (Paal, *Ber.*, 1901, **34**, 2753) was proved by preparing its aniline salt, which formed glistening, rhombic plates, *m. p.* $211.5\text{--}212.0^\circ$. The aniline salt of the acid prepared by Paal's method melted at 211° , and a mixture of the two specimens at $211\text{--}212^\circ$.

This acid crystallises from hot, aqueous solutions in anhydrous,

prismatic needles, and from dilute, almost cold solutions in fine, monohydrated needles (Found: $\text{H}_2\text{O} = 8.03$. $\text{C}_6\text{H}_5\text{O}_2\text{NClS}, \text{H}_2\text{O}$ requires $\text{H}_2\text{O} = 7.98$ per cent.); the monohydrate is not mentioned in the literature.

[Received, August 3rd, 1923.]

CCCLXXVIII.—*Sulphonation of para-Substituted Phenylcarbamides.*

By JOHN RICHARD SCOTT.

SINCE Scott and Cohen (T., 1922, **121**, 2034) have shown that the action of isocyanic acid on the *p*-halogenoaniline-*o*-sulphonic acids gives rise to biuret derivatives (I) instead of carbamido-derivatives (II), it was considered desirable to prepare the latter by other methods and to determine whether they could be converted into the corresponding biuret derivatives.

Three methods for preparing these carbamido-acids were investigated, (a) the action of ammonia on the corresponding urethane, (b) the halogenation of *o*-carbamidobenzenesulphonic acid, and (c) the sulphonation of the appropriate *p*-substituted phenylcarbamides. The last method gave the most satisfactory results; the first failed entirely. *p*-Chloro- and *p*-bromo-phenylcarbamides gave the corresponding *o*-sulphonic acids (II), respectively, whilst *p*-tolylcarbamide gave *p*-carbamidotoluene-*m*-sulphonic acid (III) and a small amount of *p*-carbamidotoluene-*o*-sulphonic acid. The *m*-acid (III) was identical with that produced from *p*-toluidine-*m*-sulphonic acid and isocyanic acid (*loc. cit.*) and was obtained in greatly improved yield. In the sulphonation of *p*-iodophenylcarbamide, iodine was split off and *p*-carbamidobenzenesulphonic acid resulted.

The following methods for converting *p*-chloro- and *p*-bromo-phenylcarbamide-*o*-sulphonic acids into the corresponding biuret derivatives were tried:

(i) The reaction between the *p*-halogenoaniline-*o*-sulphonic acids and isocyanic acid probably takes place in two stages, since the simultaneous condensation with 2 mols. of isocyanic acid

would be a termolecular reaction, which is known to be an uncommon type. If the carbamido-acid (IV) is involved as an

intermediate product, this substance should condense with a molecule of isocyanic acid to form the biuret derivative. Actually, however, no condensation took place when potassium cyanate was added to *p*-chloro- or *p*-bromo-phenylcarbamide-*o*-sulphonic acid in aqueous solution, or to the bromo-acid in dilute hydrochloric acid solution. It is therefore evident that if an intermediate carbamido-acid is produced in the reaction formulated above, it must have a structure different from that of the acids obtained by the sulphonation of *p*-substituted phenylcarbamides. The latter acids, for reasons given below, are believed to have the *iso*-carbamide structure; the intermediate product (IV) may therefore have the normal structure as shown. It may be noted that Werner (P., 1914, 30, 262) obtained a 4 per cent. yield of isobiuret by the action of isocyanic acid on carbamide in hydrochloric acid solution.

(ii) Although carbamide reacts with ethyl chloroformate to produce ethyl allophanate, the carbamido-acids do not behave similarly, and the compound $\text{SO}_3\text{H}\cdot\text{C}_6\text{H}_3\text{X}\cdot\text{NH}\cdot\text{CO}\cdot\text{NH}\cdot\text{CO}_2\text{Et}$ was not obtained.

(iii) *p*-Bromophenylcarbamide-*o*-sulphonic acid was heated with carbamide, but there was no evidence of the formation of a biuret derivative.

As ethyl chloroformate readily condenses with the amino-group in potassium *p*-bromoaniline-*o*-sulphonate (p. 3201), its failure to condense with the carbamido-acids suggested the absence of an amino-group in these compounds. This was confirmed by their behaviour towards phenylcarbimide; neither *p*-bromophenylcarbamide-*o*-sulphonic acid, nor potassium *p*-chlorophenylcarbamide-*o*-sulphonate, nor potassium *p*-carbamidotoluene-*m*-sulphonate condenses with this reagent, whereas *p*-bromoaniline-*o*-sulphonic and *p*-toluidine-*m*-sulphonic acids condense readily (this vol., p. 3189). The *isocarbamide* structure, $\text{SO}_3\text{H}\cdot\text{C}_6\text{H}_3\text{X}\cdot\text{NH}\cdot\text{C}(\text{OH})\cdot\text{NH}$, is therefore suggested for the *o*-carbamidosulphonic acids.

One of the objects of the original investigation (Scott and Cohen, *loc. cit.*) was to determine whether the *o*-carbamido-sulphonic acids could be converted into ring compounds (V) by the loss of water,

in the same way that hydantoin (VI) are formed from *o*-carbamido-carboxylic acids.

Experiments on the action of hydrochloric acid, acetyl chloride, thionyl chloride, and benzoyl chloride on *p*-carbamidotoluene-*m*-sulphonic acid gave no evidence of ring formation. The substance obtained by the action of phosphoryl chloride on this acid, as described previously (*loc. cit.*), has proved, on further examination, not to have the composition required by the ring compound (IX). It is evident, therefore, that the *o*-carbamido-sulphonic acids do not form these ring compounds so readily as the corresponding carboxylic acids, since the latter are quantitatively converted into hydantoin by heating with hydrochloric acid.

The action of phosphoryl chloride on potassium *p*-carbamidotoluene-*m*-sulphonate gives a small yield of 3-chloro-7-methyl-1:2:4-benzosulphonediazine (VII), which is probably formed as indicated:

The structure (VII) assigned to this product seemed to be more satisfactory than the alternative (VIII), since the substance is unchanged by boiling water or alcohol, and acts as a monobasic acid, the hydrogen (*) being replaceable by metals. Moreover, the chlorine is not readily removed by caustic soda solution; prolonged boiling with the latter, however, gives the hydroxy-compound (IX). This ring compound, the analogue of the hydantoin obtained from *o*-carbamido-carboxylic acids, has thus been obtained by an indirect method. The chloro-compound (VII) can also be nitrated, giving a mononitro-derivative.

EXPERIMENTAL.

Sulphonation of p-Tolylcarbamide.—A mixture of 23 grams of *p*-tolylcarbamide and 115 grams of fuming sulphuric acid (10 per

cent. SO_3) was heated at 60° until, after about thirty minutes, a test portion dissolved completely in cold water; the liquid was then poured gradually into 170 c.c. of water and, after one hour, the pink crystals of *p*-carbamidotoluene-*m*-sulphonic acid were filtered off, washed with a little hydrochloric acid, and dried in a vacuum. *p*-Carbamidotoluene-*o*-sulphonic acid was isolated from the filtrate by the method described below. The crude meta-acid, 30 grams (= 79 per cent. of the theoretical), in 150 c.c. of hot water, was treated with animal charcoal and then with an equal volume of hydrochloric acid; the pure sulphonic acid separated in short, colourless prisms, which were dried in air. The substance was identified as *p*-carbamidotoluene-*m*-sulphonic acid (III) by analysis (Found: in air-dried material, $N = 11.40$. Calc., $N = 11.29$ per cent.), and by comparison with an authentic specimen obtained from *p*-toluidine-*m*-sulphonic acid and potassium cyanate (Scott and Cohen, *loc. cit.*). The two acids, and also their aniline salts, showed identical crystalline forms and melting points, and a mixed melting-point determination with the aniline salts confirmed their identity.

The product was shown to be free from the isomeric *p*-carbamidotoluene-*o*-sulphonic acid by hydrolysis with hydrochloric acid. Microscopic examination of the product showed it to consist entirely of *p*-toluidine-*m*-sulphonic acid, no trace of the characteristic crystals of the *o*-acid being recognisable.

p-Carbamidotoluene-*o*-sulphonic Acid.—The filtrate from the crude *m*-acid was diluted, neutralised with barium carbonate, and filtered. The filtrate, after removal of barium as sulphate, was evaporated, a little unchanged *p*-tolylcarbamide and *p*-toluidine-*m*-sulphonic acid successively separating. The final liquor (30 c.c.), after the addition of an equal volume of hydrochloric acid, slowly deposited minute, oval plates of *p*-carbamidotoluene-*o*-sulphonic acid; a hot, aqueous solution of these was treated with hydrochloric acid and, on cooling, the pure sulphonic acid separated in rhombic plates (the yield was variable, the average being about 1.5 grams from 23 grams of *p*-tolylcarbamide).

p-Carbamidotoluene-*o*-sulphonic acid forms thin, colourless, rhombic plates which are anhydrous and decompose at $255-256^\circ$, after turning yellow at about 245° (Found: $N = 12.14$. $\text{C}_8\text{H}_9\text{O}_4\text{N}_2\text{S}$ requires $N = 12.17$ per cent.). It is very soluble in water, sparingly soluble in hydrochloric acid, and, like the other carbamido-acids, is decomposed by nitrous acid in acid solution with formation of nitrogen and a diazonium salt. As only two sulphonic acids of *p*-tolylcarbamide are theoretically possible and the *m*-compound has already been obtained (see above), the new

acid must be the *o*-compound. This deduction was confirmed, the acid yielding *p*-toluidine-*o*-sulphonic acid on hydrolysis with hydrochloric acid.

The *potassium* salt, which is very soluble in water, was obtained by dissolving the acid and potassium hydroxide in hot, 90 per cent. alcohol, adding acetone, and cooling. The minute prisms which separated were washed with acetone and dried over sulphuric acid (Found: K = 13.09; loss on heating at 140° = 8.02.

requires K = 13.40; $\text{C}_2\text{H}_6\text{O}$ = 7.90 per cent.). The presence of alcohol of crystallisation was proved by the iodoform reaction.

Action of Phenylcarbimide on Potassium p-Carbamidotoluene-m-sulphonate.—An aqueous solution of the potassium salt (1 mol.) was shaken with phenylcarbimide (1 mol.). After twelve hours, the salt was recovered unchanged, the carbimide having been converted into *s*-diphenylcarbamide.

Unsuccessful attempts were made to convert *p*-carbamidotoluene-*m*-sulphonic acid into a ring compound (IX) by the following methods: (i) heating with hydrochloric acid; (ii) boiling for four hours with acetyl chloride; on evaporating the mixture to dryness and adding hydrochloric acid to the aqueous solution of the residue, *p*-acetylcarbamidotoluene-*m*-sulphonic acid separated in minute prisms decomposing at 198–201° (Found: in air-dried material, N = 9.60. $\text{C}_{10}\text{H}_{12}\text{O}_6\text{N}_2\text{S}, \text{H}_2\text{O}$ requires N = 9.66 per cent.). The water of crystallisation could not be removed by heating without decomposing the substance; the presence of the acetyl group was confirmed, however, by treating the substance with nitrous acid and then with an alkaline solution of β -naphthol, which gave only a yellow coloration; (iii) heating with acetyl chloride in a sealed tube at 110°; *p*-toluidine-*m*-sulphonic acid was the only product; (iv) heating with thionyl chloride; or (v) with benzoyl chloride; in neither case was any definite product isolated.

Action of Phosphoryl Chloride on p-Carbamidotoluene-m-sulphonic Acid.—A mixture of 12 grams of the acid (dried at 130°), 35 grams of phosphoryl chloride, and 100 c.c. of benzene was heated under reflux on the water-bath for four hours. After filtering, and removal of the excess of benzene and phosphoryl chloride by distillation under reduced pressure at 80°, the viscous residue was dissolved in a little warm acetone, the solution poured into water, and the mixture boiled for some time. The spongy, insoluble residue, which hardened on cooling, was dissolved in acetone and the solution allowed to evaporate spontaneously, when a white, crystalline substance separated. This was extracted with hot acetone, and on adding water to the extract colourless, rhombic

plates separated. These were recrystallised from acetone and then formed minute rhombohedra which, after sintering at $170-180^{\circ}$, melted to a brown liquid at 277° . It dissolved sparingly in water, giving a neutral solution, and was unacted upon by sodium carbonate solution (Found: loss on heating at $140^{\circ} = 13.62$; in material dried at 140° , $N = 12.02$, 11.75 ; $S = 17.43$ per cent.). These percentages are not compatible with formula (IX) (Calc., $N = 13.21$; $S = 15.09$ per cent.). The aqueous solution in which the crude product had been boiled contained only *p*-toluidine-*m*-sulphonic acid.

Action of Phosphoryl Chloride on Potassium p-Carbamidotoluene-m-sulphonate.—A mixture of the potassium salt (43 grams, previously dehydrated by heating at 150° for eight hours) with 43 grams of phosphoryl chloride was heated under reflux in a boiling water-bath for one and a half hours, the mass gradually becoming semi-liquid and hydrogen chloride being evolved. The solid obtained on cooling was dissolved in aqueous sodium hydroxide (50 grams, in 500 c.c. of water) and the cooled solution filtered (the small quantity of prismatic needles obtained was not identified). The filtrate, on acidification with dilute hydrochloric acid, yielded a crystalline precipitate of crude 3-chloro-7-methyl-1:2:4-benzosulphonediazine together with lumps of a viscous substance (A). The latter were removed, the diazine was collected and dissolved in 170 c.c. of hot water containing just sufficient sodium hydroxide, the solution treated with animal charcoal, and the diazine reprecipitated by hydrochloric acid; purified in a mixture of alcohol and water (1:2) with the aid of animal charcoal, the product (4.4 grams) melted at 265° . On boiling the alcoholic mother-liquor with the substance A, the latter mostly dissolved, and after treatment with animal charcoal the solution was filtered and cooled, when a further 1.2 grams of the diazine (m. p. 260°) separated. The yield (5.6 grams) is 14 per cent. of the theoretical. 3-Chloro-7-methyl-1:2:4-benzosulphonediazine (VII), twice recrystallised from dilute alcohol, was obtained in colourless, flattened needles or prisms, m. p. $273-274^{\circ}$, giving a brown liquid, with slight evolution of gas (Found: in material dried over sulphuric acid, $H_2O = 7.56$; in material dried at 130° , $C = 41.90$, 41.57 ; $H = 3.34$, 3.10 ; $N = 12.01$, 12.06 ; $S = 14.17$; $Cl = 15.18$. $C_8H_7O_2N_2ClS \cdot H_2O$ requires $H_2O = 7.24$. $C_8H_7O_2N_2ClS$ requires $C = 41.65$; $H = 3.04$; $N = 12.15$; $S = 13.88$; $Cl = 15.40$ per cent.). It dissolves very sparingly in water, but readily in alcohol or hot nitrobenzene; from the latter, on cooling, it separates in anhydrous prisms (Found: $N = 12.49$ per cent.). It behaves as a monobasic acid, being soluble in sodium hydroxide or carbonate,

and giving an acid solution in water (Found: 0.1444 gram of anhydrous substance was equivalent to 6.34 c.c. of 0.1N-acid. Calc., for monobasic acid, 6.27 c.c.); it is reprecipitated from alkaline solutions by acids, including acetic acid. When it is treated with nitrous acid, no nitrogen is evolved and the subsequent addition of alkaline β -naphthol gives only a pale yellow coloration.

The sodium salt forms minute needles very readily soluble in water. The silver salt was prepared by adding silver nitrate to a neutral solution of the sodium salt; it formed a white, amorphous precipitate which was washed with hot water and dried in a vacuum (Found: Ag = 31.66. $C_8H_6O_2N_2ClS$ Ag requires Ag = 32.00 per cent.). Addition of alcoholic silver nitrate to a solution of the diazine in hot, dilute alcohol precipitated minute needles of an impure silver salt (Found: after drying at 145° , Ag = 30.87 per cent.).

Nitration of 3-Chloro-7-methyl-1:2:4-benzosulphonediazine.—The diazine, dissolved in concentrated sulphuric acid, was nitrated with fuming nitric acid (d 1.5); the mixture soon became solid and after the addition of water the nitro-compound was filtered and recrystallised from a large volume of 50 per cent. alcohol.

The nitro-derivative forms minute, pale yellow, glistening plates, which are anhydrous and melt and decompose to a brown mass at 253° (Found: N = 15.52. $C_8H_6O_4N_3ClS$ requires N = 15.25 per cent.). It resembles the unsubstituted diazine in its behaviour towards nitrous acid, and dissolves in aqueous sodium hydroxide, giving a bright yellow solution.

3-Hydroxy-7-methyl-1:2:4-benzosulphonediazine (IX).—3-Chloro-7-methyl-1:2:4-benzosulphonediazine (0.5 gram) was boiled under reflux for five hours with 20 c.c. of 10 per cent. aqueous sodium hydroxide solution. The hydroxy-derivative separated in colourless flakes on acidifying the resulting solution with sulphuric acid. It was recrystallised twice from 60 per cent. alcohol and dried over sulphuric acid; the product was then free from halogen. This substance forms colourless, flattened needles or plates which are anhydrous and melt with decomposition at 300° (Found: N = 13.07. $C_8H_8O_3N_2S$ requires N = 13.21 per cent.). It dissolves sparingly in water, but readily in alcohol; its behaviour towards alkalis and nitrous acid is similar to that of the original chloro-compound.

Sulphonation of p-Chlorophenylcarbamide.—This was carried out as in the case of *p*-tolylcarbamide (described above), with 10.7 grams of *p*-chlorophenylcarbamide and 64 grams of fuming sulphuric acid (10 per cent. SO_3); the mixture was heated for one hour.

The crude acid (yield 12.5 grams = 75 per cent. of the theoretical) was purified in the same way as the *p*-tolyl compound.

p-Chlorophenylcarbamide-*o*-sulphonic acid (II) was thus obtained in glistening, rhombic plates or rhombohedra, or occasionally in flattened needles. It decomposes to a dark-coloured, frothy mass at 253° (Found: in air-dried material, N = 10.29; H₂O = 9.11. C₇H₅O₄N₂ClS, 1.5H₂O requires N = 10.09; H₂O = 9.75 per cent.). The acid is very soluble in water or alcohol, but sparingly soluble in hydrochloric acid, the addition of the latter to an aqueous solution causing the acid to crystallise out.

As the sulphonic acid on hydrolysis with hydrochloric acid gave *p*-chloroaniline-*o*-sulphonic acid, identical with an authentic specimen, the constitution of the original carbamido-acid was conclusively proved.

The potassium salt of *p*-chlorophenylcarbamide-*o*-sulphonic acid forms colourless, narrow, rectangular plates or prisms, moderately soluble in hot, but sparingly soluble in cold water (Found: in air-dried material, by heating at 160°, H₂O = 6.08; in anhydrous material, K = 13.03. C₇H₅O₄N₂ClSK, H₂O requires H₂O = 5.88. C₇H₅O₄N₂ClSK requires K = 13.52 per cent.). The ammonium salt separates from water in rectangular plates, melting with decomposition at 241°. The aniline salt separates as a mass of fine needles on adding aniline to a hot, concentrated, alcoholic solution of the acid. After recrystallisation from alcohol, it melts to a viscid liquid, with slight decomposition, at 187°.

When an aqueous solution of *p*-chlorophenylcarbamide-*o*-sulphonic acid is treated with sodium nitrite, scarcely any nitrogen is evolved, but on acidifying the mixture, a copious evolution of gas takes place, and the resulting solution, on addition of alkaline β-naphthol, gives a red colour.

Action of Potassium Cyanate, Phenylcarbimide, and Ethyl Chloroformate on p-Chlorophenylcarbamide-*o*-sulphonic Acid (or its Potassium Salt).—An aqueous solution of the sulphonic acid (1 mol.) and potassium cyanate (3 mols.) was evaporated to dryness; the residue, after recrystallisation from water, was found to be potassium *p*-chlorophenylcarbamide-*o*-sulphonate (Found: N = 9.53. Calc., N = 9.13 per cent.).

Potassium *p*-chlorophenylcarbamide-*o*-sulphonate was recovered unchanged (Found: N = 9.38 per cent.) after shaking its aqueous solution with phenylcarbimide (1 mol.), the latter being quantitatively converted into *s*-diphenylcarbamide.

(a) An aqueous solution of *p*-chlorophenylcarbamide-*o*-sulphonic acid (1 mol.) and potassium carbonate (2 mols.) was shaken with ethyl chloroformate (2 mols.) until the latter disappeared; the

only product isolated from the resulting solution was the potassium salt of the carbamido-acid (Found: N = 9.19 per cent.).

(b) The carbamido-acid was boiled under reflux with excess of ethyl chloroformate for three hours, and the ester then distilled off; the residue consisted entirely of unchanged *p*-chlorophenylcarbamide-*o*-sulphonic acid (Found: after recrystallisation from dilute hydrochloric acid, 0.2120 gram neutralised 9.37 c.c. of 0.0856*N*-sodium hydroxide. Calc., 8.93 c.c.).

Sulphonation of p-Bromophenylcarbamide.—*p*-Bromoaniline was readily obtained from its acetyl derivative by the following method (a modification of that of Mills, *Proc. Roy. Soc.*, 1860, 10, 590). Seventy grams of *p*-bromoacetanilide were added to a solution of 60 grams of sodium hydroxide in 500 c.c. of water, and the mixture was distilled with steam. The base, which solidified in the receiver, was filtered off and dried. Yield 47 grams (= 83 per cent. of the theoretical); m. p. 60–62°.

p-Bromoaniline (47 grams), dissolved in a mixture of 41 c.c. of hydrochloric acid and 800 c.c. of water, was treated with a filtered solution of 30 grams of potassium cyanate in 100 c.c. of water. The precipitate of *p*-bromophenylcarbamide was filtered off, well washed with water, and dried in a vacuum. Yield 52 grams (= 88 per cent. of the theoretical). As this compound had not been previously prepared by this method, a portion was recrystallised from alcohol, when it formed colourless needles, decomposing and charring, without melting, at 265° and upwards (Found: N = 13.20. Calc., N = 13.02 per cent.) (compare Richter, *Ber.*, 1891, 24, 4172).

The sulphonation was carried out as in the case of *p*-tolylcarbamide (p. 3193), with 17 grams of *p*-bromophenylcarbamide and 102 grams of fuming sulphuric acid (10 per cent. SO₃); the reaction was complete in forty-five minutes. The crude acid (yield 20 grams; 78 per cent. of the theoretical) was purified like the *p*-tolyl compound.

p-Bromophenylcarbamide-*o*-sulphonic acid (II) was thus obtained in colourless, rhombic plates or rhombohedra, or occasionally in flattened needles; it decomposes to a purple, frothy mass at 258–263° (Found: in air-dried material, H₂O = 8.22; in material dried at 130°, N = 9.48. C₇H₇O₄N₂BrS, 1.5H₂O requires H₂O = 8.38. C₇H₇O₄N₂BrS requires N = 9.49 per cent.). Its properties resemble those of the corresponding chloro-compound, but it is less soluble in water and in alcohol than the latter.

Its constitution was proved by hydrolysing the substance with hydrochloric acid, *p*-bromoaniline-*o*-sulphonic acid, identical with an authentic specimen, being obtained.

The *potassium* salt of *p*-bromophenylcarbamide-*o*-sulphonic acid forms narrow, rectangular plates, or prismatic needles (Found: in air-dried material, $H_2O = 5.31$. $C_7H_5O_4N_2BrSK, H_2O$ requires $H_2O = 5.13$ per cent.). The *ammonium* salt forms rectangular plates, melting with decomposition at $235-236^\circ$. The *aniline* salt, prepared like the corresponding chloro-compound, forms fine needles melting at $183-185^\circ$ to a viscid liquid (Found: $N = 11.03$, $C_7H_7O_4N_2BrS, C_6H_7N$ requires $N = 10.83$ per cent.).

Action of Potassium Cyanate, Phenylcarbimide, Ethyl Chloroformate, and Carbamide on p-Bromophenylcarbamide-o-sulphonic Acid (or its Potassium Salt).—(a) On evaporating to dryness an aqueous solution of the acid (1 mol.) and potassium cyanate (3 mols.), the residue was found to consist of potassium *p*-bromophenylcarbamide-*o*-sulphonate (Found: after recrystallisation, $N = 8.22$, Calc., $N = 7.98$ per cent.). (b) The sulphonic acid, dissolved in hot, dilute hydrochloric acid, was treated with a large excess of solid potassium cyanate. Evaporation of the resulting solution gave a mixture of the unchanged acid and its potassium salt there was no evidence of the formation of a biuret derivative.

A solution of *p*-bromophenylcarbamide-*o*-sulphonic acid (1 mol.) in *N*-hydrochloric acid was shaken with phenylcarbimide (2 mols.) until the odour of the latter disappeared. The resulting clear solution, on standing, deposited flattened needles, consisting of aniline *p*-bromophenylcarbamide-*o*-sulphonate (Found: after recrystallisation from water, 0.2150 gram neutralised 6.63 c.c. of 0.0856*N*-sodium hydroxide. Calc., 6.48 c.c.), which, alone or mixed with an authentic specimen, was further identified by the melting-point test. This salt was formed almost quantitatively from the original acid.

Two experiments with ethyl chloroformate were performed similar to those with the chloro-acid (see above), and gave similar results.

An equimolecular mixture of *p*-bromophenylcarbamide-*o*-sulphonic acid and carbamide was heated at 140° for an hour; the resulting mass, however, was found to contain only the original materials together with a little *p*-bromoaniline-*o*-sulphonic acid. No evidence of the presence of a biuret compound could be obtained.

Attempts were made, as in the case of *p*-carbamidotoluene-*m*-sulphonic acid, to obtain a ring compound (V) from *p*-bromophenylcarbamide-*o*-sulphonic acid by the action of hydrochloric acid or acetyl chloride, but without success. By using phosphoryl chloride, a small quantity of a substance was obtained which appeared to have the properties of a ring compound, but the amount was insufficient for analysis.

Sulphonation of p-Iodophenylcarbamide.—On mixing 21.5 grams of *p*-iodophenylcarbamide with 37 grams of fuming sulphuric acid (10 per cent. of SO_3) a dark brown liquid containing much free iodine was obtained. This was heated at 55° for five hours and then poured into 400 c.c. of water, when a black, viscous mass separated. The mixture was heated for an hour on the water-bath, cooled, and filtered; the insoluble residue consisted mainly of iodine. The filtrate was neutralised with barium carbonate and filtered, the barium removed as sulphate, and the filtrate decolorised with animal charcoal and evaporated to 30 c.c. On cooling, a small quantity of fine needles separated; the amount of this substance was insufficient for its identification, but it did not possess the properties of an iodophenylcarbamidesulphonic acid. The filtrate from the needles was treated with an equal volume of hydrochloric acid, when minute, thin plates separated; they were recrystallised from dilute hydrochloric acid (1:1). The brown, thin, glistening plates thus obtained decomposed to a violet, frothy mass at 260 – 263° , and were identified as *p*-carbamidobenzenesulphonic acid by analysis (Found: in air-dried material, $\text{H}_2\text{O} = 8.06$; in material dried at 135° , $\text{N} = 12.61$. Calc. for $\text{C}_7\text{H}_8\text{O}_4\text{N}_2\text{S}\cdot\text{H}_2\text{O}$, $\text{H}_2\text{O} = 7.69$. Calc. for $\text{C}_7\text{H}_8\text{O}_4\text{N}_2\text{S}$, $\text{N} = 12.96$ per cent.) and by comparison (and also of the ammonium salts) with an authentic specimen obtained from sulphanilic acid and potassium cyanate.

p-Carbamidobenzenesulphonic acid (Ville, *Bull. Soc. chim.*, 1891, [iii], 6, 6; Pellizzari and Matteucci, *Annalen*, 1888, 248, 156) is conveniently prepared by treating the potassium salt, dissolved in the minimum of boiling water, with twice the volume of hydrochloric acid; the acid, which separates in minute flakes on cooling, is recrystallised from 25 per cent. hydrochloric acid. Ville does not mention the fact that this substance decomposes to a frothy mass at 256 – 258° , and that, although very soluble in water, it is sparingly soluble in hydrochloric acid.

The ammonium salt crystallises from water, in which it is very soluble, in fine needles, m. p. 244 – 245° (decomp.).

Potassium p-Bromophenylurethane-o-sulphonate.—A solution of *p*-bromoaniline-*o*-sulphonic acid (3 grams) and potassium carbonate (4 grams) in warm water (35 c.c.) was shaken with ethyl chloroformate (2 c.c.). The ester soon disappeared, and after a short time a bulky mass of fine needles separated; these were filtered off and recrystallised from hot water. Potassium *p*-bromophenylurethane-*o*-sulphonate was thus obtained in long, fine, colourless needles, melting with decomposition at 259.0 – 259.5° (Found: in air-dried material, $\text{H}_2\text{O} = 7.22$; $\text{N} = 3.76$. $\text{C}_9\text{H}_8\text{O}_6\text{NBrSK}\cdot 1.5\text{H}_2\text{O}$

requires $\text{H}_2\text{O} = 6.94$; $\text{N} = 3.60$ per cent.). It is readily soluble in hot, but rather sparingly soluble in cold water; when it is treated with nitrous acid, no nitrogen is evolved and the subsequent addition of alkaline β -naphthol gives only a pale yellow coloration.

Action of Ammonia.—(a) The urethane was heated with aqueous ammonia ($d\ 0.880$) in a sealed tube at 100° for five hours; the resulting solution, however, contained only the unchanged material. (b) A similar experiment was performed at a higher temperature (120 – 130°), but on acidifying the product with hydrochloric acid, *p*-bromoaniline-*o*-sulphonic acid was precipitated, this being the only substance isolated. In neither of these experiments was there any evidence of the formation of a carbamido-compound.

Action of Bromine on o-Carbamidobenzenesulphonic Acid.—The sulphonic acid (Scott and Cohen, *loc. cit.*, p. 2042), dissolved in warm, glacial acetic acid, was treated with bromine; granular crystals slowly separated, which, recrystallised from dilute hydrochloric acid, formed rhombic plates, apparently identical with *p*-bromophenylcarbamide-*o*-sulphonic acid. As the sulphonation of *p*-bromophenylcarbamide furnishes a convenient method for preparing the bromo-sulphonic acid, the action of bromine on *o*-carbamidobenzenesulphonic acid was not examined further.

The author wishes to take this opportunity of thanking Prof. J. B. Cohen, F.R.S., for his advice and suggestions during the course of this work.

CCCLXXIX.—*The Conditions of Reaction of Hydrogen with Sulphur. Part IV. The Direct Union of Oxygen and Sulphur.*

By RONALD GEORGE WREYFORD NORRISH and ERIC KEIGHTLEY
RIDGAL.

In two papers recently published on the reaction of hydrogen with sulphur, and its catalysis by oxygen (this vol., pp. 695, 1689), evidence was furnished suggesting that the work done in detaching a molecule of hydrogen sulphide adsorbed on the surface of the liquid sulphur was equal to that done in subliming a molecule of S_2 , and it followed from the theoretical considerations there developed (*loc. cit.*, p. 1700) that an equal amount of work should be expended in removing a molecule of sulphur dioxide similarly adsorbed on the

surface. It was therefore considered of interest to examine the reaction of oxygen and sulphur with a view to test if possible the theoretical prediction, and the results of this investigation are given in the present communication. Whilst the reaction proved to be more complicated than had originally been expected, and developed a very interesting feature when the influence of pressure was studied, the predictions of the theory advanced in the previous papers have received striking confirmation. Thus it was predicted that the reaction of oxygen and sulphur at the surface of the latter would have a temperature coefficient of 1.48. Actually it has been found that oxygen combines with sulphur by way of two independent simultaneous surface reactions, one of which has the predicted temperature coefficient of 1.48, whilst the other has a temperature coefficient of 1.77. The nature of this second surface reaction is discussed at the end of this paper.

The reaction of oxygen and sulphur has been studied by Bodenstein and Caro (*Z. physikal. Chem.*, 1909, 75, 30), who drew the conclusion that it is practically completely confined to the surface of the sulphur. No trustworthy data were, however, obtained on the influence of pressure and temperature on the reaction, factors of prime importance in obtaining an insight into the mechanism of the reaction.

EXPERIMENTAL.

The experimental arrangement adopted was the dynamic flow method used in the investigation of the reaction between hydrogen and sulphur (Part I, *loc. cit.*). This method has proved itself extremely trustworthy so long as great care is taken in keeping constant the rate of flow of gas through the sulphur bulb, and the temperature of the bath. In the first place, air, freed from carbon dioxide and water vapour, was passed through the sulphur bulb, and the variation in the velocity of sulphur dioxide formation with temperature studied between the limits of 235° and 385°.

The effect of variation of oxygen pressure was next investigated at the three temperatures 245°, 265°, and 285° by passing various oxygen-nitrogen mixtures of known concentration over the liquid sulphur and measuring the rate of sulphur dioxide formation.

Finally, by using bulbs of different dimensions and adding varying quantities of sulphur, the effect of surface extent was investigated.

The velocity of formation of sulphur dioxide was determined by allowing the effluent gases to pass at constant flow rate through a known volume of standard iodine solution, the time taken to discharge the colour of the latter being observed, with the help of starch solution, added as indicator as the end-point was approached. To establish equilibrium in the apparatus, it was generally found

necessary to allow the gas to stream through the reaction chamber maintained at the desired temperature, for about two hours, the rate of gas flow being kept constant. At the end of this interval, the time of discharge of the iodine colour became constant, and from it the rate of production of sulphur dioxide in the reaction bulb could be calculated, since at equilibrium the weight of the latter carried over by the gas stream per second, and absorbed by the iodine, is equal to its rate of formation in the reaction chamber. The strength of iodine solution employed varied from 10 c.c. of $N/1000$ iodine, diluted to 200 c.c., to 10 c.c. of $N/20$ -iodine, similarly diluted, according to the rate of sulphur dioxide formation to be measured. In no case was the time of discharge allowed to fall below six minutes, and if it did so, stronger iodine solutions were taken.

The effluent gases contained in some cases a considerable percentage of sulphur dioxide, and it was necessary to correct for the pressure in the bulb according to the formula

$$P = p - \frac{63 \times 10^6 x}{136 + 126 \times 10^6 x},$$

developed in Part II of this series (*loc. cit.*), where P = actual oxygen pressure in the reaction chamber, p = pressure of oxygen in gas flowing into the reaction chamber, and x = rate of formation of sulphur dioxide in grams per second.

In Table I are given the results of the investigation of the effect of temperature on the rate of sulphur dioxide formation. It is shown below that the velocity of sulphur dioxide formation is proportional to the oxygen pressure, and accordingly, in column 4, the observed velocities, in column 2, have been corrected for the lowering of oxygen pressure in the reaction bulb, being scaled up

to the oxygen pressure of the inflowing gas, — 0.21 atm. This gives a series of comparable figures which can be used for the calculation of the temperature coefficients of the reaction shown in column 5, which will be seen to remain sensibly constant between the temperatures 235° and 305°. Above this latter temperature, however, they rapidly diminish, suggesting that some disturbing factor here

becomes of importance to the course of the reaction. This disturbing action on the sulphur dioxide reaction was traced to the secondary formation of sulphur trioxide, which was found to become apparent at temperatures above 305°. Thus, at 305°, no trace of sulphate

FIG. 1.

formation could be detected on collecting the effluent gases in caustic soda solution, for half an hour, and testing with barium chloride solution, whereas similar tests carried out at higher temperatures always indicated the presence of sulphate in rapidly increasing quantity as the temperature was raised. No quanti-

tative measurements were carried out on the production of sulphur trioxide at these higher temperatures ($> 305^\circ$), all future measurements on the sulphur dioxide reaction being carried out between the temperatures 235° and 305° , where the secondary oxidation to sulphur trioxide, if it occurs at all, is too insignificant to cause any appreciable error.

FIG. 2.

In Fig. 1, the logarithms of the velocities are plotted against the reciprocal of the absolute temperatures, the dotted curve indicating the theoretical sulphur dioxide reaction if we imagine secondary sulphur trioxide formation to be absent. It will be seen that below 305° the relationship is approximately linear, corresponding to a nearly constant temperature coefficient.

The data of Table II, showing the effect of oxygen pressure on the sulphur dioxide reaction, are graphed in Fig. 2, from which it will be seen that whilst the velocity of the reaction is in all cases pro-

portional to the oxygen pressure, very marked breaks occur in the straight lines at the oxygen pressure of 0.413 atmosphere, without any appreciable variation for the three temperatures investigated. These breaks, which formed a most unexpected feature of the investigation, can only be taken as evidence of the heterogeneity* of the hitherto apparently homogeneous sulphur dioxide surface reaction. Each of the broken straight-line curves may be split up into two straight lines as has been done in Fig. 3, along one of which the reaction velocity finally reaches a maximum constant value with increase of oxygen pressure, whilst along the other it continues to increase, in a linear manner with pressure.

The figures of Table III show beyond all doubt that the total reaction is a surface reaction to such an overwhelming extent that any gaseous reaction is entirely negligible. Thus the ratio of velocity to total area is the same for flasks of widely different dimensions, whilst the velocity is independent of the weight of sulphur present (except in so far as it decreases the extent of total surfaces), and of the area of the liquid sulphur surface. In this connexion, it should be mentioned that sublimed sulphur contains much absorbed sulphur dioxide and hydrogen sulphide, and that until this is removed by continually heating the sulphur to *ca.* 300° in a vacuum figures independent of the weight of sulphur in the bulb will not be obtained. When these preliminary precautions were taken, reproducible results were always obtained.

It follows therefore that the heterogeneity of the sulphur dioxide formation must be confined to the surface and we are forced to the conclusion that the formation of sulphur dioxide can take place on the surface of the sulphur and of the vessel by way of two independent reactions, whilst the ratio in which the sulphur dioxide formation is divided between these two reactions must be independent of the nature of the surface—that is, whether liquid sulphur or glass—since variation in the liquid surface produces no appreciable change in the total quantity of sulphur dioxide formed. This fact points to the probability of a complete liquid film covering the whole of the glass surface, and identical in composition with the surface film of the liquid sulphur itself. This liquid sulphur film made itself apparent by the interference colours developed on the walls of the reaction vessel when it was rapidly withdrawn from the heating bath, and in the dendritic growth of sulphur crystals which formed on the walls as they cooled.

* The term heterogeneity is *not* used here, and in what follows, in the sense usually implied in catalysis, but rather as indicating that the sulphur dioxide reaction observed in the surface of sulphur is not simple, but the sum of two (or more) simple surface reactions.

For convenience of further discussion we shall designate the two independent surface reactions by the letters A and B, "A" referring to that reaction which reaches a constant maximum velocity with increase of pressure.

FIG. 3.

0.40	106	63	44	290	141	139	731	300	431
0.60	131	65	66	353	145	208	950	312	647
0.80	153	65	88	423	145	278	1174	312	862
1.00	175	65	110	492	145	347	1393	312	1081

The A and B reactions have been plotted in Fig. 3, for temperatures 245°, 265°, and 285°, by splitting the corresponding composite curves of Fig. 2. This was done by producing the upper segments of the curves of Fig. 2 backward to cut the ordinate, and measuring the slopes of the lines so produced. Straight lines of the same slope drawn to pass through the origin gave the B reaction curves of Fig. 3. The A reaction curves were then obtained by subtracting the B curves from the corresponding composite curves of Fig. 2.

The data from the curves in Fig. 3 have been tabulated in Table IV, and from any corresponding sets of figures in this table the temperature coefficients of the two reactions may be obtained. They are better obtained graphically, however, by taking the square root of the ratio of the slopes of corresponding pressure-velocity curves in Fig. 3.

Thus, if η represents the temperature coefficient calculated for a 10° rise, we have, for the A reaction,

$$\eta_{285}^{265} = \sqrt{\frac{\text{Slope of A reaction curve at } 285^\circ}{\text{Slope of A reaction curve at } 265^\circ}} = 1.47$$

$$\eta_{265}^{245} = \sqrt{\frac{\text{Slope of A reaction curve at } 265^\circ}{\text{Slope of A reaction curve at } 245^\circ}} = 1.49$$

Similarly, for the B reaction,

$$\eta_{305}^{285} = 1.765 \text{ and } \eta_{245}^{265} = 1.775.$$

Hence, denoting the temperature coefficients of the A and B reactions, respectively, by η_A and η_B , we have

$$\eta_A = 1.48 \text{ and } \eta_B = 1.77.$$

The temperature coefficients of the two reactions, while differing widely from each other, thus remain constant over the temperature range investigated. It follows from this that the constant temperature coefficient observed for the total reaction between 235° and 305°, and tabulated in Table I, was to some extent accidental, since the total reaction is the sum of two surface reactions of different temperature coefficients. When, however, as in Table V, the total reaction is calculated from the figures for the A and B reactions at 245° and 0.21 atm.* oxygen pressure, by means of their respective temperature coefficients, good agreement with the total observed reaction up to 305° is obtained, after which the discrepancy between theoretical and observed values gradually increases, due, as has already been shown, to the secondary formation of sulphur trioxide.

* The experimental figures for any other pressure serve equally well.

385	4217	1.06	77,200	1.73

The facts relating to the reactions of hydrogen and oxygen with sulphur at the surface of the latter, considered in this and the previous papers of this series, may now be summarised as follows :

(1) The surface reaction of hydrogen and sulphur is independent of the pressure of the hydrogen (Part I, *loc. cit.*).

(2) It is catalysed by the admixture of small percentages of oxygen with the hydrogen, but, when the quantity of oxygen is increased, the catalysis passes through a maximum, finally falling off to a complete poisoning effect, when the hydrogen contains more than 10 per cent. of oxygen (Part II, *loc. cit.*).

(3) At the same time sulphur dioxide is formed at a rate proportional to the oxygen pressure (Part II, *loc. cit.*).

(4) When the oxygen percentage is greater than that required to poison the hydrogen sulphide reaction, sulphur dioxide formation is still proportional to the oxygen pressure.

(5) A break in the curve connecting the velocity of sulphur dioxide formation with oxygen pressure, however, indicates that at these higher oxygen pressures, sulphur dioxide formation proceeds by two distinct surface reactions, having definite but different temperature coefficients, one of which becomes independent of oxygen pressure at about 0.4 atm. of oxygen, whilst the other remains proportional to oxygen pressure up to 1 atmosphere of oxygen.

(6) The temperature coefficient of the hydrogen sulphide reaction is 1.48, leading to a heat of activation of 25,750 cal. at 300°. This heat of activation is nearly equal to the heat of sublimation of a molecule of S₂ from the surface (28,000 cal.), and is half the heat of activation found for the gaseous hydrogen sulphide reaction, 51,460 cal. at 300°.

(7) The assumption was made that in the former two cases we are measuring the work done in detaching a molecule of H₂S or S₂ from

the surface by the breaking of one bond, whilst in the latter case we are measuring the work done in dissociating the S_8 molecule, by breaking two bonds. The hypothesis predicts that the work done in detaching a molecule of sulphur dioxide from the surface should be of the order 26,000 cal. This has been found to be so in the present paper for the A sulphur dioxide reaction, the heat of activation calculated from the temperature coefficient (1.48) being 25,750 cal. at 300° . For the B reaction, however, the heat of activation is 37,450 cal. at 300° .

The facts enumerated above may all be harmonised by an extension of the theory advanced in Part III (*loc. cit.*) of this series. It was there postulated that since the vapour of sulphur at 260 – 300° consists almost completely of S_8 molecules, the sulphur surface in equilibrium with it must be very largely composed of S_8 molecules also. These molecules are probably highly saturated and non-polar, and therefore incapable of the adsorption of hydrogen or oxygen. A small number, however (constant for a given temperature), may at any moment be considered to be activated to a polar form. For example, if the saturated S_8 molecule is a closed ring, it may be activated by the rupture of a bond, possibly as a result of collision, the free ends then being available for hydrogen or oxygen adsorption. If pure hydrogen be in contact with the sulphur surface, all the polarised sulphur molecules will immediately become attached to hydrogen, hydrogen sulphide formation occurring by the evaporation of the hydrogen molecule with the sulphur atom, with the concomitant rupture of a sulphur linking. The activated sulphur molecules, by reason of their high polarity, must be supposed to attach hydrogen extremely rapidly, so that at any moment all but a small fraction of the sulphur molecules available for hydrogen adsorption are occupied. This mechanism results in the surface formation of hydrogen sulphide being independent of hydrogen pressure except for very low pressures. Admixture of oxygen with the hydrogen atmosphere results in the displacement of some hydrogen from the surface, and owing to the preferential adsorption of the former, the hydrogen is completely displaced from the surface when the gaseous atmosphere contains more than 7–10 per cent. of oxygen according to the temperature, resulting in a complete poisoning of the hydrogen sulphide reaction. It has already been shown how this gradual replacement of hydrogen by oxygen on the surface can also explain quantitatively the catalytic and poisoning activity of the latter (Part II, *loc. cit.*).

It was therefore expected that when the oxygen pressure was increased beyond that required to poison the surface with respect to hydrogen sulphide formation, the rate of formation of sulphur dioxide

would become independent of oxygen pressure, since all the active sulphur molecules which previously adsorbed hydrogen would now be occupied by oxygen, and therefore the surface should be saturated with respect to oxygen.

The data of the present communication, however, do not fulfil this expectation, for the velocity of formation of sulphur dioxide continues to increase with the pressure of oxygen, far beyond the point at which the above hypothesis indicates that it should become constant. By assuming in addition, however, that oxygen molecules are able to activate some non-polar form of sulphur molecules in the surface by collision, and thereafter become adsorbed by them, the hypothesis can be extended to account satisfactorily for all the observed facts. The number of sulphur molecules activated by collision per second, and therefore the number of oxygen molecules adsorbed per second, would be proportional to the number of oxygen molecules striking the surface per second, and hence to the oxygen pressure over the sulphur surface. Thus the velocity of sulphur dioxide formation, limited by the velocity of oxygen adsorption, would be proportional to the oxygen pressure as found experimentally. We have up to the present considered only the S_8 molecules, which must constitute the major portion of the sulphur surface, at the experimental temperatures, since at these temperatures the sulphur vapour in equilibrium with it consists almost completely of S_8 complexes. It is apparent, however, since the existence of two sulphur dioxide surface reactions has been demonstrated, that at least two types of sulphur molecules must exist in the surface which can also adsorb oxygen proportionally to the pressure of the latter and give rise to sulphur dioxide. This conclusion is in harmony with the fact that liquid sulphur is known to be a mixture of at least two forms of sulphur— S_μ and S_λ —existing in dynamic equilibrium with each other. In any sulphur surface, either on the glass walls of the vessel or on the sulphur liquid itself, one only of these forms will be deposited from the vapour state, and then in the liquid film subsequently give rise to the second modification. At a certain pressure of oxygen (about 0.4 atm.) the rate at which the second form is removed by formation of sulphur dioxide is equal to its rate of regeneration from the parent form of sulphur molecules. At this point the velocity of sulphur dioxide formation will become constant and independent of any further increase of oxygen pressure, since it is now limited by the rate of formation of the allotropic sulphur molecule. In this way we can account for the A surface reaction, which is at first dependent on oxygen pressure and finally, beyond 0.41 atm., independent of it. Furthermore, at the points O, P, and Q in Fig. 3, where the A reaction just becomes independent

of pressure, the velocity of sulphur dioxide formation by the A reaction is a measure of the velocity of allotropic change of the sulphur, as explained above, and by taking the ratio of these velocities we can obtain the temperature coefficient of this allotropic change. On calculation, this is found to be 1.49 between 245° and 265°, and 1.47 between 265° and 285°, giving a mean value of 1.48, identical with that of the A reaction, and the hydrogen sulphide surface reaction.

Simultaneously, the parent form of liquid sulphur, which is deposited from the vapour on to the glass and liquid sulphur surfaces, and therefore probably consists of closed S_8 molecules, continues to give active adsorbing molecules on collision with oxygen molecules; consequently sulphur dioxide is produced at a rate proportional to the oxygen pressure as already described. This reaction constitutes the B reaction. Theoretically, if a sufficiently high oxygen pressure could be obtained in the bulb, the B reaction should also become independent of oxygen pressure, at the point where the rate of oxygen adsorption becomes equal to the rate of deposition of S_8 molecules from the vapour.

It will now be of interest to examine the A and B reactions from the point of view of their temperature coefficients.

These temperature coefficients, 1.48 for the A reaction and 1.77 for the B reaction, correspond to critical increments, calculated at 300°, of 25,750 cal. for the A reaction and 37,450 cal. for the B reaction. In Part III, reasons were given for expecting that the surface formation of sulphur dioxide would have a critical increment of 26,000 cal., corresponding, as explained there, to the breakage of one sulphur bond.* The critical increment of the A reaction above is in complete agreement with this prediction, and may therefore be taken as a measure of the work done in *either*

(1) preparing the new form of sulphur molecule from the parent form (S_8) by the rupture of one bond per potential sulphur dioxide molecule in some way, *or*

(2) activation of the new form by collision with an oxygen molecule, *or*

(3) detaching a molecule of sulphur dioxide from the surface as explained in Part III of this series.

All these processes, which together form a complete series, should have the same critical increment, namely, that required to break

* Although it might be considered somewhat speculative to associate the critical energy increment in any way with molecular structure, yet we believe that it has some connexion with the chemical conception of a bond; and the constancy of the energy value in a series of chemical actions of the sulphur molecule as shown in Table VI certainly does not disprove the conception which we have found valuable as a guiding hypothesis throughout this work.

one sulphur bond, but only that of the slowest reaction would be measured by the temperature coefficient, since, as already explained in Part III, the temperature coefficient of a chain of linked reactions is that of the slowest reaction in the chain.

Thus, the above series of reactions might be represented as follows :

Each of the above suggested reactions involves the production of one free bond for each potential sulphur dioxide molecule, and therefore, according to our hypothesis, the expenditure of 26,000 cal. per mol. of sulphur dioxide produced. When the rate of removal of S_4 by reaction with oxygen shall have become equal to its rate of production from S_8 , the velocity of the sulphur dioxide reaction would become independent of the pressure of oxygen, and would be limited by the rate of production of S_4 , as we have found experimentally for the A surface reaction.

In harmony with the above scheme, the temperature coefficient of the allotropic change of the sulphur molecules has already been shown to be 1.48, leading to a critical increment of 25,750 cal. at 300° , as required by the hypothesis put forward.

The reaction kinetics of the B surface reaction open up the interesting problem of activation by molecular collision, which it is not possible to enter into fully at this point. It may be pointed out that the critical increment, 38,000 cal., observed is approximately one and a half times that observed for the A reaction and for the hydrogen sulphide surface reaction. The supposition might be made that we are here engaged in activating by oxygen collision a molecular system differing from those already considered, in that it involves the formation of one and a half free bonds for every potential sulphur dioxide molecule produced, and that the rate of activation governs the rate of sulphur dioxide production. The constancy in the energy value of the "half" sulphur bond is shown by the figures in Table VI, which are here collected from the various sulphur reactions we have dealt with in this series.

TABLE VI.

Reaction.	Temp. coeff.	Crit. in- crement at 300°=c cal.	No. of free sulphur bonds produced × 2 = n.	Const. = c/n.

* Part I, *loc. cit.*† *Ibid.*‡ Budde, *Z. anorg. Chem.*, 1912, **58**, 169. See also Part III, *loc. cit.*¶ Pollitzer, *ibid.*, 1909, **64**, 121.¶ Person, *Pogg. Ann.*, 1849, **70**, 310, 386.

There is, however, an alternative explanation of the high critical increment of the B reaction, namely, that the critical increment of the activation of a given sulphur molecule by oxygen collision is different from the critical increment of activation of the same sulphur molecule by collision with a similar sulphur molecule. All the reactions but the last in Table VI may be represented as depending on the production of polarised sulphur molecules by the mutual collision of unpolarised sulphur molecules or atoms. The last reaction, however, depends on the collision of oxygen and sulphur molecules.

The factors governing the magnitude of the critical activation increments in the two cases depend on consideration of the momentum and energy exchanges of the colliding molecules and will be discussed in another place. It may be pointed out here, however, that if the activation of a molecule by collision depends on the exertion of a certain minimum intermolecular force, then, no matter what the mass of the second colliding molecule may be, *the same quantity of momentum must disappear in each case*. Thus, for the three collisions S_2 against S_2 , S_2 against O_2 , and S_2 against H_2 , if for simplicity we suppose the first colliding molecule (that is, the S_2) to be stationary and the second colliding molecule (that is, the S_2 , O_2 , or H_2) to move up to it with the same energy in the three cases (that is, at the same temperature), then the intermolecular forces exerted during collision will be very different in the three cases and will depend on the momenta and *not* the energies of the colliding molecules. The force exerted between the two sulphur molecules will be greater than that between the oxygen and sulphur molecules,

and both much greater than the force exerted between the hydrogen and sulphur molecules. Whilst in the former two cases the intermolecular forces exerted may be sufficient at a certain temperature to cause the distortion in the sulphur molecule which we call "polarisation" or "activation," that called forth in the latter, by reason of its much smaller magnitude, may be insufficient. It will thus be clear that it is legitimate to imagine activation by oxygen collision when it does not take place at the same temperature by hydrogen collision. Furthermore, it follows from the above reasoning that, in order that the same intermolecular force may be exerted between two colliding sulphur molecules as between a sulphur and an oxygen molecule colliding, a greater energy exchange will take place in the latter case than in the former, that is, for the same minimum polarising force in the two collisions different critical increments are involved. It is possible, with certain plausible assumptions, to calculate the ratios of the critical increments for sulphur activation by different collisions from the ordinary laws of inelastic impact, and the results obtained are of the right order, but until something more definite is known of the actual magnitude of the sulphur complexes undergoing collision, such calculations can have little further value.

Summary.

(1) The reaction of oxygen and sulphur has been studied by a dynamic flow method between the temperatures of 235° and 385°. Between 235° and 305° it proceeds normally, with an apparent temperature coefficient of 1.63. Above 305°, the temperature coefficient falls off very rapidly owing to the secondary formation of sulphur trioxide.

(2) The reaction has been shown to be practically limited to the surface of the sulphur and the walls of the vessel, and to proceed as well on the latter as on the former, pointing to the existence of a liquid film covering the whole surface of the vessel.

(3) The reaction is proportional to oxygen pressure.

(4) At 0.41 atm. pressure of oxygen, a break occurs in the pressure-velocity curves, which indicates that the reaction on the surface is complex and made up of the sum of two surface reactions, one of which—the A reaction—becomes independent of pressure beyond the above oxygen pressure, whilst the other—the B reaction—remains proportional to the oxygen pressure at least as high as 1 atm.

(5) The two reactions have been separated and their temperature coefficients obtained; these are:—

For the A reaction — 1.48.

For the B reaction — 1.77.

(6) The critical increments calculated from these temperature coefficients at 300° are

A reaction — 25,750 cal.

B reaction — 37,450 cal.

The former fulfils a prediction of the hypothesis advanced in the earlier papers of the series.

(7) The assumption is made that the sulphur surface contains two types of sulphur molecules, which react along two different courses with the oxygen striking the surface, giving rise to the A and B reactions. The fact that the A reaction finally becomes independent of the oxygen pressure indicates that the rate of production of the second allotropic form of sulphur now limits the velocity of the reaction.

(8) The temperature coefficient of the interconversion of the two allotropic forms is shown to be 1.48 as required by the hypothesis advanced.

(9) A table is given of seven different sulphur reactions, showing that their critical increments are simple multiples of a constant quantity which is considered to be the half value of the work required to create one free sulphur bond.

We desire to thank the Board of Scientific and Industrial Research for a grant to one of us (R.G.W.N.) which has enabled this research to be carried out.

CCCLXXX.—*The Hafnium Content of Zirconium Ores.*

By GEORGE HEVESY and VALDEMAR THAL JANTZEN.

THE complex nature of what has hitherto been regarded as the element "zirconium" is made very clear by the X-ray analysis of zirconium minerals. The results of such work are communicated in the present paper.

For the most part, minerals of known chemical composition were chosen. The original analyses were performed before the complexity of zirconium was known, and hence the hafnium content of these minerals is included in the zirconium estimation. The amount of zirconium found by chemical analysis had thus to be split up in conformity with the results of X-ray spectroscopy into zirconium and hafnium. In some cases, we have determined the zirconium content also by the X-ray method.

In order to determine the hafnium content of the minerals, a known amount of the neighbouring element, tantalum, was mixed with the sample, and the relative intensities of the hafnium and tantalum lines were compared. The ratio of the intensities of corresponding lines in the X-ray spectrum yielded the relative proportions of hafnium and tantalum present. A detailed account of this method has been given by Coster (*Chem. News*, 1923, **127**, 65).

The X-ray investigation of fergusonite and euxenite, the chief constituents of which are columbium and elements of the rare-earth group, gave no indication of the presence of hafnium in these minerals. From amongst twenty analyses of fergusonite (Doelter's "Handbuch der Mineralogie," 1918, III, 253), zirconium was detected in only two samples (namely, 1 per cent. and 2 per cent.), and of twenty-four analyses of euxenite (*op. cit.*, p. 203) only three contained zirconium (namely, 1.3 per cent., 1.8 per cent., and 2.8 per cent.). That the minute quantities of zirconium present in these minerals are not free from hafnium, however, is evidenced

* Lorenzen, *Min. Mag.*, 1882, **5**, 63. Potassium silicofluoride, prepared by Julius Thomsen from eudialyte, was found to contain hafnium to the extent of 0.6 per cent. of its zirconium content, an appreciable part of the hafnium originally present having been presumably removed in the mother-liquor when the crystals were prepared.

† Flink, *Medd. Grönland*, 1899, **24**, 102. In 1852, Sjögren thought he had discovered a new element, similar to zirconium, in catapleite, but his results could not be reproduced by later investigators, including Marignac. It is of interest to note that catapleite has an especially low hafnium content.

by the fact that, when fergusonite and euxenite were treated in large quantities on an industrial scale, the extracted zirconium contained 5 to 6 per cent. of hafnium. These preparations were kindly presented to us by Baron Auer von Welsbach.

It is of interest to note that thorium minerals free from zirconium were found to contain no hafnium.

(1) Thorianite: Occurrence: Ceylon (Dunstan and Jones, *Proc. Roy. Soc.*, 1906, 77, 547).

CaO.	PbO.	Fe ₂ O ₃ .	Ce ₂ O ₃ .	ThO ₂ .	U ₃ O ₈ .	HfO ₂ .	H ₂ O.
0.91	2.54	0.87	1.47	78.98	13.40	0	1.28

(2) Orangite: Occurrence: Norway (Schilling, *Z. angew. Chem.*, 1902, 15, 921).

Na ₂ O.	K ₂ O.	CaO.	Al ₂ O ₃ .	Fe ₂ O ₃ .	SiO ₂ .	ThO ₂ .	U ₃ O ₈ .	HfO ₂ .	H ₂ O.
0.36	0.41	1.13	0.82	1.20	17.59	69.98	1.08	0	6.95

(3) Thorite: Occurrence: Norway.

HfO₂ . . . 0

Furthermore, titanium minerals like rutile and ilmenite were found to be free from hafnium.

It is well known, chiefly as a result of the measurements of R. J. Strutt, that all zircons exhibit radioactive properties, by virtue of the presence in them of minute amounts of uranium and thorium. Zircons with a large thorium or uranium content were also found to contain rather large amounts of hafnium, and the radioactivity of zircons accordingly shows a rough parallelism with their hafnium content. Radioactive measurements may thus prove very useful when a search is being made for zircons with a high hafnium content. The following numbers were found for the relative activities of zircons by Strutt:

Cyrtolite	8.98
Alvite	1.81
Malakon	1.40
Zircon (Virginia)	0.52
Zircon (North Carolina)	0.30

For similar minerals we found the following relative activities:

Cyrtolite (Rockport)	3.8
Alvite (Risør).....	3.6
Alvite (Kragerø)	1.2
Zircon (Norway)	0.16

Both series show a parallel diminution in their hafnium content.

Clark ("Data of Geochemistry," Washington) estimates the zirconium content of the earth's crust at about 0.015 per cent. If we take the average hafnium content of zirconium to be 3 per cent.,

we find the hafnium content of the earth's crust to be 0.00045 per cent. The actual hafnium content of the earth's crust probably lies between 1/100,000 and 1/300,000.

Our best thanks are due to Professor O. B. Böggild, Director of the Mineralogical Museum, Copenhagen University, for supplying us with a large number of zirconium minerals, and to Dr. D. Coster, for his valuable help with the X-ray investigations.

[Received, October 26th, 1923.]

CCCLXXXI.—*The Chemistry of Posidonia Fibre.* *Part I.*

By JOHN CAMPBELL EARL.

THE fibrous remains of *Posidonia australis* accumulate in beds of very considerable extent along the coasts of certain parts of Australia, and from time to time the commercial possibilities of the fibre have been tested with some degree of success (Winterbottom, Bulletin No. 4, South Australian Department of Chemistry, Adelaide, 1917). An investigation of the material covering a considerable range was carried out by Read and Smith under the auspices of the Commonwealth Institute of Science and Industry (Bulletin No. 14, Melbourne, 1919), and among the properties observed was the behaviour of the fibre on treatment with hot 3 per cent. sulphuric acid, which occasioned a loss in weight of about 36 per cent. The acid solution on neutralisation had a strong reducing action on Fehling's solution, but was not further examined.

The Action of Hot Dilute Sulphuric Acid on Posidonia Fibre.—

The present investigation was undertaken with a view to ascertain the nature of the material extracted from the fibre by means of hot dilute sulphuric acid. To remove all likelihood of hydrolysis of the cellulose taking place, the acid employed was very dilute, at no time exceeding 2 per cent., whilst the duration of the treatment was also made as short as possible for the same reason. It was found that immersion of 100 grams of the air-dried crude fibre (containing 12.5 per cent. of moisture and 10.4 per cent. of ash) in 2 per cent. sulphuric acid with passage of steam for one and a half hours yielded 59.7 grams (corrected for moisture) of a material which underwent very slight further loss on repeating the treatment. Even under these mild conditions, the loss in weight was thus very considerable.

The reducing action of the extract, after neutralisation with barium carbonate, removal of chloride by treatment with silver

sulphate, and concentration to small bulk (250 c.c.) under diminished pressure, was found to be due mainly to a pentose or a mixture of pentoses, the quantity of which, calculated on the dry, ash-free fibre, was between 10 and 15 per cent. This estimate was arrived at from observations made on the reducing power of the solution and the formation of phenylosazones.

The optical rotation of the solution in a 1-dm. tube was $\alpha_D^{20} + 1.10^\circ$. The quantity of reducing sugars calculated as pentoses was 8.1 grams. Assuming all the reducing sugars to be pentoses, their mean specific rotation would be $[\alpha]_D^{20} + 33.5^\circ$.

Isolation of a Pentosephenylosazone.—A mixture of 25 c.c. of the above solution, 2.6 c.c. of phenylhydrazine, and 2.6 c.c. of glacial acetic acid was heated on a boiling water-bath for an hour. Dark, oily drops soon separated and, on cooling and shaking, the crude osazone was obtained as an orange-brown powder which, dried in a vacuum desiccator, weighed 1.67 grams, equivalent to 8.4 grams of pentose from the original 100 grams of air-dried fibre. When recrystallised once from benzene to which 10 per cent. of its volume of alcohol had been added, it melted at 155° . A second recrystallisation from benzene to which 20 per cent. of its volume of alcohol had been added yielded about 50 per cent. of the osazone in minute, lemon-yellow needles, melting at 160 – 161° . Further recrystallisation from the same solvent, or from dilute alcohol containing pyridine, raised the melting point to 166 – 167° . The product from the latter solvent was in the form of shining leaflets; on keeping for a few weeks, its melting point fell to 162° (Found: C = 62.3; H = 6.5; N = 17.4. Calc. for $C_{17}H_{20}O_3N_4$, C = 62.2; H = 6.1; N = 17.1 per cent.). The substance appeared to be optically inactive in pyridine-alcohol solution and is possibly a *dl*-pentosephenylosazone: the melting point corresponds with that of *dl*-arabinosephenylosazone.

A comparison of the properties of the Posidonia osazone with those of recorded pentoseosazones is shown in the following table:

Osazone from:	Highest m. p. recorded.	α_D (0.2 gram in 10 c.c. of pyridine-alcohol).
<i>l</i> -Arabinose	160°	$+1^\circ 10'$ *
<i>d</i> -Xylose	170	$-0^\circ 15'$
<i>dl</i> -Arabinose	169 – 170	inactive
<i>dl</i> -Xylose	210 – 215	inactive
Posidonia	166 – 167	inactive

Neuberg, *Ber.*, 1899, **32**, 3384.

Since the sugar solution from which the osazone is prepared is optically active, it is evident that the inactive osazone isolated represents only a part of the sugar in solution.

To determine whether any fermentable sugars were present in the solution under examination, 50 c.c. were mixed with a little fresh yeast and kept in a warm place for some hours. The solution was then filtered and made up to 100 c.c. with water. Its optical rotation was found to be practically unaltered when referred to the original concentration.

A further portion of the solution (140 c.c.) was evaporated to a syrup under diminished pressure. The syrup was extracted with boiling methyl alcohol and the solution filtered. Water (10 c.c.) was added to the insoluble residue and the resulting mixture again extracted with methyl alcohol (100 c.c.). After repeating this treatment, the united methyl-alcoholic extracts were evaporated to a thin syrup. Excess of ethyl alcohol was then added, and the precipitated syrup macerated with more alcohol until it was solid and powdery. The solid so obtained (1.2 grams) reduced Fehling's solution, but gave 14.8 per cent. of ash on ignition. Its aqueous solution showed a very small laevorotation. The alcoholic liquors were evaporated, but attempts to obtain a solid product from them were unsuccessful.

The investigation of these sugars is being continued.

The Action of Hot Dilute Sulphuric Acid on Posidonia "Cellulose."
—The source of the pentoses obtained as described above may be regarded as a readily hydrolysable pentosan present in the fibre. This pentosan is not readily affected by chlorine, and a "cellulose" isolated from the fibre by the customary method of Cross and Bevan (49.2 per cent., calculated on the dry fibre) still suffers a considerable loss on treatment with hot 2 per cent. sulphuric acid. In one case, the "cellulose" so obtained lost one-third of its weight by the acid treatment. The loss is not due to a progressive hydrolysis of the "cellulose," since there is no further loss on repeating the treatment (compare Read and Smith, *loc. cit.*, p. 19). The acid extract yielded a phenylosazone which melted, after recrystallisation, at 152° and was apparently identical with that previously obtained from the raw fibre.

The pentosan is not removed from the fibre by treatment with aqueous alkalis. The first stage in the method of Cross and Bevan involves boiling with dilute sodium hydroxide solution, yet the final "cellulose" contains a considerable quantity of pentosan. Read and Smith observed that the loss on β -hydrolysis of the fibre (boiling with 1 per cent. sodium hydroxide solution for one hour) was very small, the highest value recorded being 6.3 per cent.; moreover, treatment of the fibre with a solution of sodium hydroxide of mercerising strength resulted in a loss of only 3 per cent. (*loc. cit.*, p. 15).

The resistance of the pentosan to the chlorination treatment no doubt accounts for the divergent values recorded for the percentage of "cellulose" in the fibre. The quantity of pentosan remaining in the "cellulose" will vary with certain factors in the process, for example, the rate at which the chlorination is carried out. During the treatment the fibre mass becomes warm and hydrochloric acid is formed; this presumably brings about partial hydrolysis of the pentosan, and the extent of the hydrolysis will be affected by the temperature and by the amount of water present.

The amount of cellulose in the acid-treated fibre was found to be 48.7 per cent. This is equivalent to 33.2 per cent. of the original, dry, untreated fibre, and corresponds very closely with the value of 33.9 per cent. of cellulose obtained by treating the "cellulose" from the original fibre with hot 2 per cent. sulphuric acid.

The author acknowledges his indebtedness to the McCaughey Research Fund of the University of Sydney for a grant in aid of the investigation, to Mr. R. K. Newman, B.Sc., for assistance in its early stages, and to Professor Read for the interest he has shown throughout.

CCCLXXXII.—*The Action of Highly Concentrated
Hydrochloric Acid on Cellulose and on some
Derivatives of Glucose and of Xylose.*

By EDMUND LANGLEY HIRST and DONALD ROBERTSON
MORRISON.

FUMING hydrochloric acid on several occasions in the past proved to be a useful reagent for effecting the hydrolysis of complex carbohydrates, and on more than one of those important quantitative results were claimed. Thus Willstätter and Zechmeister (*Ber.*, 1913, 46, 2401), from a study of the hydrolysis of cotton cellulose by this method, stated that the polysaccharide is convertible quantitatively into glucose, whilst Heuser and Boedeker (*Z. angew. Chem.*, 1921, 34, 461), in the course of work with wood pulp cellulose, advanced similar claims. An examination of the recorded experimental evidence reveals that in the former case the conclusions were based on evidence provided by a comparison of the reducing powers and the optical activities of glucose and of cellulose when dissolved in fuming hydrochloric acid; whilst in the latter

case observations of the same nature were supplemented by the isolation of a substance which gave the usual reactions of glucose. The abnormal exaltation of the specific rotations of glucose and its methylated derivatives in hydrochloric acid solution introduces, however, an element of uncertainty into the deductions made from these experimental observations, and a further investigation of this subject has since been undertaken by Zechmeister (*Z. physikal. Chem.*, 1922, 103, 316), who finds that the exaltation is dependent on the concentration of the acid and that the effect is a reversible one. In view of the possibility, which was therefore still open, that profound structural changes might have taken place during the treatment of a sensitive compound such as glucose with fuming hydrochloric acid, it was felt that the whole reaction required reinvestigation before complete reliance could be placed on results obtained by this method in the course of structural investigations in the carbohydrate group. These considerations involved an investigation of the action of hydrochloric acid on glucose and on cellulose, and it seemed desirable to extend the range of the experiments to include a study of the action of the concentrated acid on typical methylated sugar derivatives. The application of the process to the constitutional study of the complex polysaccharides involves ultimately the hydrolysis of the methylated derivatives, which are in some cases substances displaying remarkable stability, and if recourse is to be had to fuming hydrochloric acid as the hydrolytic agent it is necessary to prove in the first place that the products of hydrolysis are themselves stable in the presence of the acid. For this reason it was decided to investigate the stability, under the given experimental conditions, of representative sugar compounds which might be expected to arise from the hydrolysis of substances such as the methylated derivatives of cellulose, starch, or xylan. The work of Denham and Woodhouse on the hydrolysis of methylated cellulose (*T.*, 1913, 105, 2337) may be cited as emphasising the importance of the considerations just advanced. Using fuming hydrochloric acid, these authors obtained from their methylated derivative various partly methylated glucoses, but the fully substituted tetramethyl glucose appeared to be entirely absent. This is of profound importance from the point of view of the constitution of cellulose and therefore it is essential, particularly with regard to future possible investigations, to be certain that this failure to isolate tetramethyl glucose was not due to the destructive action of the acid on the compound.

It is obvious that the value of the evidence as to constitution obtained from investigations of this nature must depend very largely on the actual yields of the various substances produced in

the course of the experiments and in view of the importance of this consideration special attention has been directed to the quantitative aspect of the reactions. Experiments have been carried out to determine the action of fuming hydrochloric acid on the following substances: tetramethyl glucose, 2:3:6-trimethyl glucose, 2:3:5-trimethyl glucose, a dimethyl glucose, trimethyl methylxyloside, trimethyl methylarabinoside, and glucose itself. Finally, in the light of the knowledge gained from these experiments, studies were made of the action of the same acid on cellulose, xylan, and esparto cellulose.

Methylated Derivatives of Glucose, Xylose, and Arabinose.

In the case of the methylated glucoses the experimental evidence points conclusively to their complete stability under the conditions of hydrolysis employed by Willstätter and Zechmeister, and the substances may be recovered unchanged after the experiment. The optical activities in acid solution of the methylated hexoses investigated all showed marked exaltation, in which respect their behaviour is parallel to that of glucose itself. The values of the specific rotations remained constant over a period of several days, and the change governing the exaltation would appear to be completely reversible. The greater stability of the methylated derivatives as compared with free glucose was, however, revealed in the observation that the specific rotations of the former remained constant under conditions which occasioned considerable changes in the case of glucose. Somewhat surprising results were obtained with the two fully methylated pentoses. It was already known that methylation tends to increase stability in the glucose series and accordingly it was thought probable that the methylated pentoses would show a similar stability. On the contrary, however, it was found that formation of furfural took place in the cold with the fully methylated derivatives of both xylose and arabinose, resulting in a rapid destruction of the sugar molecule. These results are of direct practical importance in that they show that during the hydrolysis of methylated polysaccharides derived from glucose it is improbable that the yields of the various hydrolysis products will be diminished by the destructive action of the acid employed, whilst, on the other hand, in the study of the pentosans hydrolysis cannot profitably be carried out by this method.

Glucose.—At low temperatures and for small concentrations of sugar, it is known that the specific rotation of glucose in fuming hydrochloric acid remains constant for at least twenty-four hours (Willstätter and Zechmeister, *loc. cit.*) and, in view of the results obtained with methylated glucoses referred to above, it must be considered highly probable that under these conditions glucose

remains unchanged in the presence of the acid. Slight variations, however, in concentration or temperature serve to initiate changes of a profound nature, and the inconvenience of the reaction is emphasised further by the fact that attempts to isolate the glucose quantitatively in the form of the readily recognisable crystalline methylglucoside were unsuccessful, even when optical activity and reducing power showed that the glucose was still unchanged in amount. As will appear from the details given in the experimental part, this failure was probably attributable to the necessarily protracted nature of the isolation process, during the whole of which the glucose was in contact with hydrochloric acid. From the point of view of usefulness as an experimental method, greater interest is obviously attached to the behaviour of glucose in hydrochloric acid solution when the sugar is present in moderate concentration, and accordingly a further series of experiments was carried out with a 10 per cent. solution in 43 per cent. aqueous hydrochloric acid. Here it was found possible to reduce considerably the time taken to eliminate the acid at the conclusion of the reaction, hydrolysis of any condensation products formed could be prevented, and by making use of tetramethyl glucose as the standard reference substance a ready method was available for the separation of the various products which might be formed during the reaction. Finally, approximate quantitative relationships could be obtained by comparison with the data already available on the methylation of glucose. In spite of special precautions taken to avoid loss of material, the yields of tetramethyl glucose were low, amounting in no case to more than 50 per cent. of the quantity obtainable from glucose. It is important to note that no derivatives of the γ -type were encountered. A considerable portion of the final methylated product was apparently a complex mixture of methylated substances of the dextrin type, giving on hydrolysis a syrup with the composition of a trimethyl glucose. The experiments of Fischer and Armstrong (*Ber.*, 1902, 35, 3144) showed that the action of fuming hydrochloric acid on glucose in concentrated solution leads to the production of isomaltose and of dextrin substances, and a similar series of changes would appear to have taken place even under the milder conditions of the experiments just described. It is evident, therefore, that in the hydrolysis of compounds giving glucose as one of the hydrolysis products the range of concentration within which this reaction may be employed with any degree of certainty is at the best very limited.

Cotton Cellulose.—A similar double series of experiments was performed with cotton cellulose, the glucose isolated after the reaction being identified both as methylglucoside and as tetramethyl

glucose. A quantity of methylglucoside was obtained by the first method, but again the yields were poor and the final product impure. Better results were given by the second series of experiments, using a cellulose concentration of 6 per cent., when yields of pentamethyl glucose were recorded to the extent of 70 per cent. of the amount to be expected if the hydrolysis product consisted entirely of glucose. Once more no trace of the γ -type derivatives could be identified. The high-boiling fraction already mentioned as obtained from glucose was in this case present to a smaller extent, a fact which may be readily understood if it is remembered that the glucose would be formed gradually by hydrolysis of the cellulose and the greater part of the free sugar would therefore be in contact with the acid for a comparatively short period of time. Confirmation is thus given of the conclusions already drawn from the experiments with glucose.

Esparto Cellulose and Xylan.—Treatment of esparto cellulose with fuming hydrochloric acid resulted in the formation of a dark-coloured solution with evolution of quantities of furfural, and exactly similar results were obtained with xylan prepared from esparto (compare Heuser and Kürschner, *J. pr. Chem.*, 1921, [ii], 103, 69). The polarimetric changes which take place during the solution of esparto cellulose in hydrochloric acid have been studied by Cunningham (T., 1918, 113, 173), who showed that the changes in optical activity followed a course analogous to that of cotton cellulose, and in view of the marked differences in properties between cotton and esparto cellulose she criticised adversely a method of hydrolysis which claimed to be quantitative and which could not differentiate between two such dissimilar substances. An interpretation of these observations is possible as a result of the experiment now described, taken in conjunction with recent work on the composition of esparto cellulose, which has been shown to be composed of glucose residues and of xylose residues present in the proportions of 80 per cent. and 20 per cent. respectively (Hirst, *Brit. Assoc. Rep.*, 1922, 358; Irvine and Hirst, unpublished research). During hydrolysis with fuming hydrochloric acid, the comparatively small xylan portion is destroyed with formation of furfural and the polarimetric changes become a record of the production of glucose or substances derived from glucose, the course of the change being exactly parallel to that for cotton cellulose. This similarity in optical behaviour does not necessarily indicate, however, that the glucose residues of cotton and esparto cellulose are similarly constituted, for in the investigation of structural problems little reliance can as yet be placed on evidence derived from a complicated reaction of the type now under consideration.

Summarising these results it would appear that :

1. Methylated sugar derivatives resemble the free sugars in showing when dissolved in fuming hydrochloric acid a marked exaltation of their specific rotations. These methylated substances are stable in the presence of the acid and may be recovered unchanged from the solutions.
2. Glucose is much more sensitive to the action of hydrochloric acid than its methylated derivatives, and under ordinary conditions of temperature and at comparatively low concentrations the sugar is exceedingly unstable.
3. The use of highly concentrated hydrochloric acid as a hydrolytic agent is justifiable when the products of the reaction are methylated glucoses of normal structure, but the method must be employed with great caution when free glucose is one of the hydrolysis products.
4. The method is wholly inapplicable to the hydrolysis of pentosans and their methylated derivatives.

EXPERIMENTAL.

Action of Hydrochloric Acid on Typical Methylated Sugars.

Tetramethyl Glucose.—In hydrochloric acid (d 1.200) the optical activity of tetramethyl glucose was found to show considerable exaltation and a constant value $[\alpha]_D = +100^\circ$ ($c = 1.30$) was recorded in place of $+83^\circ$. 2.84 Grams of tetramethyl glucose were dissolved in 120 c.c. of acid (d 1.200). After five hours at 0° , followed by a further sixteen hours at 15° , the excess of acid was removed by drawing air through the solution for several hours. After distilling away the greater part of the remaining acid under diminished pressure at 50° , the last traces were eliminated by treatment with silver carbonate. From the neutral solution a syrup weighing 2.71 grams was isolated, the whole of which solidified on cooling. For this crude material, the following constants were found: m. p. $60-70^\circ$; $[\alpha]_D + 82.3^\circ$ ($c = 1.513$) in ethyl alcohol; OMe = 51 per cent. [$C_6H_8O_2(OMe)_4$ requires OMe = 52.5 per cent.]. These values are in close agreement with those found by Purdie and Irvine for the equilibrium mixture of the α - and β -forms of tetramethyl glucose, and complete identity was established by a determination of the m. p. of a mixture of the recrystallised material with an authentic specimen.

2:3:6-Trimethyl Glucose.—0.99 Gram of this trimethyl glucose was treated with 10 c.c. of acid under conditions exactly parallel to those described above. $[\alpha]_D = +92^\circ$ ($c = 1.52$) in place of the normal value, $+69^\circ$. On isolation after twenty-four hours, 0.84 gram of unchanged crystalline trimethyl glucose was recovered, the

loss of 0.18 gram being within the limits of experimental error in view of the lengthy nature of the recovery process. The m. p. of the crude crystals showed a range of 85–102°, as already recorded for material which has been crystallised once only, and a mixed m. p. with an authentic specimen showed no depression (m. p. 100–102°). $[\alpha]_D = +96.5^\circ$ ($c = 0.933$) in methyl alcohol, decreasing to a permanent value, $+67.5^\circ$. The m. p. after one recrystallisation rose to 108° and therefore the sugar had been recovered almost unchanged in amount and chemically pure.

*2:3:5-Trimethyl Glucose and Dimethyl Glucose.**—Similar experiments with 2:3:5-trimethyl glucose and a dimethyl glucose (probably 2:5-dimethyl glucose) revealed an exaltation of 30° in the specific rotation, $[\alpha]_D$ being $+91^\circ$ and $+81^\circ$ ($c = 1.20$ and 1.364 , respectively). These values remained constant, and the substances appeared to be stable under these conditions.

Trimethyl Methylxyloside.—A small quantity of crystalline trimethyl methylxyloside, dissolved in fuming hydrochloric acid, developed furfural after standing for a short time at room temperature. The furfural was identified by the colour reaction with aniline acetate and also by means of the additive compound with phloroglucinol, during the formation of which the characteristic series of colour changes was observed. 0.1664 Gram of substance and 10 c.c. of acid ($d\ 1.22$) gave after twenty-four hours 0.0412 gram of the phloroglucide compound, corresponding with 0.025 gram of furfural. The methylated xylose had therefore been decomposed to the extent of at least 36 per cent. Fully methylated arabinose was found to give similar results.

Control Experiments with Glucose.

Four grams of glucose were dissolved in 400 c.c. of hydrochloric acid ($d\ 1.200$) and the solution was allowed to remain at room temperature for twenty hours. Air was then drawn through the solution for twelve hours, and thereafter the greater portion of the acid was removed by distillation, first of all from a water-bath at 40° and later at 50°, fresh water being added to the solution as required. At the end of one hundred hours, the solution, which invariably developed a slight yellow colour, was neutralised with silver carbonate, and the weight of syrup finally isolated amounted to 4.13 grams. 2.734 Grams of this material were subjected to Fischer's glucoside reaction, giving a crystalline mass of weight 2.25 grams (Found: C = 42.9; H = 7.35; OMe = 12.7. $C_6H_{11}O_5 \cdot OMe$ requires C = 43.3; H = 7.25; OMe = 15.95 per cent.). $[\alpha]_D = +$

* The authors are grateful to Dr. J. W. H. Oldham, M.A., for a supply of these two substances.

128.2° ($c = 1.402$) in methyl alcohol, and $[\alpha]_D = +139.5^\circ$ ($c = 1.202$) in water. The accepted figure for the equilibrium mixture of the α - and β -methylglucosides is $+108^\circ$. The product was therefore impure, and on the basis of the Zeisel figure the maximum amount of methylglucoside in the mixture would be 78 per cent., corresponding to an overall yield of about 60 per cent. of recovered glucose. The action of alkali on the product indicated the presence of ester-like substances. In the second series of experiments, where the concentration of sugar was higher, the process of neutralisation was shortened, and at this stage there was little possibility of decomposition of any of the reaction products. Thirty grams of glucose were dissolved in 300 c.c. of acid (d 1.203) and the solution was allowed to remain at 15° for twenty hours. Air was then drawn through the solution, which had been diluted with an equal bulk of water. Thereafter the volume was reduced to 300 c.c. by distillation under diminished pressure at 40° . The liquor was next neutralised with caustic soda (30 per cent. solution) and afterwards evaporated under diminished pressure to a mixture of solid and syrup. This was treated with methyl sulphate (110 c.c.) and caustic soda (110 grams) in the usual manner and after careful extraction and recovery of all the methylated products, followed by further repeated methylation by the silver oxide method, a final yield of 16.2 grams of a dark-coloured, viscous syrup was obtained. Distillation of this material gave the following fractions:

- I. 6.08 grams, b. p. $130-133/9$ mm., n_D 1.4440.
- II. 2.71 grams, b. p. $140-175/8$ mm., n_D 1.4530.
- III. 4.54 grams, b. p. $250-260/2$ mm., n_D 1.4694.

The first fraction crystallised almost completely, and proved to be tetramethyl methylglucoside (Found: OMe = 60.0. Calc., OMe = 62.0 per cent.). The crystals, after draining on a porous tile, gave $[\alpha]_D -15^\circ$ ($c = 1.000$), m. p. 37° , the values quoted in the literature being -17° and 39° respectively. Digestion with $N/100$ -hydrochloric acid did not alter the specific rotation, the absence of any γ -sugar derivatives being thus indicated. On hydrolysis with 8 per cent. hydrochloric acid, 4.94 grams gave 3.59 grams of crystalline tetramethylglucose (yield 72 per cent.) (Found: OMe = 51.3. Calc., OMe = 52.6 per cent.). $[\alpha]_D = +81.6^\circ$ ($c = 0.858$) in ethyl alcohol, the accepted value being 82.3° . The m. p. after one recrystallisation from light petroleum was 80° . The amount of tetramethyl glucose isolated is thus less than half that usually obtained from the same quantity of glucose.

The highest-boiling fraction consisted of a viscous syrup which was brown in colour and slightly acid in reaction, but without

action on Fehling's solution. The analytical figures obtained did not correspond closely with those required for any simple substance, but were of the order required by a trimethylated derivative of a dextrin possessing the formula $(C_6H_{10}O_5)_x$ (Found: C = 53.2; H = 8.2; OMe = 47. $C_6H_{16}O_5$ requires C = 52.9; H = 7.85; OMe = 45.6 per cent.). After being washed with alkali, the material was neutral in reaction, but the analytical figures were not appreciably altered. Hydrolysis was carried out by boiling for two hours with 8 per cent. aqueous hydrochloric acid, and the product was isolated by exhaustive extraction of the neutralised solution with chloroform. It was found to be a stiff syrup which reduced Fehling's solution vigorously. This showed b. p. 180–200°/10 mm., n_D^{25} 1.4611, and $[\alpha]_D + 82.3^\circ$ ($c = 1.410$) in ethyl alcohol. The main fraction from the distillation (b. p. 180–190°/10 mm.) had a marked action on Fehling's solution, showed OMe = 41.5 per cent., and therefore appeared to consist largely of a substance with the properties and composition of a trimethyl glucose.

Action of Concentrated Hydrochloric Acid on Cellulose.

Cotton Cellulose.—The experimental procedure was exactly similar to that described for glucose, and only the final results need be quoted. In one series of experiments, 4.00 grams gave 3.18 grams of crystalline material containing methylglucoside (Found: C = 42.3; H = 7.0; OMe = 16.2 per cent. $[\alpha]_D + 85^\circ$ for $c = 1.23$ in water). From the figures recorded, the maximum possible yield of methylglucoside obtained corresponds to less than 70 per cent. of the calculated quantity, and here again the presence of esters was indicated. Using the second method, 30 grams of cotton were dissolved in 500 c.c. of hydrochloric acid ($d = 1.205$) and the solution was maintained at 15° for twenty hours. The yield of methylated material finally obtained was 18 grams, which after distillation and remethylation of the higher-boiling fractions gave finally.

- I. 9.19 grams, b. p. 139°/13 mm., n_D^{25} 1.4438, OMe = 60.5%.
- II. 2.3 grams, b. p. 130°/10 mm., n_D^{25} 1.4462, OMe = 61%.
- III. 1.15 grams, b. p. 138°/10 mm., n_D^{25} 1.4500, OMe = 58%.
- IV. 1.38 grams, b. p. 175°/4 mm., n_D^{25} 1.4580.

The total loss during the methylations and distillations was 4 grams. The first two fractions crystallised completely and were shown to be tetramethyl methylglucoside, the yield of this compound thus being about 70 per cent. of that usually obtainable from the quantity of glucose corresponding to the cellulose used. As before, the absence of any sugar derivatives of the γ -type was demonstrated.

On hydrolysis of fractions I and II, 4.75 grams of tetramethyl glucose were obtained from 6.5 grams of syrup (yield 78 per cent.) (Found: OMe = 52 per cent., $[\alpha]_D + 81.9^\circ$ for $c = 0.806$ in ethyl alcohol). After one recrystallisation from light petroleum, the m. p. was 80° , and a mixed m. p. showed no depression.

Esparto Cellulose and Xylan.—The esparto cellulose was treated in the same manner as the cotton cellulose, and in this case rapid darkening in colour took place with simultaneous evolution of furfural, the presence of which was recognised by the aniline acetate test, until at the end of twenty hours a black, gelatinous mass remained. Two grams of xylan, isolated from esparto cellulose, were added to 25 c.c. of fuming hydrochloric acid (d 1.203), whereupon the material gradually dissolved with development of dark-coloured decomposition products. Furfural was detected after an interval of ten minutes, and was present in increasing quantities as the reaction proceeded.

The authors are grateful to Principal J.C. Irvine, C.B.E., F.R.S., at whose suggestion work on this topic was commenced, for the interest he has shown, and to the Trustees of the Carnegie Trust for generous help received.

CHEMICAL RESEARCH LABORATORY,
UNITED COLLEGE OF ST. LEONARD AND ST. SALVATOR,
UNIVERSITY OF ST. ANDREWS. [Received, October 17th, 1923.]

CCCLXXXIII.—*Preparation of 2:3-, 2:5-, and 3:4-Dinitrotoluenes.**

By HAROLD JAMES PAGE and BENJAMIN RICHARD HEASMAN.

THE work described in this paper was undertaken with the object of preparing fairly large quantities of these dinitrotoluenes, which were required for an investigation of the products of nitration of toluene, by the method of thermal analysis (see Gibson, Duckham, and Fairbairn, T., 1922, **121**, 270). For this purpose none of the methods hitherto described was suitable (for example, Rozanski, Ber., 1889, **22**, 2681; Grell, Ber., 1895, **28**, 2565; Limpricht, Ber., 1885, **18**, 1412; Nietzsche and Guitermann, Ber., 1888, **21**, 433; Olivieri-Tortorici, *Gazzetta*, 1900, **30**, i, 534. See also Brady and Williams, T., 1920, **117**, 1137, for a summary of earlier work on the 3:4-compound).

The first method to be tried was the conversion of nitrotoluidines

* This investigation was carried out in 1917, but owing to circumstances it could not be published before.

into dinitrotoluenes, based on Korner and Contardi's (*Atti R. Accad. Lincei*, 1914, [v], 23, i, 281) modification of Sandmeyer's method for the transformation of amino- into nitro-compounds, but using for the diazotisation the method of Witt (*Ber.*, 1909, 42, 2953).

It was found that the ease of formation of the diazonium nitrate is no indication of the readiness with which this substance can be converted into the nitro-compound, but rather the reverse. Thus the diazotisation of dinitroaniline, and of certain dinitrotoluidines proceeds quite smoothly and without undue evolution of heat, whereas the mononitrotoluidines react with considerable violence, and great care is needed in their diazotisation by Witt's method. On the other hand, however, many of the diazonium nitrates produced from the dinitroamines undergo conversion into trinitro-compounds with some readiness, whilst those derived from the mononitroamines with much greater heat evolution appear to be much more stable, and less amenable to conversion into dinitro-compounds. It appears probable that when there are already two nitro-groups in the ring, the basicity of the diazonium group is so reduced that the nitrate produced from it is fairly readily decomposed, but that with only one nitro-group already in the ring the basicity of the diazonium group is still so great that the nitrate is relatively stable; its decomposition is a matter of some difficulty, and when effected it is liable to proceed largely along channels other than the desired one.

The above method having been found to give poor and uncertain yields, the preparation of these dinitrotoluenes by the elimination of the amino-groups from the corresponding dinitrotoluidines was investigated. This was suggested by the method of preparation of 3 : 5-dinitrotoluene from 3 : 5-dinitro-*p*-toluidine, used by Cohen and McCandlish (*T.*, 1905, 87, 1270). As, however, none of the dinitrotoluidines suitable for this purpose, namely, 3 : 4-dinitro-, 4 : 5-dinitro-, 3 : 6-dinitro-, or 5 : 6-dinitro-*o*-toluidine, 2 : 5-dinitro-, 4 : 5-dinitro-, or 5 : 6-dinitro-*m*-toluidine, 2 : 5-dinitro- or 2 : 3-dinitro-*p*-toluidine, was known, it was necessary to study the preparation of certain of these compounds. By the nitration of 2-nitro-aceto-*p*-toluidide, prepared by the method of Beilstein and Kuhlberg (*Annalen*, 1870, 155, 14), a mixture of 2 : 3-dinitro- and 2 : 5-dinitro-aceto-*p*-toluidides was obtained in which the 2 : 3-isomeride preponderated, and from which it was readily isolated. This is substantially the method described later by Scott and Robinson (*T.*, 1922, 121, 844). This isomeride, on saponification and elimination of the amino-group, gave a good yield of 2 : 3-dinitrotoluene :

This was the method finally adopted for the preparation of this substance in bulk. The separation of 2:5-dinitroaceto-*p*-toluidide from the mother-liquors was found to present considerable difficulties. As shown in the experimental part of this paper, although the authors' results are mainly in accord with those of Scott and Robinson, there is reason to believe that the substance described as 2:5-dinitroaceto-*p*-toluidide by these workers was not, in fact, this substance, but a mixture of it with the corresponding 2:3-dinitro-compound.

By saponifying, however, 2:5-dinitro-*p*-toluidine could be obtained in a state of purity by recrystallisation of the mixed bases, and this, when treated in the same way as the 2:3-isomeride, was readily converted into 2:5-dinitrotoluene; however, since in the original nitration the 2:5-dinitro-compound was formed in relatively small proportions, the method was not suitable for the purpose required.

A similar method to the above was used in this laboratory by Brady and Williams (*loc. cit.*) for the preparation of 3:4-dinitrotoluene.

A method of preparation of 2:5-dinitrotoluene from *p*-toluquinonedioxime based on that described by Olivieri-Tortorici (*loc. cit.*) was found to give unsatisfactory yields. A satisfactory method was, however, found in the action of Caro's acid on either 5-nitroso-*o*-toluidine, prepared by Mehne's method (*Ber.*, 1888, 21, 729) or 5-nitro-*o*-toluidine:

With regard to the preparation of the latter compound, the method of Lellmann and Würthner (*Annalen*, 1885, 228, 240) as improved by Reverdin and Crepieux (*Ber.*, 1900, 33, 2498) was found to be less satisfactory than that described below (see experimental portion). The oxidation of nitrotoluidine with Caro's acid was also applied to the preparation of 3:4-dinitrotoluene with satisfactory results.*

This method of preparation of dinitrotoluenes was subsequently described by Meisenheimer and Hesse (*Ber.*, 1919, 52, 1161), thus confirming the results obtained by the authors.

* 3:4-Dinitrotoluene was first prepared by this method in another laboratory of this department by Dr. A. Forster, working independently of the authors.

EXPERIMENTAL.

I. *Preparation of 3:4- and 2:5-Dinitrotoluenes from the Corresponding Nitroaminotoluenes by the Method of Witt-Korner and Contardi.*

(i) *5-Nitro-o-toluidine. Nitration of Aceto-o-toluidide.*—The nitration of aceto-*o*-toluidide by the method of Reverdin and Crepieux (*loc. cit.*) was used in the earliest stages of this investigation for the preparation of 5-nitro- and 3-nitro-*o*-toluidine, with fairly satisfactory results, but at a later stage a simpler method was worked out. This consisted in the use of 70 per cent. nitric acid.

Twenty grams of aceto-*o*-toluidide were added in small portions to 75 c.c. of 70 per cent. nitric acid (*d* 1.42), the temperature being kept below 20°. The temperature was then carefully raised to between 40° and 50° and kept there for three-quarters to one hour. The reaction mixture was poured into water and the crude nitration product washed and collected. The yield of the dried mixture was 14 grams.

This product, consisting of a mixture of 5-nitro- and 3-nitro-aceto-*o*-toluidide, the former in considerable excess, was hydrolysed with a mixture of 50 c.c. of concentrated sulphuric acid and 100 c.c. of water by heating on the water-bath for several hours. On cooling and dilution with water, the free bases were deposited as a yellow solid, *m. p.* 123°. This was recrystallised from alcohol, giving fairly pure 5-nitro-*o*-toluidine, *m. p.* 133°. This product was used without further purification for subsequent work, although by a further recrystallisation it could easily be obtained quite pure (*m. p.* 134–134.5°).

This compound formed the bulk of the product of hydrolysis of the acetylmino-compound. The isomeric 3-nitroaceto-*o*-toluidide was present in such small amounts that no attempt was made to isolate it from the mother-liquors.

(ii) *Conversion of 5-Nitro-o-toluidine into 2:5-Dinitrotoluene.*—Twenty-two grams (3.5 mols.) of nitric acid (*d* 1.5) were cooled in ice and 7 grams (1 mol.) of sulphur dioxide passed in; the flask was then placed in a freezing mixture of ice and salt, and 15.2 grams (1 mol.) of finely powdered 5-nitro-*o*-toluidine were added gradually in very small portions. The reaction was very violent, a flash of light being sometimes produced as the powdered amine was added. After a short time, the mixture was added to about 300 c.c. of water containing crushed ice, the clear solution of diazonium nitrate poured into 2 litres of an ice-cold solution of 87 grams (3.5 mols.) of copper sulphate and 50 grams (7 mols.) of sodium nitrite, and the mixture set aside over-night. The

liquid was then heated until all gas evolution had ceased (about one hour), and the brown, friable solid obtained, which contained copper, was filtered off, washed, dissolved in 70 per cent. nitric acid, and heated on the water-bath until no more nitrous fumes were evolved. The liquor was cooled, diluted with an equal volume of water, and extracted four times with chloroform. The extract was washed thrice with dilute caustic soda solution, which removed a large quantity of dark-coloured material, then with water, and dried with calcium chloride. On removal of the chloroform, a light brown oil remained, which crystallised completely on cooling and scratching. This consisted of 5 grams of crude 2:5-dinitrotoluene. It was purified by recrystallisation, first from hot aqueous alcohol, then from 500 c.c. of boiling light petroleum, in which it dissolved with the exception of a small amount of tarry matter, giving 2.5 grams of pure 2:5-dinitrotoluene as a white, micro-crystalline powder, m. p. 48–49° (uncorr.). The same method can be applied to the preparation of 3:4-dinitrotoluene from 3-nitro-*p*-toluidine, but in this case the method described later is preferable.

II. *Preparation of 2:5- and 2:3-Dinitrotoluenes by the Elimination of the Amino-group from 2:5- and 2:3-Dinitroaceto-p-toluidides.*

(i) *Nitration of 2-Nitroaceto-p-toluidide.*—To effect the nitration of this compound, prepared as described by Limpricht (*Ber.*, 1885, 18, 1401), 100 per cent. nitric acid was used at first, but later it was found possible to use nitric acid of density 1.5 without any serious effect on the result. There was a tendency for the nitric acid on dilution to set up partial hydrolysis, but this could be prevented by diluting with a large amount of water, filtering rapidly with the aid of the pump, and washing thoroughly and as rapidly as possible with a large quantity of water. Thirty grams of 2-nitroaceto-*p*-toluidide were added in small quantities at a time to 100 c.c. of fuming nitric acid, the temperature being kept below 40°. After half an hour, the mixture was poured rapidly with vigorous stirring into a large bulk of water, when a light yellow precipitate was formed. The dry material, m. p. 160–162°, weighed 32 grams.

(ii) *Separation of the Isomeric Dinitroaceto-p-toluidides.*—The preceding product was dissolved in 300 c.c. of hot glacial acetic acid and, on cooling, 19.5 grams of a white product, m. p. 172.5° (uncorr.) separated. On further recrystallisation, a compound of constant melting point (174° uncorr.) was obtained in shining, white needles. As shown below, this consists of 2:3-dinitroaceto-*p*-toluidide (compare Scott and Robinson, *loc. cit.*).

The mother-liquors from the first recrystallisation gave a residue (10.5 grams), m. p. 130—131°. Attempts made later in the hope that 2:5-dinitroaceto-*p*-toluidide could be isolated from this residue were unsuccessful, as no product of sharp melting point could be obtained even after repeated recrystallisations from alcohol.

As already stated (p. 3237), the substance, m. p. 132.5°, which Scott and Robinson (*loc. cit.*) describe as 2:5-dinitroaceto-*p*-toluidide is considered by the authors to be a mixture of this compound and the corresponding 2:3-dinitro-compound. As noted above, attempts to separate the 2:5-compound from its isomeride by recrystallisation from alcohol were invariably unsuccessful, the product being in all cases a mixture of the two isomerides, with a melting point (130—131°) closely approximating to that given by Scott and Robinson for their product. The authors' product, as described below, is converted on hydrolysis into a mixture of 2:5- and 2:3-dinitro-*p*-toluidine, from which the 2:5-dinitro-amine can be readily obtained by recrystallisation from alcohol and benzene. This product (m. p. 189—190°), when treated with acetic anhydride and a trace of sulphuric acid, gives 2:5-dinitroaceto-*p*-toluidide, which on recrystallisation from acetic anhydride is of undoubted purity and has a constant melting point of 122° (uncorr.).

(iii) *Preparation of 2:3-Dinitro-p-toluidine*.—2:3-Dinitroaceto-*p*-toluidide (19.5 grams), separated as above, was heated on the water-bath with 75 c.c. of sulphuric acid and 150 c.c. of water and, on cooling, 14 grams of the dinitrotoluidine separated as a golden-yellow, crystalline precipitate. After recrystallisation from alcohol, the pure substance was obtained in golden-yellow, rhombic prisms, m. p. 124°.

(iv) *Preparation of 2:3-Dinitrotoluene*.—The removal of the amino-group was effected in the usual way by diazotising 10 grams of 2:3-dinitro-*p*-toluidine in the presence of absolute alcohol and sulphuric acid. The product from this reaction was heated with a little nitric acid (*d* 1.42) until evolution of nitrous fumes had ceased and the mixture was then poured into water. The product, weighing 6 grams, was almost colourless and melted at 59.5—60° (uncorr.), alone or mixed with 2:3-dinitrotoluene obtained from another source. This value for the melting point is in good agreement with that found by Sirks (*Z. Ges. Spreng. Schiessstoffwesen*, 1909), namely, 59.3°. The value quoted earlier by Rozanski (*loc. cit.*) and by Grell (*loc. cit.*), namely, 63°, is probably less trustworthy than that of Sirks.

(v) *Preparation of 2:5-Dinitro-p-toluidine*.—The residue referred

to in (ii) above was hydrolysed as in (iii) and the mixture of amines so obtained was recrystallised from alcohol and then from benzene. This gave 2:5-dinitro-*p*-toluidine, m. p. 189—190°.

(vi) *Preparation of 2:5-Dinitrotoluene*.—This was prepared from 2:5-dinitro-*p*-toluidine in exactly the same way as already described under (iv) for the 2:3-compound. Twenty-five grams of the purified amine gave 11 grams of crude 2:5-dinitrotoluene which, after steam distillation and recrystallisation from light petroleum, melted at 50.2—50.5°, alone or mixed with 2:5-dinitrotoluene obtained from another source. This value agrees with that of Sirks (*loc. cit.*), namely, 50.2°. Earlier values for the melting point of this substance are 48° (Nietzski and Guitermann, *loc. cit.*; Olivieri-Tortorici, *loc. cit.*) and 52.5° (Rozanski, *loc. cit.*; Grell, *loc. cit.*).

III. Preparation of 2:5- and 3:4-Dinitrotoluenes by Oxidation of the Nitroamino-compounds with Caro's Acid.

(i) *Preparation of 2:5-Dinitrotoluene from 5-Nitro-o-toluidine*.—Twelve grams of finely powdered ammonium persulphate were added in very small quantities to 17 grams of ice-cold concentrated sulphuric acid with constant stirring, the mixture was poured on to 70 grams of crushed ice, 2.5 grams of finely powdered 5-nitro-*o*-toluidine were added, the mixture was diluted after twelve hours, and the precipitated 5-nitro-2-nitrosotoluene collected and washed. The moist substance in small portions was dissolved in an excess of fuming nitric acid heated on the water-bath, nitrous fumes being evolved. The heating was continued until the acid was no longer deeply coloured, when it was poured into an excess of water and the precipitated dinitrotoluene, m. p. 48—49°, collected (yield 1.4 grams). After recrystallisation from alcohol, the substance had m. p. 50.5°.

(ii) *Preparation of 3:4-Dinitrotoluene from 3-Nitro-p-toluidine*.—This preparation was carried out in exactly the same fashion as that described for 2:5-dinitrotoluene. Nine grams of 3-nitro-*p*-toluidine gave a yield of 7 grams of 3:4-dinitrotoluene, m. p. 59—60°. The product so obtained was practically pure. After distillation in steam, its melting point was 59.3—59.8°. This is in good agreement with the value recorded by Sirks (*loc. cit.*), namely, 58.3°. Beilstein and Kuhlberg (*loc. cit.*) record 60°, and Häussermann and Grell (*loc. cit.*) 61°.

(iii) *Preparation of 2:5-Dinitrotoluene from 5-Nitroso-o-toluidine*.—This preparation differed from the above only in the use of 5-nitroso-*o*-toluidine, obtained by Mehne's method (*loc. cit.*), as a starting substance instead of 5-nitro-*o*-toluidine. Ten grams of

5-nitroso-*o*-toluidine gave 5.6 grams of crude 2:5-dinitrotoluene, m. p. 47–48°, which was further purified as before.

The thanks of the authors are due to the Director of Artillery, War Office, for permission to publish this work.

CCCLXXXIV.—*Dihydropentindole and its Derivatives* Part I.

By WILLIAM HENRY PERKIN, jun., and SYDNEY GLENN PRESTON
PLANT.

DURING the course of our investigations on tetrahydrocarbazol and its derivatives (T., 1921, 119, 1825; this vol., p. 676), several novel and unexpected changes have been brought to light, the nature of which, in some cases, is still obscure.

In particular, the additive compounds formed when acetyl- and benzoyl-tetrahydrocarbazole are treated with nitric acid, discussed in the second paper, are of so unusual a kind that it seemed desirable to find out whether other substances resembling tetrahydrocarbazole in type are capable of undergoing changes of a similar nature.

Although the conversion of the phenylhydrazone of cyclohexanone into tetrahydrocarbazole (Baeyer, *Annalen*, 1893, 278, 106) has long been known, it seems remarkable that this interesting development of the Fischer indole synthesis does not so far appear to have been generally investigated in the case of cyclic ketones. Thus, for example, no experiments are recorded having for their object the conversion of cyclopentanone into *dihydropentindole* (I) according to the scheme: †

* The scheme of numbering the carbon atoms in pentindole adopted in this communication is the following:

† Compare, however, the condensation of cyclopentanone with *pp'*-hydrazinodiphenylmethane (Borsche and Kienitz, *Ber.*, 1910, 43, 2337).

This may be due to the fact that the above change does not take place with such facility as in the formation of tetrahydrocarbazole from the phenylhydrazone of *cyclohexanone*. A series of comparative experiments has shown, however, that a yield of dihydropentindole of as much as 45 per cent. of that theoretically possible may be obtained when quite dilute sulphuric acid is used as the condensing agent, whereas, when stronger acid or hydrochloric or acetic acid is employed, considerable hydrolysis of the hydrazone may take place and there is a tendency to the formation of much tar. It has frequently been observed that the Fischer indole synthesis takes place with much greater facility in the case of the *as*-methylphenylhydrazones than in that of the unsubstituted phenylhydrazones, and it is interesting that this experience extends also to the dihydropentindole synthesis. Experiment has shown that the condensation of the methylphenylhydrazone of *cyclopentanone* to 8-methyldihydropentindole (II) proceeds much more smoothly than that of the phenylhydrazone of *cyclopentanone* to dihydropentindole.

The main interest attaching to our investigation of the derivatives of tetrahydrocarbazole is connected with the remarkable changes which take place when the 9-acyl derivatives are treated with nitric acid. In these circumstances, 9-acetyltetrahydrocarbazole gives rise, not only to 5-nitro-9-acetyltetrahydrocarbazole (III), but also to 9-acetyl-10 : 11-dihydroxyhexahydrocarbazole (IV).

The most remarkable property of the latter substance is its conversion into the acetyl derivative of ψ -indoxylspirocyclopentane (V) on treatment with acetic anhydride.

9-Benzoyltetrahydrocarbazole is also converted by the action of nitric acid into the 5-nitro-derivative, but the main product of the interaction is 11-nitro-9-benzoyl-10-hydroxyhexahydrocarbazole (VI), a substance produced by the addition of nitric acid to the unsaturated section of the molecule.

The interesting changes which this substance undergoes on treatment with alkalis are fully discussed in the previous communication (this vol., p. 678). It was clearly of interest to investigate the action in similar circumstances of nitric acid on acetyl- and benzoyl-dihydropentindole. 8-Acetyldihydropentindole (VII),

readily obtained from the parent substance by boiling with acetic anhydride, melts at 117° and is converted by nitric acid at 45° in the presence of a large excess of acetic acid into a nitro-derivative (m. p. 195°), which is probably 4-nitro-8-acetyldihydropentindole (VIII).

On the other hand, if the interaction is carried out at a higher temperature and in the presence of only a small quantity of acetic acid, three substances are produced, (i) the nitro-derivative of melting point 195° , (ii) an isomeric nitro-derivative melting at 154° , and (iii) a substance melting at 187° which is formed by the addition of nitric acid to the unsaturated portion of the dihydropentindole molecule and is evidently 10-nitro-8-acetyl-9-hydroxy-tetrahydropentindole (IX).

It is evident, therefore, that the action of nitric acid on 8-acetyldihydropentindole differs from the action of nitric acid on 9-acetyltetrahydrocarbazole and follows a course very similar to that observed in the case of the action of nitric acid on 9-benzoyltetrahydrocarbazole.

The investigation of this matter is being continued in various directions.

EXPERIMENTAL.

Dihydropentindole (I).

When cyclopentanone (16 grams) and phenylhydrazine (20 grams) are mixed, the formation of cyclopentanonephenylhydrazone proceeds with the evolution of a considerable amount of heat. The reaction is completed by warming for a few minutes on the steam-bath, when, on cooling, the syrup solidifies. The crude product may then be recrystallised from light petroleum (b. p. $60-80^{\circ}$), from which the hydrazone separates in long, colourless prisms which melt at 55° and, on keeping, gradually decompose.

For the preparation of dihydropentindole, it is not necessary to purify the crude hydrazone. The crude hydrazone is mixed with water (360 c.c.) and sulphuric acid (20 c.c.) and heated on the

steam-bath for half an hour with frequent shaking, during which *dihydropentindole* separates as a red syrup and solidifies on cooling. The red solid is extracted with light petroleum (b. p. 60–80°), from which the substance crystallises, on cooling, in colourless prisms which melt at 108° and gradually turn pink on keeping (Found: C = 84.0; H = 7.1. $C_{11}H_{11}N$ requires C = 84.1; H = 7.0 per cent.). The yield is about 45 per cent. of that theoretically possible, but pure materials must be used, otherwise the yield is considerably diminished.

The *picrate* separates, when dihydropentindole (1.6 grams) and picric acid (2.3 grams) are dissolved in hot alcohol, in dark red needles melting at 160°.

8-Methyldihydropentindole (II).—In preparing this methyl derivative, cyclopentanone (5 grams) and *as*-methylphenylhydrazine (6.5 grams) were mixed, but no vigorous reaction took place. The mixture was heated on the steam-bath for twenty minutes and the syrupy hydrazone mixed with water (90 c.c.) and sulphuric acid (16 c.c.); the clear solution became cloudy on warming. On gradually heating to boiling, an almost colourless syrup separated which solidified on cooling and, on crystallising from alcohol, 8-methyldihydropentindole separated in pink plates melting at 43° (Found: N = 8.2. $C_{12}H_{13}N$ requires N = 8.2 per cent.). The yield was very good. The conversion of the hydrazone into 8-methyldihydropentindole can also conveniently be brought about by warming with glacial acetic acid for half an hour on the steam-bath. After cooling, the solution is mixed with much water, when a syrup separates which solidifies to a pink solid and melts at 42° without further purification. The *picrate* separates, when 8-methyldihydropentindole (1.7 grams) and picric acid (2.3 grams) are mixed in hot alcoholic solution, in very dark red needles melting at 128°.

8-Acetyldihydropentindole (VII).—This derivative is readily obtained when dihydropentindole (20 grams) is boiled with acetic anhydride (70 c.c.) for seven hours and, on cooling, the acetyl derivative separates in colourless needles which are collected and washed with a little alcohol. The yield is good and the substance practically pure, since it melts at 117°; it may be recrystallised from alcohol, from which it separates in long, silky needles having the same melting point (Found: N = 7.1. $C_{13}H_{13}ON$ requires N = 7.0 per cent.). On heating with aqueous-alcoholic potassium hydroxide for fifteen minutes and then diluting with water, dihydropentindole separates.

Action of Nitric Acid on 8-Acetyldihydropentindole.

As explained in the introduction to this paper, the course of this interaction depends on the amount of acetic acid used as a solvent and on the temperature. In the first experiment, the acetyl derivative (4 grams), dissolved in glacial acetic acid (60 c.c.), was warmed at 45° and then nitric acid (2 grams of *d* 1.4), dissolved in a little acetic acid, added. The temperature rose to 52° and, on cooling, a substance crystallising in bright yellow prisms (0.7 gram) separated. This substance melts at 195° and is probably 4-nitro-8-acetyldihydropentindole (VIII) (Found: N = 11.4. $C_{13}H_{12}O_3N_2$ requires N = 11.5 per cent.).

When the nitration was carried out in a much smaller quantity of solvent and at a somewhat higher temperature, three products separated.

8-Acetyldihydropentindole (6 grams), dissolved in glacial acetic acid (15 c.c.) at 75°, was treated with nitric acid (3 grams of *d* 1.4), dissolved in acetic acid (3 c.c.), when a vigorous reaction took place and the temperature rose to 105°. On cooling, pale yellow prisms separated and after some time, usually about two hours, a second substance began to crystallise. The solution was rapidly filtered at this point and the filtrate left to deposit the second substance. The first compound was recrystallised from alcohol, from which it separated in almost colourless prisms melting at 187° with decomposition. Analysis showed that this substance had been produced by the addition of nitric acid to dihydropentindole and it is evidently 10-nitro-8-acetyl-9-hydroxytetrahydropentindole (IX) (Found: C = 59.6; H = 5.5; N = 10.7. $C_{13}H_{14}O_4N_2$ requires C = 59.5; H = 5.3; N = 10.7 per cent.).

The second derivative, which separated from the acetic acid on standing, was recrystallised from alcohol and obtained in long, yellow plates melting at 195°. It was shown by a mixed melting point determination to be identical with the nitro-8-acetyldihydropentindole described above. In some experiments, these two substances separated together from the acetic acid solution. It was then possible to obtain a fairly good separation by fractional crystallisation from alcohol, from which the substance of melting point 195° crystallised first, leaving the other in supersaturated solution. When the acetic acid mother-liquor of the substance of m. p. 195° was kept for some days, another nitro-derivative of 8-acetyldihydropentindole separated which crystallised from alcohol in yellow needles melting at 154° (Found: N = 12.0. $C_{13}H_{12}O_3N_2$ requires N = 11.5 per cent.).

Experiments are in progress which it is hoped will establish the

constitutional formulæ of these two nitro-derivatives, and we are engaged in a detailed investigation of the products formed by the action of nitric acid on 8-acetyl- and 8-benzoyl-dihydropentindole.

One of us (S. G. P. P.) wishes gratefully to acknowledge the receipt of a grant from the Chemical Society Research Fund which has defrayed part of the cost of this investigation.

[Received, October 23rd, 1923.]

CCCLXXXV.—Nitration of *p*-Dichlorobenzene.

By HAROLD JAMES PAGE and BENJAMIN RICHARD HEASMAN.

The nitration of *p*-dichlorobenzene was first studied by Jungfleisch (*Ann. Chim. Phys.*, 1868, [iv], 15, 257), who showed that by the prolonged action, at the boiling point, of a mixture of fuming nitric and concentrated sulphuric acids the mononitro-compound first formed was converted into a mixture of dinitro-compounds. These he separated partially by fractional crystallisation from alcohol. Engelhardt and Latschinoff (*Jahresbericht*, 1870, 521) isolated two dinitrodichlorobenzenes in a state of purity from the nitration product. They showed that the less soluble (α) isomeride (m. p. 104°) was 1:4-dichloro-2:6-dinitrobenzene; to the more soluble (β) isomeride (m. p. 101°) was assigned the constitution of 1:4-dichloro-2:5-dinitrobenzene. Korner (*Jahresbericht*, 1875, 324) confirmed these results and gave the melting points of the α - and β -isomerides as 104.9° and 101.3°, respectively.

Considerably later, Morgan (*T.*, 1902, 81, 1362) studied the same nitration and found that the mononitro-compound was formed quite readily; he stated, however, that the introduction of the second nitro-group "is far less readily effected" and that it is necessary to use a mixture of 10–15 per cent. oleum and an excess of fuming nitric acid at 110–115° in order to effect the further nitration. He did not attempt to purify the crude nitration product so obtained. Hartley and Cohen (*T.*, 1904, 85, 868), working under the same conditions as Morgan, found that the separation of the two isomerides by fractional crystallisation from alcohol was difficult, and useless as a quantitative method of separation. They estimated the relative proportions of the two isomerides in the crude nitration product by reduction to diamines and separation of the latter, and concluded that the 2:6-dinitro-compound and the other isomerides were formed in the proportion of roughly 7:1. As explained below, the authors find that these conclusions are

incorrect in so far as it is possible under suitable conditions to obtain a good yield (83 per cent.) of dinitration product containing almost equal proportions of the two isomerides. These conclusions are confirmed by the work of Sané (*Inaug. Diss.*, "Untersuchungen über Nitrophenole," Berlin, 1910), of which the authors were unaware until the completion of their work.* Not long after the completion of this work, an investigation on the dinitro-derivatives of *p*-dichlorobenzene was published by Nason (*J. Amer. Chem. Soc.*, 1918, **40**, 1602). This author nitrated *p*-dichlorobenzene under the conditions used by Rutgers (*Inaug. Diss.*, Bâle, 1893), involving a long nitration in the presence of a large excess of nitric acid, and claimed to have shown that all three possible dinitro-compounds were produced, the chief product being a hitherto unnoticed substance melting at 81° which she claimed to be 1 : 4-dichloro-2 : 5-dinitrobenzene. This constitution had hitherto been assigned to the isomeride melting at 101°, but Nason concluded that the constitution of the latter substance was fixed by implication as 1 : 4-dichloro-2 : 3-dinitrobenzene.

The latter conclusion is supported by the subsequent work of Holleman and Hollander (*Rec. trav. chim.*, 1920, **39**, 435) and of Holleman, Hollander, and van Haeften (*ibid.*, 1921, **40**, 323), who showed that all three possible isomerides are present in the nitration product prepared by Jungfleisch's method (*loc. cit.*) and that the melting point of 1 : 4-dichloro-2 : 3-dinitrobenzene (synthesised by an alternative method) is 103°, this substance being identical with Jungfleisch's β -isomeride. The assignment by Engelhardt and Latschinoff (*loc. cit.*) of the constitution of 1 : 4-dichloro-2 : 5-dinitrobenzene to this substance was thus erroneous. Holleman and Hollander (*loc. cit.*) synthesised the isomeride with the latter constitution, and found that it had a melting point of 119°. Nason (*loc. cit.*) claimed that this isomeride was the chief constituent of the dinitration product, but as the substance she isolated had a melting point of only 81°, Holleman and Hollander's conclusion that this product was impure would seem to be justified.†

It would appear from the authors' results that the great preponderance of the 2 : 6-dinitro-compound in the nitration product, observed by all the earlier workers on the subject, is to be explained by the relatively drastic conditions employed by these workers in

* This investigation was carried out during the earlier part of 1917, but owing to circumstances it could not be published before.

† Holleman and Hollander's conclusion is confirmed by the recent work of Macleod, Pfund, and Kilpatrick (*J. Amer. Chem. Soc.*, 1922, **44**, 2260), who showed that Nason's product, of melting point 81°, was a molecular compound of the 2 : 3- and 2 : 6-dinitro-compounds.

the nitration. The authors have found that the dinitration is by no means difficult to effect provided a nitration mixture of a suitable composition be used, but that by employing an unnecessarily long time of nitration the product does indeed contain a large excess of the 2:6-isomeride, owing apparently to the fact that the other isomerides undergo some secondary reaction, probably oxidation, more readily than the 2:6-compound, and therefore a relatively large quantity of them is destroyed during a protracted nitration. Increase of temperature has been found to have much greater effect on the rate of nitration than on this secondary reaction. The

FIG. 1.

Influence of Temperature of Nitration on the Setting Point of the Product (Experiments E and L).

The temperature during each stage of the nitration is shown against the part of the graph referring to that stage.

conditions of dinitration worked out by the authors involve the maintenance of the nitration mixture at a temperature not exceeding 85° for one hour, by which time the initial reaction has moderated, followed by a rapid increase to 120°, which is maintained for a further half hour. The results of the experiments on which the authors' conclusions and final method are based are given in Table II. A preliminary small-scale experiment, using mixed acid of 5 per cent. water content, having given incomplete dinitration, experiments A and B were designed to find out whether a more complete nitration could be effected by using a mixed acid of lower water content; they showed that this was not the case. In

experiments B, C, and D, the proportion of nitric acid was varied; they showed that it was necessary to employ 2.5 mols. of nitric acid to 1 mol. of mononitro-compound in order to obtain a product of high setting point. In experiments E and F, the factors of time and temperature were varied within the widest possible limits; the results throw considerable light on the course of the reaction.

If the temperature coefficient of the nitration were markedly less than that of the secondary reaction, experiment E, which was a protracted one at a low temperature, should have given the better

FIG. 2.

Content of Nitric and Nitrous Acids in the Nitrating Acid at Various Times during the Nitration.

result. On the other hand, if the nitration were more accelerated than the other reaction by increase of temperature, experiment F, which was of short duration and in which the temperature was very rapidly raised, should have given the better result. It will be seen that the product from experiment F was of much higher setting point. The contrast between these two experiments is strikingly shown in Fig. 1, where the alterations in the setting point of the product are plotted against time for experiments E and L (the latter a still better example of a nitration under the same conditions of those of F). The remaining experiments G to L were devoted to a more detailed study of the effect of slight variations in the conditions from those used in experiment F, and the method finally

adopted was based on the results of these experiments. In experiment H, samples of acid were taken at the end of stages 1B, 2A, and 2B, and Fig. 2 shows the rate of consumption of nitric acid and of production of nitrous acid as determined by the analyses of these samples. It was thought that under the improved conditions of experiment F as compared with experiment C it might still be possible to obtain a product of good setting point with less than 2.5 mols. of nitric acid, but it is seen from experiment K that this was not the case; although only 2 mols. of nitric acid were used at the outset, it was found necessary to add a further 0.5 mol. of nitric acid at the end of stage II in order to bring up the setting point.

It may be pointed out that as an indication of the degree of completeness of the nitration the percentage yield is of little value taken by itself, for the increase in weight caused by the further nitration of a partly nitrated product may be equalled or even exceeded by the loss due to simultaneous oxidation. This is illustrated by a comparison of experiments B and L, where the percentage yields are almost identical whereas the setting points differ by almost 20°.

With regard to the composition of the crude nitration product, the authors obtained by the method of separation described below only the 2 : 6- and 2 : 3-isomerides in a state of purity, and since the quantities of these obtained accounted for almost the whole of the product, the quantity if any of the 2 : 5-isomeride produced by the authors' method of nitration must have been very small.

Of the three possible isomerides only one, namely, the 2 : 6-dinitro-compound, has a labile chlorine atom. The amount of this constituent can accordingly be estimated by treatment of the crude nitration product with alcoholic ammonia in the cold for one or two days and titration of the ammonium chloride produced. An estimation by this method gave a value of 41.5 for the percentage of the 2 : 6-dinitro-compound.

Another method of studying the composition of the mixture is by thermal analysis. The fusion curve of a binary mixture of the pure 2 : 3- and 2 : 6-dinitro-compounds constructed from the data in Table I is of the usual shape. The eutectic mixture contains

TABLE I.

Freezing Points of Mixtures of 2 : 6-Dinitro- and 2 : 3-Dinitro-p-dichlorobenzene.

2 : 6-Dinitro-compound %..	0	20	30	35	40	41	45
F. p.	101.2°	86.5°	79.5°	75.5°	71.7°	73.0°	76.5°
2 : 6-Dinitro-compound %..	50	60	70	80	90	100	
F. p.	80.0°	87.5°	93.0°	98.5°	103.0°	106.0°	

40 per cent. of 2 : 6-dinitro-*p*-dichlorobenzene and freezes at 71.6°. As the top setting point of the crude nitration product, 69.5°, is only slightly inferior to the freezing point of the eutectic mixture, and as the percentage of the 2 : 6-dinitro-compound in the nitration mixture as determined by the method described above, namely, 41.5 per cent., is only slightly higher than that of the same compound in the eutectic, it would appear probable that the percentage of substances other than the 2 : 3- and 2 : 6-dinitro-compounds in the mixture is small.

The agreement between the authors' figure for the amount of 2 : 6-isomeride and that found by Sané (*loc. cit.*), namely 48.6 per cent., is tolerably satisfactory when it is remembered that Sané's method, which was to weigh the crude product of the action of aniline on the nitration product, would probably be liable to give high results.

EXPERIMENTAL.

1. *Nitration of p-Dichlorobenzene.* 1 : 4-Dichloro-2-nitrobenzene.—In conformity with the results of earlier investigators, no difficulty was experienced in effecting this nitration. Nitrating acid of the following composition : H_2SO_4 58, HNO_3 36, H_2O 6 per cent. was used. To a quantity of this acid containing only a slight excess of nitric acid beyond that theoretically required, *p*-dichlorobenzene was added gradually, the whole being stirred continuously; the rate of addition was so regulated that the temperature did not exceed 70°. When the whole of the charge had been added, the mixture was heated at 100° for fifteen to thirty minutes. The nitration product was then separated and adhering acid removed by passing steam into the molten substance, beneath water. The crude, washed product so obtained had a setting point of 52° and was practically pure 1 : 4-dichloro-2-nitrobenzene (the melting point of the pure substance is 54.5°).

2. *Experiments on the Nitration of 1 : 4-Dichloro-2-nitrobenzene.*—Twelve separate nitrations of this substance were carried out in which the influence of composition of nitrating acid and of the time and temperature of the nitration were studied. Particulars of the experiment are shown in Table II. The crude mononitro-compound obtained as above was used throughout; the nitrations were all carried out in a small iron nitrating pot with a working capacity of 1½ litres, provided with mechanical stirring and jacketed so that it could be heated with high-pressure steam or cooled with water. The results of these experiments have been discussed on pp. 3249–3251.

3. *Method finally adopted for the Nitration of 1 : 4-Dichloro-2-nitrobenzene.*—Nineteen hundred grams of nitrating acid of the following composition : H_2SO_4 78.5, HNO_3 16.7, H_2O 5.1 per cent.

(obtained by mixing 96 per cent. sulphuric acid and 90 per cent. nitric acid in the proportions of 2,400 c.c. to 665 c.c.) were placed in the nitrating pot and heated at 60°. Four hundred grams of crude 1:4-dichloro-2-nitrobenzene were added gradually in the course of twenty minutes, with constant stirring, the temperature being kept below 75° by water cooling. The mixture was then heated at 75–85° for forty minutes, after which the temperature was raised to 120° in fifteen minutes and this temperature maintained for a further eighty minutes. A sample of the crude, washed product showed a setting point of 65°. The temperature was allowed to fall to 80°, after which 275 c.c. of water were slowly run in with stirring as before, the temperature being allowed to rise to 90°. The mixture was allowed to settle and the molten nitration product separated and washed by covering it with boiling water and blowing steam through it until the wash waters were no longer acid. It was then allowed to solidify, and the solid cake wiped dry from adhering moisture and dried in the molten state at 100° for a few hours. The setting point of the product was 69.5° and the yield was 83 per cent. of the theoretical.

4. *Description of the Crude Nitration Product.*—The product obtained as above is a practically white solid of very hard consistency. The vapours produced by the molten substance are extremely irritating to the eyes, nose, and throat. An irritating rash is liable to develop if the solid substance or its solution or vapour come into contact with the skin. The density of the fused solid is d_{25}^{25} 1.72. When the fused substance is slowly cooled, the liquid clouds at 69.6° and finally gives a setting point of 69.5°.

5. *Separation and Purification of 1:3-Dichloro-2:6-dinitrobenzene and 1:4-Dichloro-2:3-dinitrobenzene.*—The separation and isolation in a state of purity of the two isomeric dinitro-compounds at first presented some difficulties. As already noted by Hartley and Cohen (*loc. cit.*), the difference in the solubilities of the two isomerides in alcohol was so small that their separation by fractional crystallisation from this solvent was a very tedious and protracted operation. A method whereby the separation could be rapidly and conveniently effected was found in the fractional precipitation of the two isomerides from their benzene solution by means of light petroleum. The crude nitration product was dissolved in benzene to form a concentrated solution. Sufficient light petroleum was added to precipitate about half of the dissolved substance, which was filtered off. The material in the mother-liquor was recovered. Each of the two fractions was then separately dissolved in benzene and precipitated with light petroleum as before. The mother-liquor from the treatment of the less soluble fraction

was evaporated and the residue added to the precipitate from the treatment of the more soluble portion. This process was continued two or three times until the products consisted of a less soluble and a more soluble fraction, the melting points of each of which were over 95°, together with a small quantity of residues in the mother-liquors. These two fractions were then separately recrystallised from carbon tetrachloride. The purified product obtained from the less soluble fraction had a constant melting point of 105–106° and was thus 1 : 4-dichloro-2 : 6-dinitrobenzene, whilst similar recrystallisation of the other fraction readily gave a product with a constant melting point of 101–102°. These values are in good agreement with those found by Engelhardt and Latschinoff (*loc. cit.*), Hartley and Cohen (*loc. cit.*), and Holleman and Hollander (*loc. cit.*). These pure substances were isolated in practically equal quantities and the amount of material remaining in the mother-liquors after as much as possible of the two isomerides had been separated in a state of purity was very small. This residual material was not specially examined for the presence of 1 : 4-dichloro-2 : 5-dinitrobenzene, but if this substance were present it must have been in considerably smaller quantity than the other isomerides. It may also be noted that the 2 : 6-isomeride is more volatile than the 2 : 3- and that if the crude substance is kept in the molten condition for long, the loss of the 2 : 6-isomeride is sufficient to bring about appreciable changes in the composition and the setting point of the mixture. This had particularly to be borne in mind in the experiments from the results of which the fusion curve was constructed.

Summary.

The authors have studied the nitration of *p*-dichlorobenzene and have shown that when the nitration is conducted in two stages the 1 : 4-dichloro-2-nitrobenzene first produced can after separation be quite readily further nitrated to give a mixture consisting almost entirely of 2 : 6- and 2 : 3-dinitro-1 : 4-dichlorobenzenes in about equal proportions.

A convenient method for the isolation of these two isomerides in a state of purity is described.

In conclusion, the authors wish to express their thanks to the Director of Artillery for permission to publish this work.

CCCLXXXVI.—*The Partial Pressures of Sulphuric Acid over Concentrated Aqueous Solutions of the Acid at High Temperatures.*

By JOHN SMEATH THOMAS and ALEXANDER GEORGE RAMSAY.

MEASUREMENTS of the total vapour pressures of solutions of sulphuric acid have been made by many workers. Regnault (*Ann. Chim. Phys.*, 1845, [iii], 15, 179) determined the vapour pressures of acids ranging in concentration from 24 to 84 per cent. over the temperature range 5–35°. This work was extended to more dilute acids by Helmholtz (*Wied. Ann.*, 1886, 27, 532), whose measurements extended over the temperature range 0–50°. Further determinations were made by Sorel (*Z. angew. Chem.*, 1889, 2, 272) for temperatures up to 95°, and by Dieterici (*Wied. Ann.*, 1891, 42, 513; 1893, 50, 47; 1897, 62, 616) at 0° for acids of widely different concentrations.

All these measurements were carried out at temperatures below 100°, and in no case did the concentration of the acid exceed 84 per cent. The vapour pressure measured was the total vapour pressure, the authors assuming that the vapour phase consisted of water only. The work of the present authors shows this assumption to have been substantially justified. Even with the delicate methods of measurement employed by them no vapour pressure due to the acid could be detected under these conditions.

The same assumption was made, however, by Briggs (*J. Soc. Chem. Ind.*, 1903, 22, 1275) and by Burt (*T.*, 1904, 90, 1339) in their measurements of the vapour pressures of more concentrated solutions of sulphuric acid at higher temperatures. Acids of concentrations up to 95 per cent. were examined, the highest temperature at which determinations were made being 235°. Burt does point out, it is true, that at the higher temperatures, and especially in the case of very concentrated solutions, the acid itself may exert an appreciable vapour pressure; nevertheless, in his calculations, the vapour is assumed to consist of water only.

The question of the loss of acid which occurs during the concentration of sulphuric acid has been investigated by Webster and MacDonald ("Manufacture of Acids and Alkalis," Lunge and Cumming, vol. I, p. 212). They state that "when precautions were taken to prevent acid being carried over mechanically, sulphuric acid could be distilled so that there was no sulphuric acid in the distillate from even 90 per cent. acid; only after the concentration of the liquid being distilled exceeded 96 per cent. did that of the distillate exceed 5 per cent."

The experiments in this paper do not support this conclusion. That concentrated sulphuric acid exerts an appreciable acid partial pressure even at the ordinary temperature is proved by the fact that filter-paper when kept for several months over concentrated sulphuric acid in a desiccator becomes charred. In the present communication, it is shown that in the case of solutions of sulphuric acid in which the acid concentration exceeds 85 per cent., the partial pressure of the acid is measurable at temperatures above 200°. No information is available regarding the magnitude of this pressure and therefore this investigation was undertaken with the primary object of obtaining accurate data concerning the acid partial pressures of concentrated solutions of sulphuric acid at high temperatures. This question has considerable interest from the theoretical point of view, and it is hoped that the results obtained may also be of value to those engaged in the sulphuric acid industry.

As the result of preliminary experiments made with the object of ascertaining the most suitable means by which the small acid vapour pressures involved could be measured, it was decided to employ the dynamical method of aspirating a known volume of air through so large a volume of acid that the change of concentration produced by the removal of vapour could be neglected, the acid being kept throughout the determination at constant temperature. The acid carried over was then estimated by a method presently to be described, and from the data thus obtained the partial pressure of the acid was calculated, the formula of Foote and Scholes (*J. Amer. Chem. Soc.*, 1911, **33**, 1309) being used for this purpose :

$$p = 760v_2/(v_0 + v_2),$$

where $v_2 = 22.4W/M$, is the volume occupied by the sulphuric acid vapour alone, W being the weight of acid in the volume of air employed, and M its molecular weight, whilst v_0 , the volume of air used, reduced to *N.T.P.*, is given by the expression

$$v_0 = 273v(p_1 - p_2)/760(T + t),$$

in which v is the unreduced volume of air and p_1 the barometric pressure, p_2 being the vapour tension of the water over which the air is collected and measured.

This method of determining vapour pressures has been employed by numerous workers. Linebarger (*J. Amer. Chem. Soc.*, 1895, **17**, 615) used it and also subjected it to a critical examination. He concluded that the method could be applied to mixtures of liquids with quite satisfactory results. The method was also employed by Jones, Lapworth, and Lingford (*L.*, 1913, **103**, 252) in their investigation of the influence of water on the partial pressures of

hydrogen chloride above its alcoholic solutions, and Tammann (*Wied. Ann.*, 1888, **33**, 322), Abegg and Riesenfeld (*Z. physikal. Chem.*, 1902, **40**, 84), Foote and Scholes (*loc. cit.*), R. Thomas (*J. Soc. Chem. Ind.*, 1922, **41**, 33), and many others have used it with excellent results.

The method has, however, been severely criticised, notably by Carveth and Fowler (*J. Physical Chem.*, 1904, **8**, 313), but Perman (*Proc. Roy. Soc.*, 1904, **72**, 72; *J. Physical Chem.*, 1905, **9**, 96), in a careful investigation of the subject, satisfactorily met the various objections raised by them, and there appears to be no doubt that, provided proper precautions are taken, this method is capable of yielding sufficiently accurate results.

EXPERIMENTAL.

The apparatus employed is depicted in Fig. 1. A current of air from the aspirator, *A*, was dried and freed from carbon dioxide

FIG. 1.

by passing it first over calcium chloride contained in the tower, *B*, then through the tube, *C*, which was about 30 inches long and contained soda-lime, whilst finally it was bubbled through concentrated sulphuric acid in the wash-bottle, *D*. The dry air was then passed through sulphuric acid of the concentration under investigation contained in the saturators, *E* and *F*, which were completely immersed in the thermostat. The saturators were of the type devised by Gahl (*Z. physikal. Chem.*, 1900, **33**, 178). The purified air entered the vessel by the small pear-shaped bulb, into which acid could also flow through a number of holes with which its walls were pierced. It then passed up the spiral tube in a series of bubbles, acid being carried with it. In this way, close contact between air and liquid was maintained for a considerable time, so that the former became saturated with the vapour while the acid was kept of uniform concentration throughout. Preliminary experiments showed that saturation of the air with vapour could be obtained when the rate

of flow of the air was as great as 1 litre per hour; in the actual measurements this rate never exceeded 0.5 litre per hour.

Glass tubes terminating in capillaries were sealed to the bottoms of the saturators and by means of these the vessels were charged with acid, and samples were from time to time withdrawn for analysis. It was found impracticable to use glass taps on account of the high temperature, which caused the taps to stick. Two saturators were used, each containing about 120 c.c. of acid. The contents were analysed before and after each experiment. In some cases, the strength of the acid in the first vessel was found to diminish slightly, but no variation in the concentration of the acid could be detected in the second vessel.

In order to prevent acid from being carried over with the air in the form of mist, the air was passed through a tube, *G*, packed with glass wool, before being led through the water in which the acid vapour was absorbed and estimated. To guard against the possibility of adsorption of acid on the glass wool, the first litre of air passed through the saturators was rejected. This was found to allow sufficient time for the vapour to come into equilibrium with the glass-wool. The acid which collected in this tube was removed after each experiment by heating the tube strongly; this was necessary because this acid was, in general, different in concentration from the acid in the saturators.

The removal of the acid vapour from the air was effected by passing the latter through conductivity water contained in a vessel, *H*, similar to the saturators already described. The tube leading from the vessels in the thermostat to this absorbing vessel was heated electrically in order that premature deposition of the acid as the air cooled should not occur. One such vessel containing about 100 c.c. of water was found to be sufficient for the complete removal of the acid. After the acid vapour had been absorbed, the air was collected by displacement of water in a vessel, *J*, the volume of which had previously been accurately determined. In this way, the volume of air passed through the saturators was found.

The temperatures at which measurements of the partial pressure were required ranged from 140° to 260°, and therefore a thermostat had to be constructed large enough to contain the saturators and capable of maintaining any desired constant temperature within the range mentioned. In the earlier experiments, an electrically heated oil-bath was used. This sufficed for the maintenance of temperatures up to 220°, but it was ultimately discarded for several reasons. In the first place, it was desirable that determinations should be made at higher temperatures. Then it was found difficult to keep the temperature constant, as, probably on account of partial "crack-

ing" of the oil used in the temperature regulator, this instrument was quite untrustworthy. Moreover, occasional breakages were unavoidable, and much loss and delay resulted when such breakages occurred and heated oil became mixed with the hot concentrated acid.

It thus became necessary to construct a thermostat of a different type, and, finally, an electrically heated air-bath was decided upon. This consisted of an inner copper vessel, 22 inches long, 15 inches high, and 15 inches deep, enclosed in a shell of asbestos slate. The space separating the inner and outer vessels, about 2 inches in depth, was packed with asbestos wool, and this insulating material was also packed between the walls of the double-walled doors with which the front of the oven was closed.

The inner shell of the thermostat was covered with asbestos paper, on which four separate and complete circuits of nichrome wire were wound. Any or all of these circuits could be used, according to the temperature desired, so that when lower temperatures were required a much smaller external resistance was sufficient to regulate the current strength and power was thus economised. This method of winding was preferable to winding in separate sections in series, since unequal heating was avoided. Each of the four circuits carried a current of 3 amperes when connected with the mains at 230 volts, and any desired temperature up to 350° could be obtained. At the outset the temperature was regulated by means of a mercury regulator, but this was found to be unnecessary. The current was found to be sufficiently steady to allow of the regulator being removed, and once thermal equilibrium was established, usually in the course of two or three hours, the temperature variation never exceeded $\pm 0.25^\circ$.

At each end of the bath, holes were made through which the tubes connecting the vessels inside the bath with the rest of the apparatus passed, whilst in the top two similar holes were provided to carry thermometers. The interior of the thermostat was easily accessible, so that repairs and replacements could be quickly effected. The loss of heat was surprisingly small; in the course of experiments at the highest temperatures employed, the temperature of the outer walls did not rise above 50°. This thermostat gave every satisfaction and it was used in the majority of the measurements recorded in this communication.

In order to estimate the amount of sulphuric acid vapour removed by the air, the acid was absorbed, as has already been mentioned, in carefully purified water, the specific conductivity of which was never greater than 0.000003 mho and therefore, except in the case of the most dilute solutions, could safely be neglected. The result-

ing acid solution was washed into a measuring flask and made up to a known volume, usually 250 c.c.

The concentration of the acid in these solutions was far too small to be estimated by the usual methods. The turbidity produced by the addition of barium chloride could only be seen in long columns of the liquid. The specific conductivity of these very dilute solutions was therefore determined. The cell employed, which was immersed in a thermostat at $25^{\circ} \pm 0.25^{\circ}$, was of well-seasoned glass, and the electrodes, circular in shape and 1 cm. apart, were slightly coated with platinum black. The cell constant was found to vary to a small extent, probably because of some slight disturbance of the electrodes, and therefore it was determined at frequent intervals. The null point was obtained by the use of a high-resistance telephone and the apparatus was found to be sensitive to 0.5 mm. on the bridge.

Fortunately, in the case of sulphuric acid, the relationship between the specific conductivity and the concentration is known with great accuracy. Whetham (*Proc. Roy. Soc.*, 1905, **76**, [A], 580) has determined the specific conductivities of sulphuric acid solutions for concentrations lying between 0.0018*N* and 0.000024*N* with extreme accuracy and values of this constant for solutions the normality of which lay between 0.01 and 0.002 were taken from the Smithsonian Tables (1920, p. 346). In both cases, the values given refer to a temperature of 18°. They were corrected for 25°, the temperature coefficient being 0.0125 for concentrations down 0.01*N* and 0.0159 in the case of more dilute solutions.

From these data a graph was constructed, and from this the concentration corresponding to the observed specific conductivity was read. In the case of the most dilute solutions the conductivity of the water was subtracted from the observed conductivity of the solution.

This method of estimation is naturally of no value if reduction of the acid takes place either by traces of organic matter or from any other cause and determinations in which any trace of charring was observed were invariably rejected. In addition, after the conductivity had been determined, sulphur dioxide and other volatile substances were expelled from the liquid by boiling and the conductivity was then re-determined. As a rule, a slight increase in the conductivity was observed; if, on the other hand, it was found to decrease, indicating that slight reduction of the acid had occurred, the experiment was rejected.

The sulphuric acid used in the investigation was the purest redistilled acid obtainable. It was free from compounds of nitrogen, and was found to contain 97.58 per cent. of H_2SO_4 . Acids

of lower concentration were prepared from it by diluting it with distilled water, whilst more concentrated acids were prepared by the addition to it of sulphur trioxide, prepared by the distillation of fuming sulphuric acid. The sulphur trioxide was prepared separately and added to the concentrated acid, instead of distilling it directly into the acid, because, when the latter course was followed, traces of sulphur dioxide were formed which dissolved in the acid and thus vitiated the results subsequently obtained.

The concentrations of the acid solutions were estimated gravimetrically in the usual way. It was found impossible to obtain consistent results by volumetric methods, but a constant check was kept on the analyses by means of the specific gravity balance.

The Variation of the Acid Partial Pressure with the Temperature.

The concentrations of the acids investigated lay between 86.76 per cent. of H_2SO_4 and 99.62 per cent. of H_2SO_4 . The partial pressures observed are collected in Table I.

In the case of the more dilute acids, measurements could only be made over a small range of temperature, for, in the first place, they have comparatively low boiling points, whilst, at temperatures below 200° , the acid partial pressures were so small that they could not be determined with accuracy.

On plotting the observed partial pressures against temperature the curves reproduced in Fig. 2 were obtained. In these curves three different pressure scales have been employed, so that they are not directly comparable. The scales have been indicated on the diagram. This procedure was necessary on account of the low acid partial pressures of the dilute acids. In the construction of the curves relating to the two most concentrated acids investigated, the same pressure scale has been used and the similarity of the

curves to one another is readily seen. In every case, the relation between the partial pressure and the temperature is almost linear at low temperatures, but with increasing temperature dp/dt , the rate of increase of the partial pressure, also becomes greater.

Various empirical expressions have been suggested for the relationship between the temperature and the partial pressures of the components of liquid mixtures. Perman (T., 1903, 88, 1168)

FIG. 2.

and that for solutions of ammonia in water this relationship can be represented with considerable accuracy by the equation

$$\log p = \alpha + \beta T + \gamma T^2 + \dots \text{etc.},$$

α , β , and γ being constants, the numerical values of which can be found by taking a series of related values of p and T from the curve and solving the simultaneous equations thus obtained.

This equation was applied to the curves shown in Fig. 3, the first and following terms on the right-hand side of the expression being neglected. The constants obtained in the manner described above are as follows:

99.62% H_2SO_4 :	$\alpha = -$	6.3258,	$\beta = 0.0145$.
97.58% H_2SO_4 :	$\alpha = -$	7.1161,	$\beta = 0.0158$.
91.43% H_2SO_4 :	$\alpha = -$	15.8923,	$\beta = 0.0317$.
86.76% H_2SO_4 :	$\alpha = -$	16.4089,	$\beta = 0.0324$.

Using these values for α and β , the partial pressures of sulphuric acid in solutions of the concentrations under investigation were calculated for a series of temperatures from 160° to 260°. The results obtained are shown in Table II, the experimental values taken from the smoothed curves being also given.

In general, the agreement between the observed and the calculated values for the acid partial pressures is fairly good, but at temperatures considerably different from those used in calculating the constants the difference between the observed and the calculated pressure becomes steadily greater. This is particularly noticeable in the case of the more concentrated solutions at low temperatures.

The variation of the vapour pressure with the temperature is also given by Rankine's formula,

$$\log p = \alpha - \beta/T - \gamma/T^2 \dots \text{etc.},$$

where, as before, α , β , and γ are constants. In this expression the third term may generally be neglected, and only the first two terms have been considered here. The applicability of the formula is readily tested by plotting $\log p$ against $1/T$. The resulting graph should be a straight line.

The $\log p$, $1/T$ curves reproduced in Fig. 3 show quite clearly that, for the concentrations investigated, Rankine's equation does represent the relationship between the acid partial pressure and the temperature with fair accuracy over a considerable range of temperature. The constants α and β were calculated in the same way as before, the following values being obtained:

99.62% H_2SO_4 :	$\alpha = 7.8315$,	$\beta = 3595$.
97.58% H_2O_4 :	$\alpha = 8.5993$,	$\beta = 3899$.
91.43% H_2SO_4 :	$\alpha = 15.3259$,	$\beta = 8183$.
86.76% H_2SO_4 :	$\alpha = 17.7644$,	$\beta = 8962$.

Little importance can be attached to the curve for the 86.76 per cent. acid or to the lower portion of that relating to 91.43 per cent. H_2SO_4 ; the pressures involved are so small that very large relative errors may be introduced in reading them from the temperature-vapour pressure curves. The pronounced deviation from the

FIG. 3.

straight line in the case of the two more concentrated solutions at high temperature is, however, of interest. Rankine's equation, being an approximate form of the Clapeyron equation, should be generally valid and an explanation must be sought for the deviation under discussion. Such a deviation would be produced if, at high temperatures, heat were absorbed by some process other than vaporisation, as, for example, dissociation of the acid, as a result of which the equilibrium

is established in the vapour.

Assuming this to be the case, the degree of dissociation may be calculated. Thus, the observed partial pressure ($p_{\text{H}_2\text{SO}_4} + p_{\text{SO}_3}$)

of 99.62 per cent. acid at 240° is 13.4 mm. The partial pressure calculated by means of Rankine's formula is, however, only 12.8 mm., whence the degree of dissociation is 0.045. At 250° , this increases to 0.09, whilst at 230° it would appear that no measurable dissociation occurs.

The Variation of the Acid Partial Pressure with the Concentration.

The vapour pressure-concentration isothermals are shown in Fig. 4. The increase of vapour pressure with increasing concentration is small in the case of solutions containing less than 92 per cent. of H_2SO_4 , and the relationship appears to be approximately linear. In the neighbourhood of the concentration mentioned,

however, the curve undergoes a marked change of direction and the acid partial pressure then increases much more rapidly.

Of the various formulæ which have been proposed to express the relationship between the composition of a liquid mixture and the partial pressures of its constituents, the best known is that of Duhem and Margules,

$$\frac{d \log p_A}{d \log M} = \frac{d \log p_B}{d \log (1-M)},$$

where p_A and p_B are the partial pressures of the vapours and M and $(1-M)$ represent their molecular fractional concentrations in the liquid phase.

Unfortunately, neither this expression nor that of Zawidzki (*Z. physikal. Chem.*, 1900, 35, 129) can be applied to the case under discussion, because the partial pressures of the water vapour have

not yet been determined. The measurements of Briggs and of Burt (*loc. cit.*) give values for two concentrations only at the required temperatures and these two points are insufficient for the slopes of the water vapour isothermals to be found.

Lehfeldt (*Phil. Mag.*, 1895 [v], 40, 402) has derived an equation which can be applied even when the slopes of the partial pressure isothermals are unknown.

$$p = \frac{Bq^r\pi_A + A^r\pi_B}{(Bq + A)^r},$$

where p is the total vapour pressure, π_A and π_B the vapour pressures of the pure constituents of the mixture at the temperature under consideration, A and B their molecular weights, q the ratio of the masses of the two substances in the liquid, and r is a constant.

In order to test the applicability of this expression, $\pi_{\text{H}_2\text{SO}_4}$ was first of all determined for each temperature by extrapolation from the isothermals and, using these values, r was then calculated for a series of mixtures. The values of r obtained in this way are not at all constant, but diminish steadily with increasing concentration, and therefore Lehfeldt's equation does not hold for concentrated solutions of sulphuric acid in water. This is not at all surprising. Lehfeldt himself points out that even in water-alcohol mixtures water behaves in an anomalous manner. In the present instance, it is very improbable that the molecular weights of the components are normal, and the question is further complicated by the formation of compounds and by the dissociation of the acid, which undoubtedly occurs at the highest temperatures at which observations were made.

The Latent Heat of Vaporisation of Sulphuric Acid.

From the variation of the vapour pressure with the temperature, the latent heat of vaporisation may be calculated by means of the Clausius-Clapeyron equation. Assuming that the vapour obeys the gas laws and that the specific volume of the liquid can be neglected, this may be written

$$M\lambda = \frac{RT^2}{p_1} \cdot \frac{dp_1}{dt},$$

λ being the latent heat of vaporisation, p_1 the vapour pressure of the solution, and M the molecular weight of the vapour. This expression is applicable to a constituent of a binary mixture, in which case p_1 denotes the partial pressure of that constituent.

If it is further assumed that λ remains constant over the small range of temperature $T_2 - T_1$, the above equation becomes on integration

$$M\lambda = 2.303 R \frac{T_2 T_1}{T_2 - T_1} \log_{10} \frac{p_2}{p_1}.$$

In calculating the latent heat of sulphuric acid by means of this expression, three different values of T_1 and T_2 were taken in each case, these being 20° , 10° , and 5° above and below the temperature for which the calculation was being made. The values for the latent heat obtained in this way agreed fairly well. They are given in Table III. At temperatures below 200° , the partial pressures become so small and the relative error in reading them from the curve is consequently so great that calculations of the latent heat for temperatures lower than this can have little value. This consideration also applies to the more dilute acids at all temperatures.

TABLE III.

Temp.	$M\lambda(99.62\% \text{ H}_2\text{SO}_4)$	$M\lambda(97.58\% \text{ H}_2\text{SO}_4)$	$M\lambda(91.43\% \text{ H}_2\text{SO}_4)$

200	$\left. \begin{array}{l} 16,200 \\ 15,600 \\ 16,400 \end{array} \right\} 16,070$	$\left. \begin{array}{l} 16,400 \\ 15,800 \\ 16,470 \end{array} \right\} 16,220$	—

The heat of vaporisation of sulphuric acid appears to increase with dilution of the acid, that of the water decreases.

The variation of the latent heat with the temperature is more interesting. From theoretical considerations, it should diminish with increasing temperature until at the critical temperature its value becomes zero. Sulphuric acid does not behave in this way. Below 220° the value of $M\lambda$ appears to be fairly constant, but from this point it increases slowly with increasing temperature.

This phenomenon can only be produced, as has already been pointed out, by the existence of some other heat-absorbing process side by side with the evaporation of the liquid. The dissociation of the acid would be such a process.

In the dissociation equilibrium, if P represent the observed partial pressure, $p_{\text{H}_2\text{SO}_4}$ the true partial pressure of sulphuric acid, and p_{SO_3} the pressure of the sulphur trioxide produced,

$$P = p_{\text{H}_2\text{SO}_4} + p_{\text{SO}_3},$$

and

$$K_p = \frac{p_{\text{H}_2\text{O}} \cdot p_{\text{SO}_3}}{p_{\text{H}_2\text{SO}_4}} \quad \dots \quad (1)$$

Now if $M\lambda_1$ = heat of vaporisation of one gram-mole of sulphuric acid from the liquid, $M\lambda_2$ = heat of vaporisation of one gram-mole of water from the liquid, and Q_p = heat absorbed when one gram-mole of sulphuric acid dissociates at constant pressure,

$$\frac{d \log p_{\text{H}_2\text{SO}_4}}{dT} = \frac{M\lambda_1}{RT^2}, \quad \frac{d \log p_{\text{H}_2\text{O}}}{dT} = \frac{M\lambda_2}{RT^2}, \quad \text{and} \quad \frac{d \log K_p}{dT} = \frac{Q_p}{RT^2}.$$

Now, from equation (1)

$$\frac{d \log p_{\text{SO}_3}}{dT} = \frac{d \log K_p}{dT} + \frac{d \log p_{\text{H}_2\text{SO}_4}}{dT} - \frac{d \log p_{\text{H}_2\text{O}}}{dT}.$$

But

$$\begin{aligned} \frac{d \log P}{dT} &= \frac{1}{P} \cdot \frac{dp_{\text{H}_2\text{SO}_4}}{dT} + \frac{1}{P} \cdot \frac{dp_{\text{SO}_3}}{dT} \\ &= \frac{p_{\text{H}_2\text{SO}_4}}{P} \cdot \frac{d \log p_{\text{H}_2\text{SO}_4}}{dT} + \frac{p_{\text{SO}_3}}{P} \cdot \frac{d \log p_{\text{SO}_3}}{dT} \\ &= \frac{p_{\text{H}_2\text{SO}_4}}{P} \cdot \frac{M\lambda_1}{RT^2} + \frac{p_{\text{SO}_3}}{P} \left[\frac{Q_p}{RT^2} + \frac{M\lambda_1}{RT^2} - \frac{M\lambda_2}{RT^2} \right] \\ &= \frac{M\lambda_1}{RT^2} + \frac{p_{\text{SO}_3}}{P} \cdot \frac{Q_p}{RT^2} - \frac{p_{\text{SO}_3}}{P} \cdot \frac{M\lambda_2}{RT^2}. \end{aligned}$$

$$RT^2 \frac{d \log P}{dT} = M\lambda_1 + \frac{p_{\text{SO}_3}}{P} Q_p - \frac{p_{\text{SO}_3}}{P} M\lambda_2.$$

And since

$$RT^2 \frac{d \log P}{dT} = M\lambda$$

and p_{SO_3}/P is the degree of dissociation of the acid it follows that

$M\lambda$ = Heat of evaporation of one gram-molecule of sulphuric acid + the heat of formation of p_{SO_3}/P gram-molecules of sulphur trioxide — the heat of evaporation of p_{SO_3}/P gram-molecules of water from the liquid.

Now for 99.62 per cent. sulphuric acid at 240°, $M\lambda_1$, the mean constant value in the foregoing calculation, = 16,100 cals.

The value of Q_p is obtained from the following data :

SO_3 (solid) + H_2O (liq.) = H_2SO_4 (liq.) + 21,500 cals. (Thomson).

SO_3 (gas) = SO_3 (solid) + 11,790 cals. (Berthelot).

H_2O (gas) = H_2O (liq.) + 9684 cals. (Dieterici and others).

H_2SO_4 (liq.) = H_2SO_4 (gas) — 16,100 cals. (from present work).

Whence Q_p = 26,600 cals.

The value of the heat of vaporisation of water from the sulphuric acid was calculated from the data given by Burt (*loc. cit.*) for the partial pressure of water over 96 per cent. sulphuric acid at 230°.

The value of $M\lambda_2$ thus obtained is 18,000 cals.

Using these values,

$$M\lambda = 16,100 + 0.045 \times 26,600 - 0.045 \times 18,000 = 16,500 \text{ cals.}$$

$M\lambda$, calculated directly from the partial vapour pressure curve, = 18,000 cal.

At 250°, the value calculated for $M\lambda$ in this way is 16,870 cal. as against 17,880 cal., the value obtained by the direct application of the Clausius-Clapeyron equation to the vapour pressure curve.

It would seem that the abnormally high partial pressures are not entirely accounted for by the dissociation of the acid. It should be pointed out, however, that the accuracy of the value for $M\lambda_2$ used in making this correction is extremely doubtful. Burt's measurements were made on 96 per cent. acid at 230° and it is questionable how far values based on these conditions are applicable to 99.62 per cent. acid at 240° and 250°. Unfortunately, however, no other observations are available.

Summary.

1. The partial pressures of sulphuric acid vapour over sulphuric acid-water mixtures containing from 86 to 99.6 per cent. of sulphuric acid have been determined at temperatures from 160° to 260°, the method employed being that of bubbling a slow stream of air through the acid, absorbing the acid vapour thus removed in conductivity water, and determining the amount of acid removed by measuring the conductivity of the resulting solutions.

2. The partial pressures are represented with considerable accuracy, except at the highest temperatures, by the expressions

$$\begin{aligned}\log p &= \alpha + \beta T + \gamma T^2 + \dots \text{etc.} \\ \log p &= \alpha - \beta/T - \gamma/T^2 - \dots \text{etc.}\end{aligned}$$

3. An attempt has been made to apply Leffeldt's equation to the partial pressure-concentration isothermals.

4. Dissociation of the acid is shown to occur at temperatures above 220°. The degree of dissociation calculated for 250° is 0.09.

5. The latent heat of vaporisation of sulphuric acid has been calculated from the experimental results and an attempt made to account for the abnormally high values obtained at temperatures above 230° by the introduction of the heat effects produced by the dissociation of the acid.

In conclusion, the authors desire to express their thanks to Prof. E. C. Baly, C.B.E., F.R.S., for providing the facilities for carrying out this work and to Mr. R. O. Griffiths, M.Sc., for much valuable advice during its progress.

[Received, August 7th, 1923.]

CCCLXXXVII.—*Studies in the Organic Polysulphides.*
Part I. The Action of Anhydrous Potassium
Pentasulphide on some Alkyl Halides.

By RICHARD WILLIAM RIDING and JOHN SMEATH THOMAS.

THE action of aqueous solutions of the polysulphides of the alkali metals on alkyl halides has been studied by several investigators. Spring and Demartean (*Bull. Soc. chim.*, 1889, [iii], 1, 314) obtained diethyl disulphide by the interaction of ethyl bromide or iodide with aqueous solutions of the sodium polysulphides. This reaction was shown by Blanksma (*Rec. trav. chim.*, 1901, 20, 121; *Proc. K. Akad. Wetensch. Amsterdam*, 1901, 3, 81) to be a general one, and he obtained many disulphides of both aliphatic and aromatic radicles by boiling alcoholic solutions of the halogen compounds of these radicles with sodium sulphide. He also states that tri- and tetra-sulphides can be obtained in a similar manner by the use of so-called sodium trisulphide and sodium tetrasulphide respectively.

As regards the preparation of trisulphides by this method, inasmuch as the existence of trisulphides of the alkali metals under the conditions mentioned has been shown by Thomas and Rule (*T.*, 1917, 111, 1063) to be extremely improbable, the reaction cannot be a simple replacement as Blanksma supposed, and the trisulphide, if obtained at all, is probably produced by the degradation of higher polysulphides.

It may also be pointed out that in the investigations mentioned, anhydrous polysulphides were not employed and therefore, even although the reactions were carried out in alcohol, the polysulphides must have been hydrolysed to a considerable extent, so that besides polysulphide-ions, hydrosulphide-, hydroxyl-, and even thiosulphate-ions must invariably have been present in the solution. This is borne out by the observation of Holmberg (*Annalen*, 1908, 359, 81) that in all cases in which aqueous sodium disulphide was used higher polysulphides were formed, together with diethyl sulphide and mercaptan, in addition to diethyl disulphide. Holmberg found no evidence of the formation of a trisulphide, and he considered the higher polysulphide to be the tetrasulphide.

The question of the formation and structure of organic polysulphides has also received considerable attention from another point of view. Holmberg (*loc. cit.*) found that mercaptans and mercaptides react with sulphur, forming disulphides, a reaction similar to that of sulphur on metallic hydrosulphides. He also observed that mercaptans readily react with chlorine derivatives of sulphur,

and he obtained various polysulphides by the interaction of these substances with sulphur monochloride, sulphur dichloride, thionyl chloride, etc. This work has been considerably extended by Smythe and Forster (T., 1910, 97, 1195) and by Rây and his co-workers. It is of interest that Holmberg failed to obtain diethyl tetrasulphide from ethyl mercaptan and sulphur chloride, whereas Chakravarti (this vol., p. 954) succeeded in preparing it by a modification of the method.

Polysulphides have also been obtained by the action of sulphur on alkyl monosulphides (Müller, *J. pr. Chem.*, 1871, [ii], 4, 40; Klason, *ibid.*, 1877, [ii], 15, 216), and it is stated by them and also by Hinsberg (*Ber.*, 1910, 43, 1874) that higher polysulphides are produced by the thermal decomposition of the disulphides in accordance with the typical equation

The present authors, in an extended investigation of these compounds, have found no evidence of the occurrence of reactions of this type.

Staudinger and Siegwart (*Helv. Chim. Acta*, 1920, 3, 824) observed that dithiodibenzyl trisulphide is formed by the action of thionyl chloride on dithiobenzoic acid. Reference may also be made to the work of Otto (*J. pr. Chem.*, 1888, [ii], 37, 211) and of Troeger and Hornung (*ibid.*, 1899, [ii], 60, 113), who succeeded in preparing certain organic tetrasulphides. Recently, again, it has been shown that polysulphides are produced in the synthesis of $\beta\beta'$ -dichlorodiethyl sulphide from sulphur monochloride and ethylene. Thus, Green (*J. Soc. Chem. Ind.*, 1919, 38, 469R) isolated $\beta\beta'$ -dichlorodiethyl disulphide. Conant, Hartshorn, and Richardson (*J. Amer. Chem. Soc.*, 1920, 42, 585) obtained the pentasulphide together with some trisulphide, and this observation has been confirmed in respect of the trisulphide by Mann, Pope, and Vernon (T., 1921, 119, 634).

The investigation of the organic polysulphides is, however, still far from complete; in particular, the work of Spring and Demartean and of Holmberg left our knowledge of the action of alkyl halides on the polysulphides of the alkali metals in a somewhat unsatisfactory state. The main obstacle encountered by them has, however, been removed by the preparation of pure and anhydrous di-, tetra-, and penta-sulphides of the alkali metals (Rule and Thomas, T., 1914, 105, 177, 2819), and therefore the present investigation was undertaken in the first instance with the object of preparing from these compounds corresponding alkyl derivatives. In the second place, the constitution of these compounds, and especially of the tetrasulphide, has given rise to considerable discussion, and

it was hoped that in the course of the work further evidence bearing on this problem would be obtained. In the present paper, the action of potassium pentasulphide, this being the polysulphide most readily obtained in the required degree of purity, on methyl, ethyl, and propyl halides is described. The interaction of this substance with allyl and benzyl halides and the action of lower polysulphides on organic halogen compounds will be described in subsequent communications, where the question of the structure of the polysulphides will also be discussed.

In some preliminary experiments, an attempt was made to prepare alkyl pentasulphides by boiling potassium pentasulphide with a dry alcoholic solution of an alkyl halide. Although pentasulphides were obtained, the method was not a very satisfactory one. In the first place, the yield of pentasulphides obtained was always small, probably on account of the dissociation which potassium pentasulphide is known to undergo in alcoholic solution (Thomas and Rule, *loc. cit.*), and the isolation of the pentasulphide from the reaction mixture required in consequence considerable handling of the material, a serious disadvantage in view of the fact that, speaking generally, these polysulphides are readily decomposed by traces of moisture. Moreover, traces of mercaptan were always obtained, and since these substances react with sulphur to form disulphides, their formation would vitiate any conclusion which might be drawn with regard to polysulphide structure.

In the course of these preliminary experiments an observation of some interest was made. When the crude diethyl pentasulphide was distilled under reduced pressure (1—2 mm. of Hg), pure disulphide was first obtained, and on heating the residual pentasulphide to a higher temperature it decomposed into approximately equal amounts of the di- and tri-sulphides, sulphur finally remaining in the distillation flask. This observation is directly opposed to the statements of Müller and of Klason (*loc. cit.*) to the effect that higher polysulphides are formed when the lower members of the series are heated. This decomposition of diethyl pentasulphide into an equimolecular mixture of the di- and tri-sulphides is in entire accord with the observation of Conant, Hartshorn, and Richardson (*loc. cit.*) that $\beta\beta'$ -dichlorodiethyl pentasulphide is decomposed by superheated steam into a di- and a tri-sulphide. It is suggested that the pentasulphide first decomposes into the disulphide and sulphur, a reaction actually observed by Thomas and Riding (this vol., p. 1726), and that the disulphide then reacts with sulphur, forming the trisulphide.

The method of preparation was eventually modified as described in the experimental section. The modified process yielded excellent

results, the only serious objection being the extreme slowness of the reaction under the conditions mentioned. Ethyl, propyl, allyl, and benzyl pentasulphides have been obtained in this way, the yield in every case exceeding 90 per cent. of the theoretical. Although dimethyl pentasulphide has not yet been isolated in a high state of purity, conclusive evidence of the existence of this compound has been obtained.

A certain amount of disulphide was always found in the crude products, and these might also have contained small amounts of the tri- and tetra-sulphides, although from theoretical considerations these would not be expected to occur, and, in fact, no evidence of the presence of these substances was ever found. No trace of free sulphur could be observed even when the crude oil was diluted with about ten times its volume of pentane.

That the substances finally obtained were true compounds and not stable solutions of sulphur in the disulphide was established by determinations of their molecular weight in boiling ether. The results obtained were about 5 per cent. low, but they left no doubt as to the chemical nature of these substances.

The stability of these compounds increases with increasing weight of the alkyl group. An approximate indication of the stability is given by the following figures: methyl 1, ethyl 7, allyl 10, propyl 20, benzyl 50. For example, dimethyl pentasulphide rapidly decomposes at 50–60°, whilst dibenzyl pentasulphide may be boiled with water without marked decomposition occurring. Diethyl pentasulphide slowly decomposes at the ordinary temperature, and an investigation of this decomposition showed that it results in the formation of diethyl disulphide and sulphur only. This observation is of the highest importance because of the light it throws on the structure of these compounds.

With the object of facilitating the purification of the products and, if possible, obtaining some idea of the valency relationships in the polysulphide group, attempts were made to prepare crystalline double compounds of the pentasulphides with a variety of substances, both organic and inorganic, widely different in chemical character, but in no case was a crystalline compound obtained. The only substance found to combine with the pentasulphides was piperidine. On the addition of this substance a deep red coloration was immediately produced and an oily compound was obtained from which the free pentasulphide could be recovered by treatment with dry hydrogen chloride. The composition of these additive compounds was found to be $R_2S_5 \cdot 3C_6H_{11}N$, but every attempt to crystallise them ended in failure. Reference may be made here to the colorations observed by Thomas and Rule (*loc. cit.*) and by Thomas and

Riding (*loc. cit.*) when the polysulphides of the alkali metals and also ammonium pentasulphide were treated with piperidine or pyridine. The results now obtained support the view previously expressed that in these cases too the colour is really due to the formation of additive compounds.

EXPERIMENTAL.

Diethyl Pentasulphide.—A mixture of 9.5 grams of ethyl iodide (which had been treated with a little sodium to remove free iodine), 100 c.c. of dry alcohol, and 7.3 grams (the calculated quantity) of anhydrous potassium pentasulphide was boiled under reflux for forty-eight hours and cooled. The insoluble residue consisted mainly of potassium iodide with some free sulphur and yielded only a trace of potassium iodide to acetone.

The alcoholic solution was distilled. The distillate contained sufficient mercaptan to give a faint coloration with alcoholic ferric chloride and acid 1 per cent. isatin, but no trace of diethyl sulphide could be detected. The residue after distillation of the alcohol was semi-solid. It was kept for several days in a vacuum desiccator over phosphoric oxide and a portion was then extracted with acetone. The extract was boiled with ethyl iodide and mercuric iodide for six hours, and ether added to the cold liquid, whereupon a viscous oil was precipitated from which, after purification, crystals melting at 106° were obtained; this was presumably the compound $C_2H_5S_2.HgI_2.C_2H_5I$, m. p. 110° , described by Rây.

From the main portion of the residue ether extracted a yellow oil, leaving potassium iodide. This oil, on distillation under reduced pressure, yielded two fractions and left a residue which proved to be sulphur. The first fraction boiled at $64^{\circ}/1-2$ mm. (Found: S = 51.95. Calc. for Et_2S_2 , S = 52.50 per cent.). The second fraction, b. p. $64-81^{\circ}/1-2$ mm., was a red, viscous, highly refractive liquid, from which a small quantity of sulphur slowly separated as a thin film on the sides of the vessel. The appearance of this film was found to be a very sensitive indicator for the decomposition of all the polysulphides examined. This fraction (Found: S = 57.35. Et_2S_2 requires S = 52.50. Et_2S_3 requires S = 62.38 per cent.) certainly contained disulphide, as it yielded a precipitate with alcoholic silver nitrate. It would appear to be a mixture of the di- and trisulphides in approximately equal proportions formed by the decomposition of the pentasulphide, a decomposition analogous to that observed by Conant, Hartshorn, and Richardson (*loc. cit.*) in the case of $\beta\beta'$ -dichlorodiethyl pentasulphide.

In a second experiment, 5 grams of potassium pentasulphide, 6.5 grams of ethyl iodide, 100 c.c. of dry ether, and a few glass beads

were placed in a bottle, the air was displaced by dry hydrogen, and the bottle sealed and shaken at the laboratory temperature until the solid became colourless. The clear liquid was then decanted, the ether removed, and the residual yellow oil distilled (1—2 mm.), the temperature of the water-bath being kept below 80°. A small quantity of the disulphide distilled over, leaving a faintly red oil, which was freed from the last traces of solvent and of the more volatile lower polysulphides by keeping for three weeks over phosphoric oxide in an evacuated desiccator. The yield of *diethyl pentasulphide*, 4.22 grams, was 92 per cent. of the theoretical (Found: C = 22.09; H = 4.56; S = 73.50; *M*, in boiling ether, = 205, 207. Et_2S_5 requires C = 21.98; H = 4.57; S = 73.45 per cent.; *M* = 218).

If light petroleum is substituted for ether in the preceding preparation, the reaction proceeds much more slowly, being only about half completed at the end of two months; the final yield of the pentasulphide, however, is the same.

Diethyl pentasulphide is a faintly yellow, highly refractive oil which has a most disagreeable odour. Its density at 18° is 1.233. It is insoluble in water, moderately soluble in alcohol, and miscible in all proportions with the other common solvents. It decomposes when heated, and therefore its boiling point could not be determined. It is volatile, with considerable decomposition, in steam. Water decomposes it slowly at the ordinary temperature, monoclinic sulphur (m. p. 119°; rapid heating) separating (compare Thomas and Riding, *loc. cit.*, on the formation of monoclinic sulphur during the decomposition of alcoholic solutions of ammonium pentasulphide).

The decomposition of diethyl pentasulphide was further studied with reference to the nature of the lower polysulphide produced. A specimen which had been kept for two months was treated with ether to precipitate dissolved sulphur, the clear solution decanted, and the ether evaporated. The residual oil proved to be diethyl disulphide (Found: S = 52.42 per cent.). It therefore appears that as in the case of ammonium pentasulphide the decomposition of diethyl pentasulphide results in the formation of the disulphide together with free sulphur.

Oxidation of diethyl pentasulphide effected by aspirating bromine vapour through the oil resulted in the precipitation of much sulphur and the formation of a mixture of acetic and monobromoacetic acids. No evidence of the formation of thio-acids was obtained.

Reference has already been made to the difficulty of removing the last traces of solvent from the pentasulphides. This difficulty is especially marked in the cases of ether, the complete removal

of which could only be accomplished by keeping the substance in an evacuated vessel for several weeks.

Dimethyl Pentasulphide.—The reaction between potassium pentasulphide and methyl iodide took place extremely slowly, and therefore methyl sulphate, which reacts much more readily, was employed in the preparation.

Five grams of potassium pentasulphide and 2.6 grams of methyl sulphate were shaken with dry ether at the ordinary temperature. As soon as the reaction was complete, the clear liquid was decanted and divided into two portions.

From one portion the ether was rapidly distilled and an attempt was made to remove the disulphide by distillation under reduced pressure in the manner already described, the temperature of the bath being kept at 80°. A considerable quantity of a pale yellow oil was collected which boiled without decomposition at 110°, leaving no residue of sulphur. After this oil had stood for some days in a desiccator, it was analysed (Found: C = 25.30; H = 6.11; S = 68.71. Calc. for Me_2S_5 , C = 25.50; H = 6.36; S = 68.14 per cent.). The residue in the flask contained scarcely any polysulphide and consisted of almost pure sulphur.

The second portion was examined in the following way. The ether was allowed to evaporate at the ordinary temperature and the crude oil remaining was kept in an evacuated vessel over phosphoric oxide and paraffin wax for a month, the sulphur content being determined at intervals. At the outset the substance contained 71.91 per cent. of sulphur, but as the disulphide and the last traces of solvent were removed the percentage of sulphur steadily increased until the value 82.7 was reached. Beyond this point the removal of impurity took place so slowly that even after a week no appreciable change was noticed in the sulphur percentage.

The complete analysis of the substance was only effected with difficulty on account of its extremely unstable nature, and the results obtained are not altogether satisfactory (Found: C = 12.60; H = 2.99; S = 82.77. Me_2S_5 requires C = 12.61; H = 3.16; S = 84.22 per cent.). Although the yield of the crude oil was good, 75 per cent. was lost during the purification of the substance, so that only a small amount of the final product was obtained.

Dimethyl pentasulphide is a pale yellow, highly refractive oil, slightly heavier than water, in which it is insoluble but undergoes rapid decomposition. Like the ethyl compound, it is miscible with the common organic solvents, and it also resembles this compound in that it decomposes into the disulphide and free sulphur. It is, however, much less stable than diethyl pentasulphide, and is, in fact, the most unstable pentasulphide as yet obtained.

All these compounds have highly toxic properties which are especially marked in the case of dimethyl pentasulphide.

Dipropyl Pentasulphide.—This substance was prepared in the usual manner by the interaction of propyl bromide (2.6 grams) with anhydrous potassium pentasulphide (5 grams) in dry ether. The reaction was one of the slowest investigated, three months being required for its completion. The ethereal solution was separated from the solid residue, and after the ether had been distilled off an oil remained from which the last traces of solvent and the more volatile disulphide were removed by keeping it over phosphoric oxide in a vacuum desiccator for four weeks. The oil remaining weighed 4.7 grams, the yield thus being 91 per cent. of the theoretical (Found: C = 29.13; H = 5.82; S = 64.69. Pr_2S_5 requires C = 29.21; H = 5.69; S = 65.10 per cent.).

Dipropyl pentasulphide is a lemon-yellow oil, *d* 1.18. It has a peculiar, sickly odour which is, however, less marked than that of the compounds previously noticed. It is readily soluble in the usual organic solvents, but insoluble in water. Its stability is much greater than that of diethyl pentasulphide, and it is only slowly decomposed by water or moist air at the ordinary temperature. When heated, it decomposes into the disulphide and free sulphur.

Summary.

1. The action of anhydrous potassium pentasulphide on certain alkyl halides and similar compounds has been investigated. Under certain conditions, this reaction results in the formation of pentasulphides in 90 per cent. yield.

2. These compounds are heavy, highly refractive oils insoluble in water and highly toxic in character, this property being especially marked in the case of dimethyl pentasulphide.

3. All the organic pentasulphides so far obtained are unstable, the stability increasing with increasing molecular weight. As products of their decomposition, disulphides are formed together with free sulphur, the pentasulphides resembling in this respect ammonium pentasulphide.

In conclusion, the authors desire to express their thanks to Professor E. C. C. Baly, C.B.E., F.R.S., for his unfailing kindness and interest during the progress of this investigation, and to Mr. J. H. Jones, B.Sc., for valuable assistance in the experimental work.

CCCLXXXVIII.—*The Chemical Constitution of Bacterial Pigments. Part I. The Isolation of Pyocyanine and the Preparation of its Salts.*By HAMILTON MCCOMBIE and HAROLD ARCHIBALD
SCARBOROUGH.

It has been known for a long time that *Bacillus pyocyaneus* can be grown on such media as agar-peptone, bouillon, milk and potatoes with the production of the characteristic blue pigment, pyocyanine, and that this colouring matter can be extracted from the culture with chloroform. Thus Fordos (*Compt. rend.*, 1860, **51**, 215; 1863, **56**, 1128) added ammonia to the culture and was able to extract the pigment with chloroform; further, he showed that the colouring matter was basic and could be precipitated by the usual precipitants for substances of an alkaloidal nature. The product obtained by a simple extraction with chloroform must obviously be contaminated with fats from the medium and by any substances, soluble in chloroform, the production of which accompanies that of pyocyanine. The method of Fordos was improved by Gessard (*Annales Instit. Pasteur*, 1890, **4**, 88; 1891, **5**, 737; 1892, **6**, 801; 1901, **15**, 817; 1902, **16**, 313), who extracted the pigment from a culture, rendered feebly ammoniacal, with chloroform; the filtered sky-blue extract was shaken with a dilute mineral acid, when the pyocyanine was converted into a water-soluble, red salt. The chloroform retained the fatty matters and a yellow, non-basic colouring matter, which has been named pyoxanthose, the production of which accompanies that of pyocyanine. The aqueous layer after separation and filtration was rendered alkaline with ammonia and the colouring matter extracted with chloroform. By evaporation of the chloroform extract there was obtained a confused mass of deep blue, needle-shaped crystals which were very unstable.

An attempt to obtain an empirical formula for pyocyanine was made by Ledderhose (*Deut. Zeit. Chirurgie*, 1888, **28**, 201), who prepared the picrate by shaking a saturated aqueous solution of picric acid with a chloroform solution of the colouring matter and recrystallised the precipitate from ethyl alcohol. From the analysis of this picrate he assigned to pyocyanine the empirical formula $C_{14}H_{14}ON_2$. He attempted also to prepare a chloroplatinate, but was unable, judged by his analytical figures, to obtain a uniform product. It seems probable from the authors' work that both the picrate and the chloroplatinate as prepared by Ledderhose were contaminated with ammonium salts. Apart from this work, no

other attempt appears to have been made to elucidate the chemical constitution of pyocyanine.

In an attempt to determine the empirical formula for pyocyanine, the authors realised that if the free base were as unstable in the solid state as is recorded by Gessard no consistent analytical figures would be obtained, and this was found to be the case. On the other hand, the salts of pyocyanine are known to possess considerable stability, and it was believed that much information might be obtained by the analysis of a series of salts. Thus pyocyanine perchlorate was found to have the composition $C_{26}H_{28}O_3N_4 \cdot 2HClO_4$, pyocyanine chloroplatinate, $C_{26}H_{26}O_2N_4 \cdot H_2PtCl_6$, pyocyanine chloroaurate, $C_{26}H_{26}O_2N_4 \cdot 2HAuCl_4$, and pyocyanine mercurichloride,

Two iodides were obtained, a pentaiodide, $C_{26}H_{28}O_3N_4I_5$, and a heptaoidide, $C_{26}H_{28}O_3N_4I_7$. The picrate gave on analysis figures agreeing with a formula $C_{26}H_{28}O_3N_4 \cdot 2C_6H_3O_7N_3 \cdot 2CH_3 \cdot OH - 2H_2O$ or $C_{26}H_{26}O_2N_4 \cdot 2C_6H_3O_7N_3 \cdot C_2H_5 \cdot OH$ according to the solvent used in the recrystallisation. The picrolonate,

was also prepared.

An examination of these formulæ seems to indicate that pyocyanine has an empirical formula $C_{26}H_{28}O_3N_4$, but that it may lose one or even two molecules of water and that salts may be derived from any one of these three forms. That the molecular formula is identical with the empirical formula is, at present, dependent upon a determination of the molecular weight of the free base, which is unstable, in chloroform solution. The value 397 was obtained, which is in fair agreement with the value required for the simple formula.

Of the four nitrogen atoms present in the molecule, one can be removed by the action of nitrous acid in the cold.

Cultivation of the Bacteria.

The amount of pigment produced by the bacillus is small, and thus it was essential that it should be grown on a large scale on an as inexpensive medium as possible. Three factors had to be taken into consideration: (a) the medium should not be so stiff that the extraction of the pigment is rendered difficult, (b) the period of incubation for a maximum development of colour should be as short as possible, (c) the bacteria should produce the pigment over long periods on the same medium.

In the first experiments which were conducted, a stiff agar-peptone medium was employed, using Parke Davies's bacteriological peptone. This medium is made from 80 grams of peptone, 100

grams of agar, 20 grams of salt, and 8 grams of Lemco, the whole being made up to 4 litres and the reaction of the medium adjusted with sodium hydroxide to $p_H = 8.0$.

This medium proved to be too stiff to allow the pigment to be extracted with reasonable ease and, further, the cost of the peptone proved to be very high; after many experiments it was found possible to reduce the peptone to 40 grams and the agar to 50 grams per 4 litres without appreciable reduction in the pigment production or increased time of incubation. It was found advisable, however, to return to the richer medium at intervals of a few months in order to keep the pigment production at a high level.

A less expensive medium was obtained by digesting two minced pigs' stomachs in 3 litres of water and 40 c.c. of concentrated hydrochloric acid for 7.5 hours at 50° . The temperature was then raised to 90° to arrest the digestion and to destroy the pepsin. The product was made alkaline with sodium hydroxide, heated at 110° in an autoclave for one hour, and filtered. The medium was then made up as follows: 750 c.c. of extract, 50 grams of agar, and 6 grams of Lemco, and diluted to 4 litres.

The colour produced, judged on the yield of perchlorate, was some 60 per cent. of that produced on the peptone medium; it was necessary, however, to return to the peptone medium at short intervals in order to maintain the yield at this level.

A third medium which was employed with limited success was prepared from bullock's heart. It was found to give a yield of pigment corresponding to about 25 per cent. of that obtained from the Parke Davies peptone.

It was found that *B. pyocyaneus* could produce a small amount of pigment when grown on a synthetic medium containing ammonium citrate or ammonium succinate together with some glycerol. This medium was not found to be satisfactory on a large scale.

The medium was prepared and transferred to large, flat bottles with a capacity of 1 litre, about 350 c.c. of medium being placed in each bottle. By employing these bottles, a large surface was obtained and further the bottles could be sterilised readily and were of a convenient shape for keeping in large numbers in the incubators.

After inoculation, the bottles were kept in an incubator at 37° for 4 to 6 days; longer periods of incubation did not give rise to an increased yield of pigment.

The original culture of *B. pyocyaneus* employed in these experiments was obtained from the Lister Institute and sub-cultures were made from this.

Extraction of the Pigment.

After incubation, the contents of the bottles were shaken with some 200 c.c. of water until the medium had broken up into pieces no larger than a pea, and were then transferred to a large aspirator. A little sodium carbonate was added and the mixture extracted with chloroform until the chloroform layer was only a faint blue in colour; four extractions were usually sufficient.

The chloroform extract was filtered through glass wool to render the solution clear and then shaken with a fixed quantity of dilute sulphuric acid (1 per cent.). By this procedure the pyocyanine was converted into the water-soluble, red sulphate, while the chloroform became almost colourless. There remained in the chloroform an appreciable quantity of dissolved fats and a minute quantity of the yellow colouring matter, pyoxanthose. The red aqueous solution was separated, filtered, and stored until a sufficient quantity had accumulated. At intervals, this sulphate solution was neutralised with sodium carbonate, filtered, extracted with chloroform, and the chloroform solution shaken with dilute sulphuric acid (1 per cent.) in such quantities that the final concentration of the sulphate solution approximated to 0.2 gram of pyocyanine per 100 c.c. This solution was the starting point for the preparation of the salts and for any reactions it was desired to investigate.

Pyocyanine.

This substance is very unstable and judged by analyses was never obtained in a pure state, but its salts are stable. The purest specimen of the free base was obtained from the pure recrystallised perchlorate, which was neutralised with sodium carbonate and the colouring matter extracted with chloroform. The chloroform solution was dried carefully over sodium sulphate and the chloroform removed under reduced pressure. There resulted a confused mass of small, dark blue, needle-shaped crystals resembling indigo. It was recrystallised from water, care being taken not to allow the temperature to rise above 60°. It separated in beautiful dark blue needles and melted with decomposition at 130°. A sample of pyocyanine left in a vacuum desiccator slowly decomposed and there was obtained from this a small quantity of a yellow substance which is probably identical with one of the decomposition products obtained with sodium hydroxide. An analysis of the recrystallised pyocyanine indicated that it was not quite pure. A determination of the molecular weight in chloroform solution gave $M = 397$ ($C_{28}H_{28}O_3N_4$ requires $M = 444$). Pyocyanine is soluble in hot water, in dilute alcohol, chloroform, acetone, or ethyl acetate. It is insoluble in

ether, benzene, xylene, carbon tetrachloride, light petroleum, or carbon disulphide. It is strongly basic, and its salts are dark red in colour, and in aqueous solution are appreciably hydrolysed. When it is heated with potassium, sodium, or barium hydroxide, ammonia is evolved slowly, the colour of the solution changes from blue to purple, and on acidification several decomposition products can be isolated which are at present under investigation.

When pyocyanine is treated with nitrous acid in the cold, the solution turns green, a solid product, which is at present being studied, is formed, and nitrogen evolved in the quantity indicating that one of the four nitrogen atoms has been detached. This was shown in the case of the sulphate solution of the base by determining the ratio of the total nitrogen in the solution to the nitrogen evolved by the action of sodium nitrite (Van Slyke's method) (Found : 100 c.c. of solution contained 0.0282 gram of total nitrogen, whilst on addition of sodium nitrite 100 c.c. yielded 0.0074 gram of nitrogen).

If the salts of pyocyanine are boiled with concentrated nitric acid, there seems to be produced a second blue colouring matter which differs from pyocyanine in that when a chloroform solution is shaken with dilute sulphuric acid a red salt is not produced.

Hydrogen peroxide and potassium persulphate are almost without action on pyocyanine. In alkaline solution, sodium hypochlorite has no apparent action, but on acidification the colour is discharged. Pyocyanine is readily attacked by potassium permanganate in acid, neutral, or alkaline solution, the colour being destroyed immediately. Ferrous sulphate in neutral solution completely destroys the colour of pyocyanine. Potassium ferrocyanide appears to have no action on the colouring matter. Sulphur dioxide gives a reddish-brown solution with pyocyanine, which changes to a faint green on rendering the solution ammoniacal. Zinc and sulphuric acid give a reddish-brown solution which changes to a grass-green solution on further action. Stannous chloride gives the grass-green coloration immediately. Sodium hydrosulphide destroys the blue colour immediately, but after a further period a grass-green coloration appears.

Pyocyanine can be precipitated from dilute solution by means of phosphomolybdic acid.

Pyocyanine Perchlorate.—The pyocyanine sulphate solution was extracted with chloroform to free it from fatty matters, neutralised with sodium carbonate, filtered, and the base extracted with chloroform. The chloroform solution after filtration was shaken with perchloric acid (*d* 1.12), when the *perchlorate* separated and the chloroform became colourless. The *perchlorate*, recrystallised from hot water containing a little perchloric acid, formed beautiful, dark

red needles which melted with decomposition at $221\text{--}223^\circ$ (Found: C = 48.5, 48.4; H = 4.4, 4.4; N = 8.9, 8.9; Cl = 10.9, 10.9. $\text{C}_{26}\text{H}_{28}\text{O}_3\text{N}_4\cdot 2\text{HClO}_4$ requires C = 48.4; H = 4.3; N = 8.68; Cl = 11.0 per cent.). Heated at 120° , this perchlorate lost two molecules of water (Found: H_2O lost = 5.2, 5.4. The residue on combustion gave C = 51.2; H = 4.22. $\text{C}_{26}\text{H}_{28}\text{O}_3\text{N}_4\cdot 2\text{HClO}_4 - 2\text{H}_2\text{O}$ requires H_2O = 5.58; C = 51.2; H = 3.9 per cent.).

Pyocyanine Chloroplatinate.—A chloroform solution of the free base which had been freed from fatty matters was shaken with platinum chloride in hydrochloric acid. The *chloroplatinate* separated as a dark red powder and was recrystallised from dilute hydrochloric acid (Found: C = 37.3; H = 2.9; N = 7.2, 7.3; Cl = 25.9, 25.5; Pt = 23.4, 23.7, 23.7. $\text{C}_{26}\text{H}_{26}\text{O}_2\text{N}_4\cdot \text{H}_2\text{PtCl}_6$ requires C = 37.3; H = 3.2; N = 6.7; Cl = 25.5; Pt = 23.3 per cent.).

Pyocyanine Chloroaurate.—Pure pyocyanine perchlorate was dissolved in water, neutralised with sodium carbonate, and the free base extracted with chloroform. To this chloroform solution was added gold chloride in hydrochloric acid solution and after vigorous shaking of the mixture the *chloroaurate* was precipitated as a dark reddish-brown powder. It was found impossible to purify it by crystallisation (Found: C = 28.4, 28.5, 28.8; H = 2.1, 2.8, 2.6; Au = 35.25, 35.1; Cl = 25.3, 25.2. $\text{C}_{26}\text{H}_{26}\text{O}_2\text{N}_4\cdot 2\text{HAuCl}_4$ requires C = 28.2; H = 2.4; Au = 35.6; Cl = 25.7 per cent.).

Pyocyanine Periodides.—a. *The Pentaiodide*. A solution of the pure base in dry chloroform was treated with an excess of iodine, also in chloroform. The precipitated *pentaiodide* was separated by filtration and washed with chloroform (Found: I = 59.0, 59.1. $\text{C}_{26}\text{H}_{28}\text{O}_3\text{N}_4\text{I}_5$ requires I = 58.8 per cent.).

b. *The Heptaoidide*. The free base was dissolved in water, a solution of iodine in potassium iodide added, and the mixture warmed gently. The *heptaoidide*, which was precipitated as a brown powder, was separated by filtration, washed with potassium iodide solution, and dried, when it was found to melt at $152\text{--}153^\circ$ (Found: I = 66.7, 66.7. $\text{C}_{26}\text{H}_{28}\text{O}_3\text{N}_4\text{I}_7$ requires I = 66.7 per cent.).

Pyocyanine Mercurichloride.—A chloroform solution of the free base was shaken with dilute hydrochloric acid, and an excess of a 2.5 per cent. solution of mercurichloride added to the hydrochloric acid solution. The mixture was warmed for half an hour on a water-bath and, on cooling, dark red, needle-shaped crystals of the *mercurichloride* separated, which were recrystallised from hot water (Found: C = 30.4, 29.9, 30.0; H = 2.6, 2.5, 3.4; N = 5.3, 5.3. $\text{C}_{26}\text{H}_{26}\text{O}_2\text{N}_4\cdot 2\text{HCl}\cdot 2\text{HgCl}_2$ requires C = 30.0; H = 2.7; N = 5.4 per cent.).

Pyocyanine Picrate.—A chloroform solution of the free base was

shaken with a saturated aqueous solution of picric acid and the dark red solid which separated, when recrystallised from dry methyl alcohol, crystallised in dark red, almost black leaflets with a violet sheen. The substance melted with decomposition at 194–195° (Found: C = 51·5, 51·3; H = 3·9, 3·3; N = 15·2, 15·2; loss of weight on heating at 120° = 10·8. $C_{26}H_{28}O_3N_4 \cdot 2CH_3 \cdot OH - 2H_2O$ requires C = 51·6; H = 4·1; N = 15·1; loss of $2CH_3 \cdot OH + 2H_2O$ = 10·75 per cent.).

The picrate crystallised from ethyl alcohol in deep violet leaflets which melted with decomposition at 194–195° (Found: C = 51·38, 51·56; H = 3·5, 3·75; N = 15·5, 15·07.

$C_{26}H_{26}O_2N_4 \cdot 2C_8H_3O_7N_3 \cdot C_2H_5 \cdot OH$
requires C = 51·6; H = 4·1; N = 15·05 per cent.).

Pyocyanine Picrolonate.—The pure perchlorate was dissolved in water, neutralised with sodium carbonate, and the pyocyanine extracted with chloroform. To the chloroform solution was added excess of picrolonic acid dissolved in methylated spirits diluted with ten volumes of water. The chloroform became colourless and the *picrolonate* separated as a reddish-black precipitate, which was separated by filtration and on recrystallisation from ethyl alcohol melted at 195–196° (Found: C = 58·5; H = 4·5; N = 17·5. $C_{26}H_{24}ON_4 \cdot 2C_{10}H_8O_5N_4 \cdot C_2H_5 \cdot OH$ requires C = 58·7; H = 4·7; N = 17·1 per cent.).

The authors desire to thank the Lister Institute, from whom the original cultures were obtained, Dr. C. G. L. Wolf for much kind assistance, and the Department of Scientific and Industrial Research, without whose assistance the work could not have been undertaken.

CCCLXXXIX.—*The Action of Hydrogen Sulphide on Lithium Ethoxide. Lithium Hydrosulphide.*

By JOHN HENRY JONES and JOHN SMEATH THOMAS.

WHILST the sulphides of the more electropositive alkali metals have been investigated from several different points of view, little attention has been directed to the sulphur compounds of lithium, none of which appears to have been prepared in the pure and anhydrous condition.

Berzelius (*Pogg. Ann.*, 1826, 6, 439) obtained a solution of the hydrosulphide by reducing lithium sulphate with carbon, lixiviating the melt with water, and passing hydrogen sulphide through the

solution. A modification of this method was also employed by Sabatier (*Ann. Chim. Phys.*, 1881, [v], 22, 21), but neither he nor Berzelius succeeded in isolating the pure hydrosulphide. According to Sabatier, the solid obtained by saturating a solution of lithium sulphide with hydrogen sulphide, evaporating to a syrup, and finally drying in a vacuum over anhydrous potassium carbonate, has the composition $\text{Li}_2\text{S}_2\text{H}$. Attempts have also been made to prepare the hydrosulphide by the action of the metal on hydrogen sulphide, but Sabatier states (*Compt. rend.*, 1879, 89, 254) that the products always contain polysulphides.

The present investigation was commenced with the object of devising a convenient method of preparing pure lithium hydr. sulphide, considerable quantities of which were required for another purpose.

As the compound undergoes considerable hydrolysis in aqueous solution, it seemed clear that satisfactory results could be obtained only by the use of non-aqueous solvents and therefore preliminary experiments were made along the lines indicated by Rule (T., 1911, 99, 558), who obtained sodium and potassium hydrosulphides by the action of hydrogen sulphide on alcoholic solutions of the ethoxides of these metals, ether or benzene being used as the precipitating agent. In this way, the anhydrous compounds were obtained.*

In the preparation of the hydrosulphides of sodium and potassium a solution of the ethoxide is first obtained by dissolving the metal in dry alcohol. This mode of procedure was found to be unsuitable in the case of lithium; although small amounts of the hydrosulphide were ultimately obtained, serious difficulties were encountered. In the first place, lithium dissolves very slowly in ethyl alcohol even at 80° , and although this difficulty is to some extent overcome by the use of methyl alcohol, the high cost of the metal together with the fact that all the specimens used contained much impurity, which contaminated the final product, ultimately led to the abandonment of the method. For the same reasons, Scott's method, referred to by Bloxam (T., 1900, 77, 763), although yielding promising results, had also to be abandoned. It became clear, however, that if pure lithium were readily obtainable the anhydrous hydrosulphide could most easily be obtained in this way.

Experiments were thereupon made with the object of preparing

* Rule appears to have been unaware of the experiments of Wanklyn (*Phil. Mag.*, 1869, [iv], 37, 177, 358), who investigated the action of hydrogen sulphide on dry sodium ethoxide, obtaining a white solid to which he assigned the formula $\text{HS}\cdot\text{NaH}\cdot\text{OEt}$. On heating this substance to 100° , he obtained a compound which, on analysis, yielded results closely approximating to those required for anhydrous sodium hydrosulphide.

the hydrosulphide by double decomposition. Anhydrous sodium hydrosulphide reacts readily in the cold with an alcoholic solution of lithium chloride, but it was found impossible to free the lithium hydrosulphide thus obtained from sodium chloride. A solution of lithium ethoxide is, however, easily obtained by the action of sodium on an alcoholic solution of lithium chloride, and, after removing the precipitated sodium chloride, this can then be converted into the hydrosulphide by passing hydrogen sulphide through the solution. The isolation of the hydrosulphide from the solution is, however, difficult. On the addition of ether it is precipitated as a "fog" which can be filtered only with difficulty; moreover, the presence of even a minute quantity of water which, owing to the hygroscopic nature of lithium chloride, could scarcely be excluded, rendered the isolation of the anhydrous compound almost impossible. The hydrosulphides of sodium and potassium are very hygroscopic, but the lithium compound was found to have an even greater affinity both for alcohol and water.

For these reasons it was found advisable first to isolate the ethoxide and then to convert it into the hydrosulphide by passing hydrogen sulphide into ether in which the dry substance was suspended, a method similar in principle to that employed by Wanklyn (*loc. cit.*) in the case of sodium hydrosulphide. In this way excellent yields of an alcoholate, $\text{LiHS} \cdot \frac{1}{2} \text{C}_2\text{H}_5 \cdot \text{OH}$, were obtained. Attempts made to remove alcohol from this compound, leaving the anhydrous hydrosulphide, were unsuccessful.

A considerable amount of work has been done in connexion with solutions of lithium ethoxide, notably by Acree, but a careful search of the literature revealed no reference to the isolation of the substance in the pure state. It has already been pointed out that solutions of lithium ethoxide are readily obtained by the interaction of sodium ethoxide with lithium chloride in alcohol, the sodium chloride formed being precipitated owing to its slight solubility in that solvent. Lithium chloride is more readily soluble in methyl than in ethyl alcohol. According to Turner and Bissett (T., 1913, 103, 1904), at 25° the solubilities in grams per 100 grams of solvent are as follows: lithium chloride 25.83 and 42.36, sodium chloride 0.065 and 1.31, in ethyl and methyl alcohol, respectively. The advantage gained by the greater solubility of lithium chloride in methyl alcohol is, therefore, more than neutralised by the relatively much greater solubility of sodium chloride in that solvent.

In practice, the formation of a saturated solution is difficult; equilibrium appears to be reached very slowly, so that solutions of much lower concentrations were generally employed. In order to make sure that the lithium chloride contained no water (the

anhydrous salt was always used), the fused substance was employed in one experiment, but it was then found that the solubility had greatly diminished and a solution of suitable concentration could not be obtained. This observation is in agreement with that of Patten and Mott (*J. Physical Chem.*, 1904, 8, 157), who found the solubility of fused lithium chloride in ethyl alcohol at 25° to be only 2.475.

On evaporating the lithium ethoxide solution in a vacuum, a light powder was obtained, white when first prepared, but which rapidly darkened in colour on exposure to the air. The substance thus obtained always contained a small quantity of sodium chloride and the lithium content was invariably about 1 per cent. too high. Evaporation in a current of hydrogen led to similar results.

It was noticed, however, that when solutions of lithium ethoxide in alcohol were heated at about 70° crystals were deposited. Some of these were separated and examined. They were perfectly white, readily soluble in cold alcohol, but very sparingly soluble in hot alcohol. These crystals were free from sodium compounds and they proved to be pure lithium ethoxide. The method of separation finally adopted was based on this observation.

In order to obtain a satisfactory yield of the ethoxide, it was found necessary to work with fairly dilute solutions and to keep the lithium chloride in slight excess in order to ensure the complete decomposition of the sodium compound. When these precautions were neglected the final product was always found to contain sodium compounds.

EXPERIMENTAL.

The metallic lithium and the anhydrous lithium chloride used were supplied by British Drug Houses, Ltd., as the purest obtainable; the metal, however, contained impurities which rendered its use impracticable. The alcohol and the ether were carefully dried, the former by shaking for twenty-four hours with freshly burned quicklime followed by distillation, the latter by means of metallic sodium. Sodium hydrosulphide was prepared by Rule's method (*loc. cit.*).

At the commencement of the work gravimetric methods of analysis were employed. It soon became evident, however, that a very large number of determinations would have to be made and test experiments were carried out in which volumetric methods were employed. Finally, lithium was estimated by direct titration with *N*/10-sulphuric acid, and sulphur by adding a dilute aqueous solution of the substance under examination slowly and with constant stirring to excess of a dilute solution of iodine acidified with hydrochloric acid. The excess iodine was then estimated by

means of *N*/10-sodium thiosulphate solution. The results obtained in this way were found to be in good agreement with those obtained by the usual gravimetric methods.

Lithium Ethoxide.

To 5 grams of anhydrous lithium chloride, dissolved in a minimum of alcohol (a slight residue always remained; even after standing for several hours, the liquid was slightly turbid), was added a solution of sodium ethoxide obtained by dissolving 2.7 grams of sodium, rather less than the quantity theoretically required, in alcohol. The whole operation was carried out in a large flask fitted with a reflux condenser and guard tubes containing calcium chloride and soda-lime, and through which a current of dry hydrogen was continually passed. A milky precipitate of sodium chloride immediately formed and the separation of this precipitate from the solution proved to be difficult. When first formed, it remained in suspension indefinitely, but when the liquid was boiled the precipitate settled fairly rapidly, but much lithium ethoxide was carried down with it and the recovery of this from the precipitate caused the volume of the solution to become inconveniently large.

The method ultimately adopted was to shake the mixture vigorously and then to allow the precipitate to settle for twenty-four hours, after which the clear liquid was blown over by means of dry hydrogen. A small quantity of fresh alcohol was then added and the operation repeated. Exposure of the solution to air or to moisture was thus avoided. When this alcoholic solution was heated at 70° in a stream of dry hydrogen, white crystals of lithium ethoxide formed. These were separated and, after evaporating the solution, a second and a third crop of crystals were obtained in a like manner.

Owing to the ease with which lithium ethoxide absorbs water and carbon dioxide the separation of pure lithium ethoxide from the alcohol was not easy. Even when the filtration was carried out as quickly as possible and the product was transferred rapidly to a vacuum desiccator where it was stored over phosphoric oxide, experiments carried out as nearly as possible under the same conditions furnished products which, on analysis, were found to differ considerably in composition. Thus, in one case the first precipitation yielded 3.7 grams of a substance containing 13.68 per cent. of lithium (LiOEt requires $\text{Li} = 13.35$ per cent.). In other cases, however, the lithium content of the first fraction was much higher and only the third fraction could be considered to be reasonably pure. The following is a typical example. *Fraction 1*, 2.5 grams (40 per cent. of the theoretical); $\text{Li} = 18$ per cent. *Fraction 2*,

0.61 gram (10 per cent.); Li = 16.65 per cent. *Fraction 3*, 3.0 grams (solution evaporated almost to dryness); Li = 13.30 per cent.

In general, only about 50 per cent. of the total yield was obtained in a sufficiently pure condition for the preparation of the hydrosulphide, although the impure first fraction could be utilised in the preparation of the polysulphide. The principal impurity was lithium hydroxide, formed during filtration by the action of water vapour from the air. Attempts to remove this impurity were not successful. An apparatus was therefore devised by means of which the precipitation and subsequent filtration could be carried out in dry hydrogen. By means of this apparatus, sketched in Fig. 1, much more satisfactory results were obtained.

Lithium ethoxide was prepared in the vessel A, which was immersed in the bath B. On raising the temperature of the bath to 70°, the solid was precipitated. After settling, the tap, C, was opened and the solid was transferred to the funnel, D, where it was filtered by suction. As much liquid as possible was removed by means of the pump and the solid was then rapidly transferred to a vacuum desiccator, where it was kept over phosphoric oxide until the last traces of alcohol had been removed (Found: Li = 13.42; C = 46.01; H = 9.53. LiOEt requires C = 46.17; H = 9.61; Li = 13.35 per cent.).

Lithium Hydrosulphide.

The Action of Hydrogen Sulphide on Alcoholic Solutions of Lithium Ethoxide.

Five grams of anhydrous lithium chloride were dissolved in dry alcohol, care being taken to exclude moisture and carbon dioxide, 2.7 grams of sodium were added, and the mixture was gently warmed under a reflux condenser. Sodium chloride was precipitated in a very finely divided form and was separated from the solution in the manner already described.

Pure dry hydrogen sulphide was then passed into the solution for several hours, after which the liquid was concentrated to about one-third its original volume by distilling off alcohol in a current of hydrogen. It was found necessary to continue alternately saturating the cold solution with hydrogen sulphide and removing

alcohol by distillation until crystals began to be deposited on the walls of the vessel, otherwise the amount of ether required for the precipitation of the hydrosulphide was very large.

On the addition of ether a white "fog" formed which passed through filter-paper. It was found advantageous to transfer the liquid to a dry stoppered bottle and to shake it vigorously for at least an hour. This treatment caused the precipitate to coagulate somewhat and it could then be separated by filtration. The solid was washed with dry ether and stored in a vacuum desiccator over phosphoric oxide and chips of paraffin wax. After standing a week, the substance was analysed (Found: Li = 11.02; S = 50.40. $2\text{LiHS}, \text{C}_2\text{H}_5\cdot\text{OH}$ requires Li = 11.01; S = 50.85 per cent.).

The freshly prepared substance was a pure white, crystalline powder which dissolved readily in dilute hydrochloric acid, hydrogen sulphide being vigorously evolved. The solution was perfectly clear and the preparation therefore contained no polysulphide. The substance is extremely soluble both in water and in alcohol. It is extremely deliquescent and is decomposed rapidly by carbon dioxide. When heated, the substance loses alcohol, but the anhydrous hydrosulphide cannot be obtained in this way, as dissociation of the hydrosulphide also occurs; the final product is yellowish-brown in colour.

The product obtained by evaporating the alcoholic solution to dryness instead of precipitating with ether was also an alcoholate, yielding on analysis figures practically the same as those already quoted. The substance was, however, less pure; it contained a trace of polysulphide and had in consequence a faint buff colour.

In another experiment an attempt was made to prepare the ethoxide by dissolving lithium in alcohol. The result was by no means satisfactory. The metal dissolved very slowly, a considerable amount of residue remained, and the solution was discoloured by impurities present in the lithium. Methyl alcohol gave much better results. After passing hydrogen sulphide through the solution, it was concentrated in a vacuum at room temperature, the ratio $[\text{Li}]/[\text{S}]$ being determined at intervals. For this ratio the following values were obtained: 0.976, 0.990, 1.05. As before, the final product was an alcoholate, but for reasons already mentioned this method of preparation is very unsatisfactory.

The Action of Hydrogen Sulphide on Lithium Ethoxide Suspended in Ether.—Five grams of lithium ethoxide, prepared in the manner previously described, were added to 250 c.c. of dry ether in a flask provided with a reflux condenser and the usual guard tubes. A current of hydrogen sulphide was then bubbled through the liquid, which was kept cool by immersing the flask containing it in iced

water. The gas reacted readily with the suspended solid, a considerable amount of heat being evolved, and a marked change occurred in the appearance of the suspension. The ethoxide was extremely light and remained in small, flocculent masses; the hydrosulphide was denser and settled fairly rapidly as a white, crystalline powder.

This powder was filtered, washed with ether, and dried in the usual way over paraffin wax and phosphoric oxide. On analysis, it was found to be the alcoholate and this proved to be the most convenient method of preparing this substance. The presence of alcohol in the compound in no way interfered with its use in the preparation of polysulphides, which was the ultimate object of the work. The yield of the alcoholate was 5.6 grams (92 per cent. of the theoretical) (Found: Li = 11.35; S = 51.00. $2\text{LiHS}, \text{C}_2\text{H}_5\cdot\text{OH}$ requires Li = 11.01; S = 50.85 per cent.). Both the sulphur and the lithium values are slightly high. This is probably due to the presence of a little anhydrous hydrosulphide with the alcoholate.

The Action of Hydrogen Sulphide on Lithium Metal.—The difficulty experienced in the preparation of anhydrous lithium hydrosulphide from the alcoholate led to the investigation of the action of hydrogen sulphide on the metal in the hope that in this way a specimen of the pure hydrosulphide would be obtained.

A small piece of lithium was scraped under ether. A clean metallic surface could not be obtained, as the fresh surface was found to contain numerous black specks which penetrated the metal to varying depths. This impurity was removed as completely as possible and the metal was then placed in a small conical flask with 30 c.c. of ether, on which it floated. The flask was provided with a small double-surface reflux condenser and the usual guard tubes.

On passing a stream of dry hydrogen sulphide into the ether, bubbles of hydrogen were observed to be liberated from the surface of the metal and a white substance was formed which collected at the bottom of the flask. The action was complete in twenty-four hours. An examination of the solid product showed it to be contaminated with some darker-coloured material; it was separated, washed with ether, and dried in a vacuum over paraffin wax and phosphoric oxide. The substance readily dissolved in water, leaving a slight residue, and the solution was faintly green. When this solution was treated with hydrochloric acid, hydrogen sulphide was freely evolved and no sulphur was precipitated. The substance was therefore free from polysulphide (Found: Li = 16.1; S = 69.63; $[\text{Li}]/[\text{S}] = 1.06$. LiHS requires Li = 17.35; S = 80.15 per cent.; $[\text{Li}]/[\text{S}] = 1$).

It appears, therefore, that pure lithium hydrosulphide could be

prepared by the action of hydrogen sulphide on the metal if the latter could be obtained sufficiently pure. An attempt to remove the impurities from the substance by dissolving it in the smallest possible quantity of alcohol and reprecipitating with a large excess of ether resulted in the formation of the alcoholate.

It was noticed, however, that when the impure substance was shaken with ether the dark-coloured impurity settled much more rapidly than the white hydrosulphide. This difference in density can be utilised for the purification of the impure material. The crude product was shaken with dry ether and when most of the impurity had settled the supernatant layer was decanted. This process was repeated until a separation into two fractions was effected and the whole process was then repeated with the purer product. Both the purified material and the residue were then analysed (Found : in the residue, Li = 17.49; S = 19.45 per cent.).

This appears to indicate that the impurity is mainly lithium carbonate, which is insoluble in ether and would be acted on by hydrogen sulphide very slowly. Assuming 95 per cent. of the residue to consist of lithium compounds, 70 per cent. being lithium carbonate and the remainder hydrosulphide, the percentage of lithium and of sulphur would be 17.5 and 20, respectively.

The purified material proved to be the pure alcoholate. This is accounted for by the fact that, unfortunately, the substance was placed in a desiccator which had previously been used to store a product containing alcohol. Although the phosphoric oxide, appeared to be fresh, the anhydrous hydrosulphide took up alcohol from it and was completely converted into the afore-mentioned alcoholate. Owing to the difficulty of obtaining the metal, no further experiments were made in this direction, but the authors are satisfied that by adopting this method of purification pure lithium hydrosulphide can be obtained even from impure lithium. Given pure metal, this is the most convenient method of preparing the substance.

In this connexion attention may be directed to a statement of Bloxam (*loc. cit.*). Referring to the preparation of sodium hydrosulphide by this method, he states that when a small amount of alcohol is present in the ether the hydrosulphide is not obtained but oxidation products of the ethoxide. In view of the results obtained in this and in previous investigations, this statement is difficult to understand. Potassium, sodium, and lithium ethoxides, whether dry or in solution in alcohol, are converted into hydrosulphides by the action of hydrogen sulphide, and in the presence of sufficient ether these compounds are precipitated, the only difference being that whereas the substances precipitated in the

cases of sodium and potassium are the pure hydrosulphides, the corresponding lithium product is an alcoholate. It might even be suggested that a trace of alcohol acts as the medium in which the reaction really occurs.

Summary.

1. A method is described for the preparation of lithium ethoxide by the interaction of sodium ethoxide and anhydrous lithium chloride.

2. Lithium ethoxide is a white, crystalline substance, the solubility in alcohol of which decreases with increasing temperature. This property was utilised in the separation of the substance.

3. The action of hydrogen sulphide on lithium ethoxide has been investigated under a variety of conditions. The reaction results in the formation of an alcoholate of the hydrosulphide having the formula $2\text{LiHS}, \text{C}_2\text{H}_5\cdot\text{OH}$. This substance is best obtained by the action of hydrogen sulphide on lithium ethoxide suspended in dry ether.

4. Pure lithium hydrosulphide may be obtained by the action of hydrogen sulphide on lithium in dry ether. Impurities in the metal render the product very impure. These can best be removed by repeated shaking with dry ether; the impurities, being of greater density than the hydrosulphide, settle more rapidly.

5. The properties of lithium hydrosulphide and of its alcoholate have been investigated. The former is remarkable for the ease with which it absorbs alcohol.

CCCXC.—*Use of the Quinhydrone Electrode for the Estimation of Amino-acids and of Acid and Basic Functions.*

By LESLIE J. HARRIS.

THE quinhydrone electrode (Billmann, *Ann. Chim.*, **15**, 109; Billman and Lund, *ibid.*, **16**, 321; Sørensen and others, *ibid.*, p. 283; Granger and Nelson, *J. Amer. Chem. Soc.*, 1921, **43**, 1401) furnishes a convenient and rapid method of determining the hydrogen-ion concentration of solutions having a value of p_a less than 8.

The procedure adopted for the purposes of the present investigation was as follows. A gold electrode (1×1 sq. in.) was suspended in the liquid (usually about 25 c.c., saturated with quinhydrone),

into which was then introduced the capillary tube forming the potassium chloride bridge establishing connexion with a saturated potassium chloride-calomel half-cell. The resulting potential difference was read off on a null-point potentiometer. The liquid was titrated with *N*/10-hydrochloric acid or *N*/10-sodium hydroxide, and the *E.M.F.*'s were again measured. Hydrogen-ion concentrations were calculated from the observed *E.M.F.* by the formula

$$p_H = (E_{\text{cell}} - E_{\text{obs}})/0.059 \quad . \quad . \quad . \quad (1)$$

the constant for the cell, E_{cell} , having been determined from measurements made with solutions of known p_H , namely, *N*/10-hydrochloric acid and buffer solutions of amino-acids plus hydrochloric acid. All operations were carried out in a warm box at 25°. It was found possible to estimate the acid or alkali in a pigmented solution with an accuracy equal to that obtained in a titration in presence of an indicator, and, when a solution was being titrated to a given *E.M.F.* end-point, with scarcely any increased expenditure of time. Satisfactory micro-titrations were carried out with 4 c.c. of liquid by the use of a needle-shaped electrode and a micro-burette.

In the case of solutions having hydrogen-ion concentrations appreciably different from that of pure water, the titration readings were diminished by a correction equal to the amount of titrant required to bring water alone (in absence of solute) to the same volume and same hydrogen-ion concentration. In general, two methods of titration were employed: either the complete p_H -titration curve was traced, or titrant was run in until a fixed arbitrary p_H end-point was reached, the corrected volume of titrant required being proportional to the amount of titratable substance present.

I. *Estimation of Amino-acids.*

The author has recently shown (*Proc. Roy. Soc.*, 1923, [B], 95, 440; 1924, 95, 500) that amino-acids in solution may be estimated with considerable accuracy by titrating the basic and acidic groups with acid and alkali, respectively; the conditions of the titration, p_H end-points, etc., being fixed by considerations based on the application of the mass law and the theory of titration, and depending on the K_a and K_b values of the ampholyte. In many cases, various amino-acids in a mixture may be estimated individually. For such of these titrations as are carried out in acid solution or to an acid end-point, the quinhydrone technique for determining p_H may be conveniently employed: namely, for the estimation of an amino-acid by titrating with hydrochloric acid the amino-group or groups; for the estimation of total amino- or basic groups in a mixture;

for the estimation of dicarboxylic acids or diamino-acids or histidine in a mixture of amino-acids.

Titration of Glycine.—The results are given in Table I. After the addition of the amount of $N/10$ -hydrochloric acid shown in column d to 25 c.c. of $M/10$ -aqueous glycine, the resulting p_H , as calculated by the formula given above, was that shown in column f . The correction for the blank was made according to the author's formula (*loc. cit.*)

$$i = d - ge/100 \quad (2)$$

where i = corrected amount of acid used in titrating to a given p_H , d = uncorrected amount of acid used in titrating to the given p_H , g = blank for 100 c.c. (c.c. of acid necessary to bring the solvent alone to the given p_H and to a final volume of 100 c.c.), and e = total volume of titrated fluid at the given p_H . The blank correction, g , in the above equation was read from a curve constructed from my formula

$$p_H = -\log \{(\alpha \cdot g)/100N\} \quad (3)$$

where α = extent of ionisation of hydrochloric acid = 0.9 approx., and N = normality of hydrochloric acid employed = 0.1.

TABLE I.

In Fig. 1 the unbroken line represents the theoretical titration curve calculated from the formula

$$p_H = \log (K_b/K_a) + \log \{(1 - \alpha)/\alpha\} \quad (4)$$

* There is no appreciable dissociation of the ampholyte as an acid at the hydrogen-ion concentrations mentioned.

where α = fraction of amino-acid converted into hydrochloride; the circled points are the experimental uncorrected values, and the squares the experimental values corrected for blank. At the acid end of the titration the corrected values tend to lie on either side of the theoretical curve rather than to be strictly coincident with it, owing to the very large magnitude of the blank corrections; a very slight percentage error in reading the correction, g , leading to a comparatively large error in the corrected value. For purposes of quantitative estimation, therefore, more accurate results are obtainable by utilising the data corresponding to the lower section

○ Observed, uncorrected. □ Observed, corrected for blank. — Theoretical.

of the titration curve. A method has been described by which the upper part may be deduced by algebraic or geometric extrapolation (*Proc. Roy. Soc., loc. cit.*).

Titration of Valine.—A similar method was adopted, and from the corrected values the basic dissociation constant of valine, hitherto unknown, was determined (*Biochem. J.*, 17, No. 6).

Estimation of Leucine.—Solutions of leucine of various strengths were taken, the potentiometer was set at a fixed reading (corresponding to a definite p_H), and standard hydrochloric acid added from a micro-burette, until zero deflection was observed. Since, by the mass law relation, a given proportion of amino-acid is neutralised as hydrochloride at a given p_H , the amounts of hydro-

and a second volume for the neutralisation of the carboxyl group, that is, for the titration curve *DC*, where the reaction is

The experimental results are plotted in Fig. 2.

The effect of hydrochloric acid on the solvent was corrected for in a manner similar to that described above for glycine and should be clear from the following table.

C.c. of <i>N</i> /10- NaOH added.	C.c. of <i>N</i> /10- HCl remaining.	<i>p</i> _H .	Correction (c.c.).			C.c. (corr.) of <i>N</i> /10-HCl remaining.
			Total vol. (c.c.).	From curve for 100 c.c.	For given total vol.	
0	20	1.61	20	27	5.4	14.6
2	18	1.74	22	20	4.4	13.6
5	15	1.94	25	13	3.25	11.75
10	10	2.30	30	6	1.8	8.2
15	5	2.63	35	2.5	0.9	4.1
19	1	3.09	39	1	0.39	0.61

The titration of glutamic acid hydrochloride has not hitherto been investigated.

Estimation of Glutamic Acid in a Mixture of Amino-acids.—Glutamic acid mixed with monoamino-monocarboxylic acids was readily estimated by titrating to *p*_H = *ca.* 6.2, at which end-point the "neutral" ampholytes were infinitesimally minutely ionised. Thus a mixture of 1 vol. of *M*/10-glutamic acid hydrochloride and 2 vols. of *N*/10-sodium hydroxide containing 5 c.c. of *M*/10-glycine had *p*_H 6.08, whilst the same mixture containing 10 c.c. of *M*/10-glycine and 2 c.c. of valine had *p*_H 6.06.

The same method may be adopted for the estimation of aspartic acid, which has a similar *K*_a value.

Estimation of Lysine.—The more strongly basic group in this diamino-acid is approximately 100 per cent. neutralised as hydrochloride at *p*_H 7 and more strongly acid reactions. The second basic group is very feeble (*K*_b = 10⁻¹²) and for its neutralisation the solution must be brought to a strongly acid reaction (14 - *pK*_b = 2), whilst the carboxyl group is correspondingly feebly acid and becomes neutralised as sodium salt only in strongly alkaline solution (*pK*_a = 10.7). Lysine was accordingly readily estimated by titrating to *p*_H 6 to 7, one equivalent of hydrochloric acid being required.

Estimation of Lysine in a Mixture.—The same procedure applies to the estimation of lysine in a mixture of the "neutral" mono-amino-monocarboxylic acids.

Estimation of Arginine.—*K*_b for arginine is of the same order as *K*_b for lysine and the same methods are applicable.

II. *Estimation of Acids.*

A number of acids have been estimated, both organic and inorganic, strong and moderately weak, with the aid of the quinhydrone electrode. Only in the case of very weak acids, with $K_a < 10^{-6}$, is the method inapplicable, as titration with sodium

FIG. 3.

Titration of acids.

hydroxide in such cases yields alkaline solutions. In Fig. 3 are shown the titration curves of (1) a strong acid, namely, a pigmented solution of hydrochloric acid, and (2) a moderately weak acid (acetic acid), as determined by the quinhydrone electrode. When determining the strength of the solution of a given acid it is sufficient to titrate to a single predetermined p_H end-point (that is, until the galvano-

meter shows no deflection, the potentiometer being set at a standard reading), the amount of salt formed being proportional to the amount of acid originally present—the exact ratio *salt* : *acid* being calculated from the formula $p_H = \log 1/K_a + \log\{\alpha/(1 - \alpha)\}$, where α = fraction of acid neutralised; or the fraction neutralised at a given p_H may be determined from the result obtained by titrating a solution of known strength.

Estimation of Bases.—Alkalis and the strongest bases are estimated by adding sufficient hydrochloric acid, the excess of which is titrated. For moderately weak bases, the method of direct titration is available as described for lysine; as also for very weak bases (compare titration of the amino-group in glycine). In the latter case, the blank corrections assume an important magnitude.

The general method is not applicable when substances are present which react with the quinhydrone, for example, aniline.

Summary.

The quinhydrone electrode furnishes a ready method of estimating acids and bases in pigmented solutions where indicators would be inapplicable, and of obtaining titration curves with much greater ease and rapidity than is possible with a hydrogen electrode.

The electrode (which is available only for acid solutions) may be used for the estimation of bases of any strength, and for any but the weakest acids ($K_a < 10^{-6}$), provided no reaction occurs with the quinhydrone.

Methods have been evolved for the estimation of amino-acids in solution, depending on the application of the theory of titration to amphoteric electrolytes. The following estimations are described: Estimation of an amino-acid by titrating the amino-group; estimation of the total amino-groups present in a mixture; estimation of lysine and arginine or of histidine, alone or in a mixture of "neutral" amino-acids; estimation of glutamic (and aspartic) acid alone or in a mixture of "neutral" amino-acids (by titration of the stronger carboxyl group).

Two types of procedure have been employed: (1) The complete corrected or ideal titration curve has been deduced, each titration reading being diminished by the volume of titrant required to produce in a hypothetical blank—consisting of solvent alone in absence of titratable solute—the same p_H and the same final volume. (2) The potentiometer was set at a given reading and titrant added until zero deflection was attained, the corrected volume of titrant so required being proportional to the original concentration of titratable substance.

I desire to express my thanks to Prof. F. G. Hopkins, F.R.S., who has given me every facility and encouragement in the carrying out of this research.

CCCXCI.—*The Chemistry of Polycyclic Structures in Relation to their Homocyclic Unsaturated Isomeres. Part V. Orientation in the gem-Dimethyldicyclopentene Series.*

By ROBERT CHARLES GRIMWOOD, CHRISTOPHER KELK INGOLD, and JOCELYN FIELD THORPE.

PROOF has been adduced by Farmer and Ingold (T., 1920, 117, 1362) and by Farmer, Ingold, and Thorpe (T., 1922, 121, 128) that derivatives of dimethyleyclopentadiene (I) are tautomeric with corresponding derivatives of dimethyldicyclopentene (II). So mobile is the five-carbon nucleus that substances known to belong to either class frequently exhibit the properties of both; for example, the oxidation of one and the same substance may lead to an unsaturated acid (type III), and also to a cyclic acid (type IV), the former derived from the monocyclic and the latter from the dicyclic form of the original compound.

A considerable number of compounds of this series were prepared by Perkin and Thorpe (T., 1901, 79, 729) before the mobile character of the five-carbon nucleus was understood, and therefore, quite apart from the fact that the nucleus of each such substance has now been shown to possess two distinct phases which together confer on the compound a dual chemical character, there are certain questions of structure, principally relating to the orientation of attached groups, which, in the light of the newer knowledge, require reconsideration.

Perkin and Thorpe's compounds were synthesised by a method which indicated the dicyclic constitution (II), and therefore were formulated throughout as dicyclic substances. The parent (from the preparative point of view) of the series was a sodio-ester, to which both of the formulæ (V) and (VI) must now be assigned,

and numerous derivatives of this substance were obtained, either by direct hydrolysis, or by methylation and subsequent hydrolysis. The nuclear constitution of the direct hydrolysis products has been dealt with in earlier parts of this series, and as to the orientation of the groups there appears to be no ambiguity. On the other hand, the determination of the structure of the methylation products involves, not only a consideration of phenomena depending on the intra-annular tautomerism of the nucleus, but also a special problem in orientation, the solution of which forms the subject of the present communication.

There are two positions in which the above sodium compound might methylate on carbon; namely, position (4), through the operation of the β -ketonic ester group derived from $\text{CO}_2\text{Et} \cdot \text{C}^{(3)}\text{ONa}$ in (V), or position (2), through the β -ketonic ester group derived from the residue $\text{C}^{(3)}\text{ONa} \cdot \text{C}^{(2)}\text{CO}_2\text{Et}$ in (VI). The product might therefore have either formula (VII) or formula (VIII), and it is important to note that in either case, since enolisation is rendered impossible by the absence of the mobile hydrogen atom, the nucleus cannot revert to its quasi-aromatic structure (I or II), and intra-annular tautomerism must therefore be suspended. Hence the substance is static, and should be capable of being orientated, either as (VII), or as (VIII), by the usual methods applicable to a static individual.

The importance attaching to the orientation of the methyl group in this substance lies in the fact that it is the parent of a considerable series of hydrolysis products all of which have been formulated in accordance with Perkin and Thorpe's assumption that the methylated ester has formula (VIII) and not formula (VII). However, there is no evidence at present on record proving that this is the case, and, were it not so, the chemistry of the whole group of compounds would require reinterpretation.

On hydrolysis by mineral acids, the methylated ester yields an acid the structure of which must be represented by formulae (IX) and (X) if the ester has formula (VII), or by (XI) and (XII) if the ester has formula (VIII). In either case, the acid is closely related

to the monocarboxylic acid (XIII and XIV) previously investigated (Farmer, Ingold, and Thorpe, *loc. cit.*), and might be expected to undergo similar reactions.

It will be recalled that the acid (XIII and XIV) was converted by nitrosyl chloride into a static oximino-derivative having the monocyclic structure (XV). This on hydrolysis yielded a very characteristic diketone (XVI), which existed in bluish-red and yellow modifications, and on oxidation by hydrogen peroxide passed quantitatively into dimethylaconitic acid (XVII).

Evidently a similar series of experiments must clearly distinguish an acid having formulæ (IX) and (X) from one having formulæ (XI) and (XII), for only in the latter case could a corresponding chain of reactions occur without extrusion of the methyl group.

Actually, the results show that the methylated acid has formulæ (XI) and (XII), and not formulæ (IX) and (X). Like the unmethylated acid, it is readily converted into an oximino-derivative (XVIII), similar in all respects to the compound (XV). This, on hydrolysis, gives a diketone (XIX), which exists in bluish-red and yellow modifications and bears a striking resemblance to the diketone (XVI) * previously described. On oxidation by

* Since these 1 : 2-diketones are the five-carbon ring analogues of *o*-benzoquinone, it is of interest to note that in both cases the red form is the more stable, the yellow modification reverting to the red on warming, or on mere keeping at the ordinary temperature. Willstätter and Müller showed (*Ber.*, 1908, 41, 2580) that *o*-benzoquinone exists in an unstable colourless form as well as a stable red modification, and they formulated the isomeric change as follows :

The analogy suggests the following explanation of the chromoisomerism

hydrogen peroxide, the new diketone yields trimethylaconitic acid (XX), the structure of which was placed beyond doubt by its general similarity to dimethylaconitic acid* and, secondly, by its oxidation to dimethylmalonic acid (XXI) and pyruvic acid (XXII).

From these results it follows that of the alternative formula (VII) and (VIII) for the methylated ester, formula (VIII) is the correct one; and, as this is the formula which Perkin and Thorpe assigned to the substance, no revision of the series of acids and lactones to which it gives rise is necessary.

Moreover, the fact that methylation of the tautomeric sodium compound proceeds in such a way as to give rise to the static bridged compound (VIII) provides additional evidence, if any were required, that the assumption of a bridged phase is necessary to interpret the reactions of this series of compounds.

EXPERIMENTAL.

[Note on nomenclature.—All intra-annular tautomeric substances are designated by the names of their bridged modifications.]

which we have observed to occur amongst the corresponding 1:2-diketones of the five-carbon ring series:

It is noteworthy that a similar kind of isomerism has not been observed either with *p*-benzoquinone or the analogous 1:4-diketones obtained by oxidative degradation of the five-carbon nucleus:

* A curious property possessed by all the *gem*-dialkylaconitic acids which we have handled hitherto consists in their passing spontaneously or with extreme ease into anhydro-acids, all of which crystallise from benzene with solvent of crystallisation, which is lost, with disintegration of the crystals, on exposure in an evacuated desiccator.

The sodium compound of ethyl 5:5-dimethyldicyclopentan-3-ol-1:2:4-tricarboxylate was prepared by Perkin and Thorpe's method (*loc. cit.*) and methylated by means of an excess of methyl iodide (*loc. cit.*). The methylation product, ethyl 2:5:5-trimethyldicyclopentan-3-one-1:2:4-tricarboxylate, was then hydrolysed by alcoholic potassium hydroxide to the potassium salt of 2:5:5-trimethyldicyclopentan-3-one-1:2-dicarboxylic acid, which was further hydrolysed to the monobasic acid in the manner described below.

2:5:5-Trimethyldicyclopentan-3-one-1-carboxylic Acid.—The above-mentioned potassium salt, prepared by Perkin and Thorpe's method, was dissolved in a small amount of water and decomposed with 2 per cent. more than the theoretical quantity of concentrated hydrochloric acid. The solution was boiled for ten minutes, and then heated at 180° in a closed tube for half an hour. On cooling, the monobasic acid crystallised nearly completely, and was collected, washed with a little water, and dried.

Action of Nitrosyl Chloride on 2:5:5-Trimethyldicyclopentan-3-one-1-carboxylic Acid: Formation of Oximino- and Dichloro-derivatives.

4-Oximino-2:5:5-trimethyl- Δ^1 -cyclopentan-3-one-1-carboxylic Acid.—The trimethyldicyclopentanonecarboxylic acid (5 grams) was dissolved in 50 c.c. of dry chloroform, and the solution treated at 0° with nitrosyl chloride prepared from 150 grams of "chamber crystals" and 100 grams of sodium chloride. After twenty minutes, the pale yellow, crystalline substance was collected, and crystallised from boiling water, from which it separated in yellow needles which melted with decomposition at 207° (Found: C = 54.6; H = 5.5. $C_9H_{11}O_4N$ requires C = 54.8; H = 5.6 per cent.). The yield was 3 per cent. of the theoretical.

The oximino-compound gives orange solutions in alkalis, instantly decolorises cold alkaline permanganate, and gives a red solution, containing the diketone described below, on boiling with concentrated hydrochloric acid.

2:4-Dichloro-2:5:5-trimethyldicyclopentan-3-one-1-carboxylic Acid, $CM_2 \begin{array}{c} C(CO_2H) \cdot CClMe \\ | \\ CCl - CO \end{array}$, or 4:4-Dichloro-2:5:5-trimethyl- Δ^1 -cyclopentan-3-one-1-carboxylic Acid, $CM_2 \begin{array}{c} C(CO_2H) \cdot CMe \\ | \\ CCl_2 - CO \end{array}$.

—This acid remained in the chloroform solution, and, after the oximino-compound had been collected, was obtained by evaporating the solvent at the ordinary temperature. It separated from water in leaflets, m. p. 142° (Found: C = 45.25; H = 4.35; Cl = 29.4. $C_9H_{10}O_3Cl_2$ requires C = 45.5; H = 4.2; Cl = 29.5 per cent.).

This acid was also obtained in the experiment (below) with amyl nitrite and hydrogen chloride, and was the sole product which was obtained when a stream of chlorine was used in place of nitrosyl chloride in the above preparation.

*Action of Amyl Nitrite and Hydrogen Chloride on
2 : 5 : 5-Trimethyldicyclopentan-3-one-1-carboxylic Acid.*

Owing to the small yield of oximino-compound produced by nitrosyl chloride, a better method of preparation was sought, and one was ultimately found in the process described below, by means of which the whole of the oximino-compound required to carry out the subsequent stage-by-stage decomposition was prepared.

4 - Oximino - 2 : 5 : 5 - trimethyl - Δ^1 - cyclopenten - 3 - one - 1 - carboxylic Acid.—The trimethyldicyclopentanonecarboxylic acid (5 grams), dissolved in 50 grams of dry ether, was treated at 0° with 7 grams of amyl nitrite and a rapid stream of dry hydrogen chloride. The solution at first turned dark green, and then the colour gradually changed to pale yellow, and a yellow precipitate separated. The solution was now allowed to warm to the ordinary temperature, and the precipitate collected and washed with ether. It consisted of practically pure oximino-acid, the yield being 30 per cent. of the theoretical.

The Dichloro-acid.—This was obtained on evaporating the ethereal solution and crystallising the residue from water.

Decomposition of the Oximino-compound by Stages to 2 : 5 : 5-Trimethyl- Δ^1 -cyclopentene-3 : 4-dione-1-carboxylic Acid, Trimethylaconitic Acid, and Dimethylmalonic and Pyruvic Acids.

2 : 5 : 5-Trimethyl- Δ^1 -cyclopentene-3 : 4-dione-1-carboxylic Acid, *Yellow and Bluish-red Modifications.*—The oximino-compound (1 gram) was boiled for two minutes with 10 c.c. of concentrated hydrochloric acid and 4 c.c. of 40 per cent. aqueous formaldehyde. The red solution was cooled and repeatedly extracted with ethers. The extract on evaporation yielded 0.92 gram (nearly the theoretical amount) of a mixture of the two modifications of the diketone. On warming, the yellow diketone passes into the bluish-red form, which melts at 140°; recrystallisation from benzene does not alter this melting point (Found : C = 59.1; H = 5.3. $C_9H_{10}O_4$ requires C = 59.3; H = 5.5 per cent.).

$\alpha\gamma$ -Trimethylaconitic Acid.—Half a gram of either modification of the diketone was dissolved in a slight excess of aqueous sodium carbonate and treated gradually at the ordinary temperature with "twenty volume" hydrogen peroxide. In the course of ten minutes, a quantity of hydrogen peroxide equivalent to one atom

of available oxygen was added, and during this period the colour of the solution became much paler. A few minutes later, decoloration was complete and the solution was then acidified with hydrochloric acid and extracted with ether. The crystalline product obtained on evaporation of the ether (0.5 gram) was found to be partly soluble and partly insoluble in boiling benzene. The insoluble portion consisted of the tribasic acid and the soluble portion the corresponding anhydro-acid (below).

The insoluble portion was purified by adding light petroleum to its solution in dry ether, and was thus obtained as a microcrystalline powder, which melted at 120° with evolution of steam and the formation of a clear, colourless liquid (Found: C = 49.9; H = 5.2; *M*, by titration, = 216. $C_9H_{12}O_6$ requires C = 50.0; H = 5.4 per cent.; *M* = 216).

On melting or treatment with acetyl chloride, the acid is converted into the anhydro-acid.

This was deposited from the benzene solution in feathery, flattened needles, m. p. 142° . These, when freshly prepared, contained benzene of crystallisation, which was gradually evolved on exposure in an evacuated desiccator, the crystals becoming opaque and friable (Found: C = 53.3; H = 5.6. $C_9H_{10}O_5$ requires C = 53.5; H = 5.6 per cent.).

On cooling and acidifying its solution in hot alkalis, the anhydro-acid is converted into the original tribasic acid, which may then be isolated by extraction with ether.

Dimethylmalonic and Pyruvic Acids.—A solution of trimethylaconitic acid (0.5 gram) in aqueous sodium carbonate was diluted to 50 c.c., cooled to 0° , and treated gradually with a neutral 3 per cent. solution of potassium permanganate while a rapid stream of carbon dioxide was passed through the alkaline liquid. The colour of the liquid became permanent after the addition of an amount of permanganate corresponding with one atom of available oxygen, and a further quantity, equivalent to three atoms of oxygen, was run in, and the solution allowed to remain in a carbon dioxide atmosphere at the ordinary temperature for sixteen

* These two formulae for the anhydride correspond with the fumaroid structure for the tribasic acid. There should be two other anhydro-acids corresponding with the maleoid acid. We believe, however, that the fumaroid constitution of the tribasic acid is placed almost beyond question by its formation from a cyclic structure:

hours, after which decoloration was complete. The solution was treated with steam and filtered, and the manganese oxides were treated twice with steam. The aqueous solutions were combined and concentrated, strongly acidified with hydrochloric acid, and extracted with ether. The extract on evaporation smelt strongly of pyruvic acid, which was isolated in the form of its characteristic phenylhydrazone (Found: C = 60.9; H = 5.8. Calc., C = 60.7; H = 5.6 per cent.). A second portion of the product was placed in an evacuated desiccator over potassium hydroxide until it solidified. The solid was crystallised from water, from which pure dimethylmalonic acid, m. p. 189°, separated (Found: C = 45.4; H = 6.2. Calc., C = 45.4; H = 6.1 per cent.). Both products were further identified by comparison with authentic specimens.

We wish to thank the Royal Society for a grant with the aid of which the cost of some of the materials used in this investigation has been met.

CCCXCII.—*The Interaction of Primary Amines and 2-Dithiobenzoyl.*

By ERNEST WILSON MCCLELLAND and JOHN LONGWELL.

IN a previous communication (McKibben and McClelland, this vol., p. 170) it has been shown that 2-thiobenzimide (I) is produced by the action of ammonia on 2-dithiobenzoyl (II). It might therefore be predicted that the reaction between 2-dithiobenzoyl and a primary amine would take the course shown:

As previously pointed out (*loc. cit.*), 2-dithiobenzoyl on treatment with aniline yields the anilide (III; R = Ph) of 2:2'-dithiobenzoic acid, and not a heterocyclic compound as with ammonia. It is to be noted that during the reaction between aniline and 2-dithiobenzoyl, hydrogen sulphide is continuously evolved, and, secondly, that no reaction takes place between 2-dithiobenzoyl and substances such as methylaniline and dimethylaniline, which have not a primary nitrogen atom. These two facts suggest that the sulphur atom of the compound is removed as hydrogen sulphide, from which it follows that the first stage in the reaction is neces-

sarily the formation of a heterocyclic compound of the type shown above (Ia).

The present investigation was therefore undertaken with the object of determining if the formation of the disulphide type of compound, as a result of the action of primary amines on 2-dithiobenzoyl, is of a general nature; and, if so, why ammonia differs from its substitution products in its action upon 2-dithiobenzoyl.

The interaction of aqueous methylamine and 2-dithiobenzoyl yields a compound of the disulphide type (III; R = Me). In some experiments a substance of lower melting point was produced, which, on standing or on treatment with ferric chloride, rapidly oxidised to the disulphide. It would therefore seem that the mercaptan also is formed.

Since in the production of 2-thiobenzimide dry ammonia was employed, whilst in the methylamine experiment an aqueous solution of the gas was used, it seemed probable that the presence of water in the reaction mixture was an influencing factor. It has been found, however, that when dry methylamine is substituted for aqueous methylamine, the end-product is the same. Similarly, aqueous or pure propylamine reacts with 2-dithiobenzoyl to yield the propyl amide of 2:2'-dithiobenzoic acid (III; R = Pr). The identity of this compound has been established by its synthesis from the acid chloride of 2:2'-dithiobenzoic acid and propylamine.

In all the cases studied, the interaction of 2-dithiobenzoyl with an amino-compound results in the formation of the disulphide type of compound. A heterocyclic compound of the type shown (Ia) could not be isolated.

The authors take the view that the tendency of the carbonyl group to acquire an adjacent hydrogenated atom is the factor which determines the end product in these reactions, and further that a cyclic compound in which this condition is not satisfied will be easily reduced.

When a primary amine reacts with 2-dithiobenzoyl, the formation of a cyclic compound as postulated involves a system in which the carbonyl group is without an adjacent hydrogenated atom. Since hydrogen sulphide is a product of the reaction, the easily reducible cyclic compound will necessarily undergo reduction to the disulphide, thus accounting for the failure to isolate a cyclic compound. The fact that the mercaptan is sometimes obtained as well as the disulphide indicates that reduction is taking place

in the reaction mixture. The reaction between a primary amine and 2-dithiobenzoyl may then be represented as follows:

In the case of the reaction between ammonia and 2-dithiobenzoyl, the analogous cyclic compound, namely, 2-thiobenzimide, having an imino-group adjacent to the carbonyl group, will be relatively stable towards a weak reducing agent such as hydrogen sulphide and therefore can be isolated.

It has been pointed out by Kenner (*Ann. Rep.*, 1921, 114; see also Thole and Thorpe, *T.*, 1911, **99**, 2183) that the instability of certain cyclic compounds seems to be due to the tendency of the carbonyl group to acquire a tautomeric hydrogen atom. For example, the condensation of 2-thiolbenzoic acid with acetylacetone (*T.*, 1921, **119**, 1810) under mild conditions of reaction yields the 2-acetyl derivative (V), and not the 2:2-diacetyl derivative (IV); whilst under other conditions 3-oxy(I)thionaphthen is obtained. Since the latter compound and its acetyl derivative exist to some extent in the enolic form, the decomposition of the diacetyl compound appears to be the result of its tendency to acquire a tautomeric hydrogen atom.

It seems therefore that the tendency of the carbonyl group in 2-dithiobenzoyl to acquire an adjacent hydrogenated atom is fundamentally of the same nature. There is no evidence that the amides investigated exist in an enolic form. Nevertheless, since acid amides show many enolic properties, especially with regard to salt formation, it seems reasonable to assume that the presence of an adjacent hydrogenated atom will tend to stabilise the system in that the affinity of oxygen for hydrogen is partly satisfied.

It has been pointed out (*loc. cit.*) that 2-thiobenzimide gives a characteristic coloration with alcoholic ferric chloride, which tends to show that this compound exists to some extent in the enolic modification (VII). If, therefore, the hypothesis which has been advanced be correct, a derivative of 2-thiobenzimide, the formation of which involves the loss of the imino-hydrogen atom, should be unstable. This is found to be the case with the acetyl derivative. Thiobenzimide on treatment with acetic anhydride yields an acetyl

derivative (VIII), which is hydrolysed by warming with water, yielding the original substance.

It has been suggested that a cyclic compound of the type shown above (IX) will undergo reduction at the point indicated by the dotted line. If this be the case, 2-thiobenzimide on reduction should yield the amide of 2:2'-dithiobenzoic acid (X) or the amide of the corresponding mercaptan. Reduction of 2-thiobenzimide yields a substance which rapidly oxidises in solution, or on addition of ferric chloride, to the amide of 2:2'-dithiobenzoic acid, which has also been prepared by the action of ammonium hydroxide on 2-dithiobenzoyl.

EXPERIMENTAL.

2:2'-Dithiobenzamide (Formula X).—(A) From 2-dithiobenzoyl. A solution of 1 gram of 2-dithiobenzoyl in ethyl alcohol was mixed with an excess of ammonium hydroxide. After keeping for four hours at room temperature, the precipitated sulphur was filtered off and the filtrate concentrated. On cooling, 2:2'-dithiobenzamide was deposited. The crude material was crystallised from glacial acetic acid, from which it was obtained in fine, white needles, m. p. 250°. The mixed melting point of this product with that obtained from (b) was 250°.

(B) From 2-thiobenzimide. A solution of 0.3 gram of 2-thiobenzimide in glacial acetic acid was shaken with zinc dust for two hours. The mixture was then heated on the water-bath for a few minutes and the undissolved zinc filtered off. On addition of water to the filtrate, a white substance was precipitated which was washed with water and then with dilute hydrochloric acid and again with water. This substance, which melted at 145°, was dissolved in glacial acetic acid and solid ferric chloride added. After standing for a short time, 2:2'-dithiobenzamide was precipitated by the addition of water and crystallised from glacial acetic acid. M. p. 250° (Found: C = 55.2; H = 4.1; S = 21.1. Calc. for $C_{14}H_{12}O_2N_2S_2$, C = 55.2; H = 4.0; S = 21.1 per cent.). 2:2'-Dithiobenzamide has previously been prepared by Bind-schedler (D.R.-P. 80713) from 2:2'-dithiobenzoyl chloride, who

gives the melting point of the substance as 239°. The amide as obtained above oxidises to *o*-benzoic sulphinide ("saccharin"), as observed by Bindschedler.

2:2'-Dithiobenzomethylamide (Formula III; R = Me).—An excess of methylamine (33 per cent. solution) was added to a solution of 2-dithiobenzoyl in ethyl alcohol. After standing for twelve hours at room temperature, the precipitated sulphur was removed by filtration and the filtrate concentrated by evaporation. On cooling, the solution deposited crystals of the compound, which after recrystallisation from ethyl alcohol melted at 221° (Found: C = 57.9; H = 4.8; S = 19.2. $C_{16}H_{16}O_2N_2S_2$ requires C = 57.8; H = 4.8; S = 19.3 per cent.). It was found that the same product resulted when dry methylamine, generated by the action of alcoholic sodium ethoxide on methylamine hydrochloride, was used instead of the 33 per cent. solution in the above method.

2:2'-Dithiobenzopropylamide (Formula III; R = Pr).—(A) From 2-dithiobenzoyl and propylamine. An excess of propylamine was added to a solution of 2-dithiobenzoyl in ethyl alcohol and the mixture kept over-night. After removal of the precipitated sulphur, the mother-liquor was concentrated by evaporation. On cooling, a white substance separated out which was purified by crystallisation from ethyl alcohol. M. p. 200° (Found: C = 61.7; H = 6.2. $C_{20}H_{24}O_2N_2S_2$ requires C = 61.8; H = 6.2 per cent.). The substitution of aqueous propylamine in the above reaction did not alter the product.

(B) From 2:2'-dithiobenzoyl chloride and propylamine. The acid chloride was prepared by the action of phosphorus pentachloride on 2:2'-dithiobenzoic acid and was used in the crude condition.

One gram of propylamine was placed in a freezing mixture and 3 grams of the acid chloride were gradually added. The reaction mixture was then heated for an hour at 50°, after which a 50 per cent. solution of hydrochloric acid was added until an acid reaction was obtained. The solid which separated out was washed with ethyl alcohol to eliminate an impurity of an oily nature. The washings were discarded and the residue was crystallised from ethyl alcohol, from which it was eventually obtained in fine, white needles melting at 200°. The melting point of a mixture of this substance with the product obtained by the action of propylamine on 2-dithiobenzoyl showed no depression.

Acetyl-2-thiobenzimide (Formula VIII).—The acetyl derivative was prepared by heating 2-thiobenzimide with an excess of acetic anhydride at 100° for one hour. The solution, when cold, was diluted with water and the solid which separated out was immedi-

ately collected and washed with water. It was found that if the solution was heated with water in order to hydrolyse the excess of acetic anhydride, the product obtained was mostly 2-thiobenzimide. If the excess of acetic anhydride was not too great, the acetyl derivative usually crystallised out on cooling and a further quantity was precipitated by the addition of water as above. The crude material was purified by crystallisation from glacial acetic acid, from which it was obtained in white, needle-shaped crystals, m. p. 138° (Found: C = 56.4; H = 3.9; S = 16.7. $C_9H_7O_2NS$ requires C = 55.9; H = 3.65; S = 16.6 per cent.). The acetyl compound yields 2-thiobenzimide on boiling with water.

The authors desire to express their thanks to Professors Stewart and Smiles for their interest in this work.

CCCXCIII.—*Studies in Fluorescence Spectra. Part I.* *Some Benzenoid Hydrocarbon Vapours.*

By JOSEPH KENNETH MARSH.

IN connexion with investigations in progress in this laboratory, wherein it is being found that many vapours may be electrically stimulated into the emission of a characteristic spectrum (McVicker, Marsh, and Stewart, this vol., p. 2147), the author has undertaken the measurement of the fluorescence spectra of various organic compounds in the state of vapour, as, with one or two exceptions, the fluorescence of vapours has not been investigated. The present paper deals with some of the simple benzenoid hydrocarbons and the experimental arrangements.

Our knowledge of the fluorescence of organic compounds is due mainly to Stark and Ley and their pupils, who worked with alcoholic solutions of about 0.005*M* strength, using a silica mercury lamp as the source of exciting light. The fluorescence spectra, except in the case of some of the hydrocarbons, were found generally to consist of a single broad band spreading over wave-lengths immediately greater than those which the substance absorbs. In the case of the absorption spectra of organic compounds, Hartley and Purvis have shown that the broad bands of the solution spectra are generally resolved into a number of finer bands when the substance is in the state of vapour. It might similarly be expected that fluorescing vapours would yield spectra showing numerous fine bands. To a certain extent this has in fact been realised, but only in

the case of some compounds of very simple structure. Thus it will be seen later that benzene shows about 100 fine bands, a single methyl substituent reduces the number to about 40, whilst an ethyl group or two methyl groups almost complete the fusion into one broad band, and at the same time the wave-length of the fluorescent light is increased.

Apparatus.—A mercury lamp of the Kromeyer type designed for therapeutic use was employed. The burner consists of an inverted U-tube, surrounded by a silica bulb. This is placed in a metal case provided with a quartz window of about 4 cm. effective diameter, and water circulates between the case and the silica bulb. In front of the window a diaphragm may be placed into which is fitted a quartz condensing lens opposite the brightest part of the burner. Thus a narrow pencil of light of great intensity is obtained. Part of this lens was blackened so as to leave a transparent portion about 2 by 1 cm.

A suitable cell for containing the vapour under investigation was constructed by the Thermal Syndicate, Ltd. This consisted of a piece of square-section silica tubing about 3 cm. long and 1.5 cm. cross-section, one face of which was polished flat. One end was closed by a fused-on plate, also of optical quality silica, and at the other end a silica tube of round section was attached. The latter was closed by a rubber bung through which passed one arm of a T-tube. Through this arm passed another tube attached to a specially constructed tap-funnel. The silica cell was placed inside an asbestos-covered metal cylinder, together with a heating element such as is used in electric hot plates, consisting of three sheets of mica, round the middle one of which is wound resistance wire. By putting this heater in series with a variable resistance, the cell could be kept at any desired temperature. By means of the tap-funnel, liquid was delivered into the hot cell, where it was volatilised. The stem of the T-tube acted as the exit pipe for the vapour, and to it was attached the side tube of a distilling flask. This side tube was bent slightly upwards and acted as an air condenser for the vapour, the flask itself acting as receiver. The neck of the flask was closed by a rubber stopper bearing a tube attached to a pressure gauge and water-pump.

The cell described had the disadvantage that it could be used only at temperatures up to about 140°, as this was the highest at which the rubber could be heated without serious decomposition, and thus observations have been confined to substances boiling below about 220°/760 mm. Another cell has therefore been made with a ground joint which it is hoped will be more universally useful. Fig. 1 is a diagram of the original apparatus, and inset is a

representation of this newer cell, which, although not used in connexion with any of the substances under consideration in this paper, may with convenience be referred to here. Ready access to the interior of the cell is necessary for cleaning purposes, for reasons given later.

The spectrograph employed was one of Messrs. A. Hilgar's size C, and most of the plates used were the Imperial Plate Company's Eclipse of H. & D. 650.

FIG. 1.

EXPERIMENTAL.

It was possible to place the end of the observation tube at a distance of about 1 cm. from the slit of the spectrograph. The unblackened portion of the lens of the mercury lamp was placed against the optically worked face of the cell, the beam being directed horizontally. The distance between the centre of the lamp burner and the cell was not more than 6 or 7 centimetres. To prevent stray light entering the slit, the metal case holding the cell was treated with black lead, as also was the inside of the round portion of the cell, and the top and bottom faces of the square tube and a part of the end were blackened with enamel. With these precautions and a careful placing of the apparatus, the amount of mercury light entering the slit was not deleterious; on the contrary, it was of use in calibrating the scale of the instrument. The strong mercury lines at $\lambda = 2803.7$ and 2700, however, made observations in their immediate neighbourhood a little uncertain in one or two instances. On each plate, below the fluorescence spectrum, a spectrum of the mercury light itself was taken.

At the beginning of an experiment, when the cell had been heated to the requisite temperature and the pressure reduced, a few drops of liquid were run into the cell to displace the remaining air by vapour. Thereafter a slow stream of liquid was allowed to enter the cell to ensure that it remained full of vapour, but a flow of more than 2 or 3 c.c. per hour was not necessary. As, except with substances having appreciable vapour pressures at room temperature, there was practically no loss, only a small quantity of material was necessary. Unless otherwise stated, all observations were made with vapour at a pressure of 12 to 15 mm., obtained by the use of a water-pump. For each substance the temperature was about the minimum considered necessary to ensure volatilisation.

All observations are to be regarded as qualitative only, as some of the governing factors were subject to uncontrollable variation. Thus the slit was in such close proximity to the cell that its width varied with the expansion of the jaws at different temperatures. Another source of very serious trouble was the coating of the window of the cell with a yellow film. This occurred to varying extents with almost every substance investigated. Sometimes the film was nearly transparent, and invisible until scratched. At other times, it was yellow or brown and often iridescent, and could be seen covering just that part of the window through which the beam of light passed. The film was very opaque to ultra-violet light and hence destroyed the fluorescence. Long exposures were therefore useless, and the apparatus had to be taken apart and cleaned at frequent intervals. After one hour, the efficiency was probably greatly impaired and cleaning advisable. In most cases, with a slit 0.05 mm. wide, an exposure of three separate hours with the rapid plates employed was sufficient to give a satisfactory negative.

Benzene.

A note on the fluorescence spectrum of this substance has already been published (McVicker and Marsh, this vol., p. 820), but since then it has been again examined with the aid of the mercury lamp, more rapid plates, and a new spectroscopic slit, and much more satisfactory spectra have been obtained. A spectrogram was also taken with a large prism spectrograph giving a dispersion of about 20 cm. over the region of the fluorescence of benzene vapour. This, however, showed no new bands and clearly indicated that there was nothing in the nature of a linear structure. Many of the bands run to a head at one end, but even this does not terminate with absolute abruptness.

s = strong, *f* = faint, *b* = broad.

The above grouping is the same as in previous papers (this vol., pp. 646, 818). Arrows point in the direction of the sharper side of a band.

In addition to the ultra-violet spectrum at low pressures, benzene was found to emit the three chief heads of the "blue bands" which have been observed with many substances under the influence of the Tesla discharge (this vol., p. 2147). At pressures of 5 or 6 cm. they were not seen, but at pressures of 12 to 20 mm. they were always present. Otherwise, between these pressure limits very little difference was observable.

The fluorescence spectrum differs from the luminescence spectrum in that it shows more complete series of bands at short wavelengths. Thus the bands tabulated above were produced under 60 mm. pressure, whilst the bands of groups H and G were found only at a pressure of 1.6 mm. in the case of luminescence.

Benzene being sufficiently volatile, no heating of the observation tube was necessary.

Toluene.

A pressure of 3 cm. was maintained and a temperature of about 40°. Below is a table of the bands observed. These were read from two different plates and are not all common to both.

TABLE II.

The groups are lettered to show their correspondence with benzene.

Ethylbenzene.

The temperature of observation was about 65°. The spectrum was much fainter than that of toluene, and only three or four bands were found. The elevated temperature had probably produced an appreciable effect, as at 16° and 2—3 mm. the Tesla-luminescence spectrum showed seven or eight bands.

TABLE III.

Ethylbenzene.

Start 3758.	3749 <i>f</i> 3649 <i>bs</i>	3721 <i>vf</i>	3672 <i>bs</i>
-------------	---------------------------------	----------------	----------------

o-Xylene.

Examination was made at 50° and a remarkably strong spectrum obtained. This consisted of two narrow bands at $1/\lambda$ 3731 and 3722 respectively, and, at 3718, the sharp edge of a continuous region, extending to about $1/\lambda$ 2960, and strongest between $1/\lambda$ 3583 and 3525.

The *o*-xylene was a sample of Kahlbaum's, but no purification was attempted.

Mesitylene.

Here the benzene molecule is symmetrically weighted without interference with valency relationships, yet the benzene band system is completely upset. Whilst not marked, the spectrum has, however, one or two characteristics worth noting. The start is indefinite at about $1/\lambda$ 3690—3700; at 3616 there is a faint band and at 3598 a sudden increase of intensity followed by a slight decrease to 3502, where there is another sudden although slight increase.

Thence the intensity is constant to about 3295, and then it dwindles to zero at about $1/\lambda$ 3000.

Mesitylene was examined at about 100° , and the fluorescence did not appear to be very strong.

Styrene.

The spectrum at 60° was not strong. It started at about $1/\lambda$ 3525, and bands appeared at 3490 and 3483; at 3474 there was sudden increase in intensity, whilst a decrease occurred at 3425. Between 3413 and 3378 four or five bands were distinguishable, but these were too slightly differentiated from the continuous background to permit of accurate location. A band was seen at $1/\lambda$ 3372 and at 3356 a band stood at the head of a region of increased intensity. Two or three more faintly distinguishable bands occurred in the neighbourhood of $1/\lambda$ 3330. The upper limit of the spectrum was indefinite, but may be placed at about $1/\lambda$ 2725.

Phenylacetylene.

Four exposures were made with this substance. Two showed no spectrum, and two showed a continuous spectrum starting at about $1/\lambda$ 3560 with a sudden increase at 3520. The whole spectrum was rather faint and the other end was not well defined, as it merged into the continuous emission spectrum of stray mercury light, but it probably reached to beyond $1/\lambda$ 2775. Some doubt as to whether there was a genuine fluorescence spectrum has been felt but dismissed, and the above is in good agreement with the observation of Ley and Englehardt (*Z. physikal. Chem.*, 1910, 74, 1), who give the limits for an alcoholic solution at $1/\lambda$ 2450 and 3550, but they regard the intensity as equal to that of benzene, whilst the author finds that in the vapour state the intensity is undoubtedly much less.

Discussion of Results.

Fig. 2 is a diagram representing the chief characteristics of each spectrum. The intensities are roughly shown by vertical heights. From this figure and through all the foregoing measurements may be traced a certain regularity. This can best be seen from Table IV, where the intensity heads of the various substances examined are given together with the frequency differences between them.

TABLE IV.

C_6H_6 .	$C_6H_5 \cdot CH_3$.	$C_6H_5 \cdot C_2H_5$.	$C_6H_5(CH_3)_2$.	$C_6H_5 \cdot CH:CH_2$.
3749	3748	3749		
3651 98	101	3649 100		
3552 99	3647 98		3695 97	
3453 99	3549 103		3598 96	
3394 99	3446			3474 102
3354 100			3502	3372

This interval, it will be seen, is almost constant and is evidence of the benzene ring being the place of origin of the fluorescence. Substitution in the ring modifies and may shift the whole position of the spectrum without entirely effacing these signs of origin. Nevertheless the spectra of substances in the vapour state are found to give a very delicate response to slight chemical variations. Thus, chemically, benzene and toluene bear the closest resemblance, but the spectrum of the latter, whilst undoubtedly closely related to that of benzene, is clearly differentiated from it. The benzene system as a whole must be involved in a very delicately balanced system of vibration. It can then be easily understood that any change involving loss of symmetry in the benzene nucleus may upset the vibrations of the whole system. This is what is found. Much of the fine band system is lost in toluene, and in ethylbenzene

FIG. 2.

$\lambda = 2500 \quad 26 \quad 27 \quad 28 \quad 29 \quad 3000 \quad 31 \quad 32 \quad 33 \quad 34 \quad 3500 \text{ \AA.U.}$

nearly the whole. That mesitylene should differ so widely from benzene may appear strange at first sight, but this substance must in reality be considered highly unsymmetrical. Considering benzene as some such dynamic system as Collie has postulated, it will be seen that the three methyl groups lie in one plane and the three hydrogen atoms in a parallel plane at the extreme phases of the vibrational swing, and the molecule is divisible by an intermediate plane into two quite unsymmetrical portions.

It has already been pointed out (McVicker, Marsh, and Stewart, this vol., p. 642) that the luminescence bands of groups F and G of benzene may be identified with absorption bands observed by Hartley (*Phil. Trans.*, 1908, A, 208, 475) in benzene vapour, and the further observations recorded above show that this overlapping or Fraunhofer effect is of fairly general occurrence. In Table V, Hartley's bands are confronted with fluorescence bands, and if the

two spectra overlap it will be found that the bands in the common region are in the same position.

	3789	3656	5 bands	o-Xylene. 45°.	50°.
3782	3784	3650	3651		
			5 bands	2678	2680
		3621	3622—19	2685	2686
		3617—8	3618	2690	2689

Any omissions in either set of bands are indicated.

The fluorescence spectra are always more banded at the end of shorter wave-length, and sometimes the only banding is in the region of overlap with the absorption spectra. For fine banding to be seen in fluorescence spectra, a high degree of symmetry in the molecule would appear to be necessary, and this, of course, benzene possesses pre-eminently. A preliminary experiment with naphthalene showed some broad bands, and other observers have found bands in the spectra of some of the triple nuclear hydrocarbons. Experimental difficulties with these high-boiling substances have up to the present prevented their examination, and it is doubtful if at the temperature necessary for their volatilisation many fine bands will be observable, for high temperature would seem to have a considerable effect in obliterating them.

Summary.

- (1) Apparatus for observing the fluorescence of vapours is described.
- (2) Measurements of the fluorescence spectrum of benzene,

3324 FARMER : MUCONIC AND HYDROMUCONIC ACIDS. PART III.

toluene, ethylbenzene, *o*-xylene, mesitylene, styrene, and phenylacetylene vapours at about 15 mm. are given.

(3) The spectra are more complicated than when observed in solution, especially in the case of benzene and toluene. Throughout the series a regular rise and fall in intensity may be traced attributable to the common possession of a benzene nucleus.

(4) The vapour absorption and fluorescence spectra often overlap and are then found to consist of identical bands.

The author wishes to acknowledge with gratitude the keen and helpful interest of Prof. A. W. Stewart and Mr. W. H. McVicker.

CCCXCIV.—*Muconic and Hydromuconic Acids. Part III. Valency Interchange in the Hydromuconic System.*

By ERNEST HAROLD FARMER.

IN Part I of this series (T., 1922, 121, 2015) dealing with the addition of esters to ethyl muconate, it was shown that the addition obtained with sodiomalonic and sodiocyanoacetic esters did not agree with either of the orthodox types associated with conjugated systems. In place of addition of the expected 1:2- or the rarer 1:4-type the reaction was *in effect* of a 1:3-type which had previously only been met with in connexion with glutaconic esters.

The problem then arose as to whether the symmetrical four-carbon system of the muconic esters was such as to render the 1:3-addition of esters as much the normal mode of reaction as the 1:2- and 1:4-addition of esters in the case of unsymmetrical conjugated systems, or whether the structures found were the result of internal reorganisation subsequent to addition.

In consideration of the total lack of evidence then available in favour of the latter hypothesis the view was taken that the mobility of the muconic system was such as to allow each of the three types of addition to take place in suitable circumstances. Steps were immediately taken, however, to obtain further experimental evidence bearing on the matter and the investigation of the stereoisomerism of the muconic system (this vol., p. 2531) and the exami-

to the $\beta\gamma$, $\alpha\beta$ -change in unsaturated acids, is intimately connected with the potentialities of the hydromuconic system—a subject little investigated hitherto.

The conversion of Δ^{β} -dihydromuconic acid into its Δ^{α} -form was accomplished by Rupe (*Annalen*, 1890, **256**, 26) in the usual way, but numerous repetitions of his experiments failed to secure such a complete transformation by use of alkalis as his brief description suggests; indeed the similarity of the various products strongly suggested the attainment of an equilibrium between the two forms. Examination of the possibility of converting the esters of the Δ^{β} -acid wholly or partly into their Δ^{α} -forms led to interesting results.

When Δ^{β} -dihydromuconic ester is heated with an alcoholic solution of sodiummalonic ester, addition occurs precisely as though the double bond were in the $\alpha\beta$ -position. The reaction proceeds to completion, no trace of dihydromuconic acid being recognisable on hydrolysis:

The additive product (III) yields on hydrolysis an *isopentane*tetracarboxylic acid (IV) which readily loses carbon dioxide to yield the tricarboxylic acid (V). Accompanying the ester (III) is a

quantity of a ketonic ester formed as the result of an internal Dieckmann condensation on the latter and probably represented by formula (VI). From the cyclic ester the corresponding *cyclopentanone*acetic acid (VII) is obtained on hydrolysis. Thus if it

be assumed that the addition occurs at the $\alpha\beta$ -double bond as is usually the case, the change of the Δ^{β} -ester into its Δ^{α} -form is complete under the conditions of the experiment. The rapid molecular change appears to be an effect consequent on the presence of alcoholic sodium ethoxide, and it seemed probable that by the action of the latter on the Δ^{β} -ester, in the absence of other reagents, considerable or complete transference into the Δ^{α} -form might result. Actually, however, such change, which almost certainly occurred, was masked by the addition of the elements

of alcohol at the double bond, the dihydromuconic ester completely disappearing to produce, in the case of methyl dihydro-

muconate and sodium methoxide, methyl β -methoxyadipate (VIII). From this the corresponding methoxyadipic acid (IX) and lactonic acid (X) were obtained on hydrolysis.

The recent work of Birch, Kon, and Norris (this vol., p. 1361) on the $\alpha\beta$, $\beta\gamma$ -change as manifested in *cyclohexenylacetone* and *cyclohexylideneacetone* indicates very clearly that the factor which is responsible for the rapid mobility of such systems is sodium alkoxide, although the same changes, differing only in velocity and degree of completion, probably occur with reagents such as piperidine. The tautomerism described by these authors is essentially a tautomerism in sodium ethoxide solution and an expression of reversible reaction. Without considering the tendency towards equilibrium which probably exists in greater or less degree between most free $\alpha\beta$ -unsaturated ketones and esters and their $\beta\gamma$ -isomerides, it appears certain that the reversible change $\cdot\text{CH}\cdot\dot{\text{C}}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{CH}_3 \rightleftharpoons \cdot\text{CH}_2\cdot\dot{\text{C}}\cdot\text{CH}\cdot\text{CO}\cdot\text{CH}_3$, which is regarded as taking place through the conjugated forms $\cdot\text{CH}\cdot\dot{\text{C}}\cdot\text{CH}\cdot\text{C}(\text{OH})\cdot\text{CH}_3$ and $\cdot\text{CH}_2\cdot\dot{\text{C}}\cdot\text{CH}\cdot\text{C}(\text{CH}_3)\cdot\text{O}$, is capable of being driven one way or the other in the presence of sodium ethoxide by adding an appropriate reagent. The movement of the equilibrium in favour of the $\beta\gamma$ -form is in most cases difficult to demonstrate directly and in the case of *cyclohexylideneacetone* was shown by effecting methylation. In view of the obscurity of the relation between acidity and enolisation, the non-formation of a methylated derivative by any particular $\alpha\beta$ -unsaturated ketone cannot be regarded as evidence that the enolic form ($\beta\gamma$ -) does not exist in equilibrium with its tautomeride in the presence of sodium alkoxide.

The capacity of carbethoxyl groups to enolise is a matter of considerable uncertainty. Assuming that sodium is attached to oxygen in those esters which yield definite sodio-derivatives, the cases in which carbethoxyl groups are sufficiently acidic to yield such salts are those in which conjugation is secured by the participation of both ketonic (cyano-, etc.) and enolic groupings as in malonic and glutaric esters: $\text{EtO}\cdot(\text{ONa})\text{C}\cdot\text{CH}\cdot\text{C}(\text{OEt})\cdot\text{O}$ and $\text{EtO}\cdot(\text{ONa})\text{C}\cdot\text{CH}\cdot\text{CH}\cdot\text{C}(\text{OEt})\cdot\text{O}$. Experiment has shown that

Δ^8 -dihydromuconic ester, which might be written in the conjugated forms $\text{RO} \cdot (\text{OH})\text{C} : \text{CH} \cdot \text{CH} : \text{CH} \cdot \text{CH}_2 \cdot \text{C}(\text{OH}) : \text{O}$ and

cannot be methylated, and in the presence of sodium alkoxide—although how far the change is dependent on the manifested tendency to add the elements of alcohol is uncertain—the $\beta\gamma$ -unsaturation disappears in favour of the $\alpha\beta$ -phase. Nevertheless, even in such cases it appears certain that where subsidiary reactions do not interfere, the $\beta\gamma$ -form exists in the presence of sodium alkoxide in equilibrium with the probably greatly preponderating $\alpha\beta$ -form.

If this is so, the symmetrical Δ^8 -dihydromuconic system presents a case in which two such equilibria are connected. Representing the respective phases by the prefixes indicating the position of the double bond, equilibrium in the system $\overset{\alpha}{\text{C}} \cdot \overset{\beta}{\text{C}} \cdot \overset{\gamma}{\text{C}} \cdot \overset{\delta}{\text{C}}$ may be stated, $\alpha\beta \rightleftharpoons \beta\gamma \rightleftharpoons \gamma\delta$.

It should therefore be possible in a suitably substituted dihydromuconic ester to secure recognisable movement of the double bond from the α - to the α' -position, and such a case the author believes the additive products of ethyl muconate to represent. In the muconic system the $\beta\gamma$ -phase cannot exist and the system is static. When, however, addition has occurred, the system is no longer locked; there comes into play a system of connected equilibria in which, although the tendency to the $\beta\gamma$ -form be small,

equilibrium is established when conversion into the $\gamma\delta$ -form is almost complete. The equilibrium represented by $\beta\gamma \rightleftharpoons \gamma\delta$ is, of course, identical with the reversible $\alpha\beta$, $\beta\gamma$ -change which the work of Kon and his collaborators (*loc. cit.*; this vol., p. 2440) has shown to characterise the alkylidenecyanoacetic esters; but where conditions are suitable the reversible $\alpha\beta$, $\beta\gamma$ -change is just as capable of manifestation when the activating group is carbethoxyl as when it is a ketonic, cyanoacetic, or malonic group. In short, the difference in the nature of the activating group affects the position rather than the possibility of equilibrium.

* It is not intended in the present paper to distinguish between the alternative positions of the double bond inside the cyanoglutaconic system; the position which applies to the sodio-derivative of the ester is here represented.

EXPERIMENTAL.

Addition of Ethyl Sodiomalonate to Ethyl Δ^2 -Dihydromuconate.

Ethyl Butane- α -dicarboxylate- β -malonate (Formula III).—A well-shaken mixture of ethyl malonate (16 grams), a solution of sodium (2.3 grams) in absolute alcohol (35 c.c.), and ethyl Δ^2 -dihydromuconate was heated on a steam-bath for four hours, cooled, and poured into water. Extraction of the aqueous alkaline liquor with ether yielded a neutral ester which, after drying and distilling, was obtained as a colourless oil, b. p. $213^\circ/15$ mm. This substance, which gave no coloration with ferric chloride and represented the result of a simple additive process, constituted about 50 per cent. of the total yield (Found: C = 56.59; H = 7.69. $C_{17}H_{23}O_8$ requires C = 56.66; H = 7.77 per cent.).

Ethyl cyclopentan-1-one-2:5-dicarboxylate-3-acetate (Formula VI).

—The alkaline liquid (above), after removal of the neutral ester, was acidified and extracted with ether. The ethereal extract was well washed with water and sodium carbonate solution, which removed that portion of the material (about 25 per cent.) which had suffered partial hydrolysis during the reaction. The ester still remaining in the ether was worked up in the usual way and was obtained as a colourless, mobile oil, b. p. $210^\circ/16$ mm., which gave a deep blue colour with ferric chloride and dissolved readily in caustic alkali. The ready formation of this substance, which cannot be other than a cyclic ketonic ester, not only affords a further illustration of the ease of closing five-carbon rings, but also indicates a suitable way of preparing cyclopentan-1-one-3-acetic acid. Yield about 25 per cent. (Found: C = 57.51; H = 7.04. $C_{15}H_{22}O_7$ requires C = 57.32; H = 7.01 per cent.).

The acidic oil obtained from the sodium carbonate washings gave a blue coloration with ferric chloride. A portion of it was hydrolysed to ascertain whether it contained any ethyl hydrogen hydromuconate. This was not the case; the conversion of the original ester into additive derivatives appeared to be complete.

Butane- α -dicarboxylic- β -acetic Acid.—Ethyl butanedicarboxylate-malonate was boiled with dilute sulphuric acid (25 per cent.) until the ester had completely dissolved. Extraction of the cooled solution yielded a pale yellow syrupy acid which from its basicity evidently represented *butane- α -dicarboxylic- β -malonic acid*. This acid, on heating with water in a sealed tube at 180° for thirty minutes, lost carbon dioxide, thereby suffering conversion into a tribasic acid. The latter, which soon crystallised out after its aqueous solution had been evaporated to dryness, was obtained as a coarsely crystalline, white powder (m. p. 123°) after twice recrystallising from ether [Found: C = 46.70; H = 6.00; M (tribasic, CXXIII).

basic) = 205. $C_8H_{12}O_6$ requires C = 47.06; H = 5.88 per cent.; $M = 204$].

cyclopentan-1-one-3-acetic Acid.—The best conditions for obtaining this acid by hydrolysis of the *cyclopentanonedicarboxylicacetic ester* obtained above were not worked out. As in the production of its isomeride, *cyclopentan-1-one-2-acetic acid*, from ethyl *cyclopentan-1-one-2-carboxylate-2-acetate* (Kötz, *Annalen*, 1906, 350, 229), the yield of the syrupy decarboxylated acid obtained by use of dilute sulphuric or hydrochloric acid was rather poor. For analysis, the acid was converted into its *semicarbazone*, which crystallised from concentrated aqueous alcoholic solution in white flakes which melted with decomposition at 199° (Found: C = 48.4; H = 6.83. $C_8H_{13}O_3N_3$ requires C = 48.24; H = 6.53 per cent.).

Action of Sodium Alkylxide on Δ^8 -Dihydromuconic Esters.
Attempted Methylation of Methyl Δ^8 -Dihydromuconate.—Methyl dihydromuconate (25 grams) was added to a solution of sodium (3.3 grams) in methyl alcohol (40 c.c.). On pouring excess of methyl iodide into the deep red solution so obtained, sufficient heat was developed to bring about energetic ebullition. After heating on a steam-bath for two hours, the product was poured into water. The ethereal extract of the aqueous liquor contained an oil which, after removal of a small acidic portion by sodium carbonate, was found on isolation and fractionation to consist mainly of a colourless, mobile liquid, b. p. $137^\circ/17$ mm. A small quantity of a viscous, yellow oil (b. p. about $240^\circ/17$ mm.), formed apparently by intermolecular condensation of dihydromuconic ester, was also obtained. The colourless oil, which was thought at first to represent a methylated product, was ultimately identified by reason of its ready transformation into the derivatives described below as *methyl β -methoxyadipate* (Found: C = 53.03; H = 7.78. $C_9H_{16}O_5$ requires C = 52.94; H = 7.84 per cent.).

When the ester was heated at 100° with a saturated solution of hydrogen bromide in acetic acid in a sealed tube, almost quantitative conversion into β -bromoadipic acid occurred. This acid was obtained in crystalline form on evaporation of the solvent. Recrystallisation from acetic acid or ether yielded colourless prisms, m. p. 147° . Direct comparison with authentic specimens prepared by addition of hydrogen bromide to Δ^8 -dihydromuconic acid established the identity of the bromo-acid (Found: Br = 35.62. Calc., Br = 35.55 per cent.).

β -Methoxyadipic Acid.—When methyl β -methoxyadipate was boiled with dilute sulphuric acid until solution was just effected, the resulting acid was obtained as a colourless syrup which soon solidified. Longer boiling yielded a mixed product which under-

went partial solidification on standing for a week. The solid in each case, after recrystallisation first from benzene and then from concentrated ethereal solution, was obtained in colourless, prismatic nodules, m. p. 88–89°. This was β -methoxyadipic acid (Found: C = 47.72; H = 6.76; $M = 177$. $C_7H_{12}O_5$ requires C = 47.72; H = 6.82 per cent.; $M = 176$).

Lactone of β -Hydroxyadipic Acid.—The syrupy acid formed by prolonged hydrolysis of β -methoxyadipic ester could not be obtained in solid form. It was therefore distilled to separate small amounts of dissolved methoxy-acid and was thus obtained as a colourless syrup which on analysis gave figures closely approximating to those required for the lactone of β -hydroxyadipic acid. The correctness of this identification was further borne out by its basicity (mono-basic) and its conversion, under the conditions described above, into β -bromoadipic acid. A substance obtained in very small amount by Leuchs and Möbis (*Ber.*, 1909, 42, 1233) was described as a lactone of β -hydroxyadipic acid. Although two forms of the lactone are theoretically possible, the description suggests that the substance was actually the isomeric Δ^8 -dihydromuconic acid.

Action of Sodium Methoxide on Methyl Δ^8 -Dihydromuconate.—Mixing of a cold absolute methyl alcoholic solution of sodium methoxide and methyl Δ^8 -dihydromuconate in equimolecular proportions led to some development of heat and the production of a deep red solution. If this solution, after standing for some minutes, were poured into water, the liquor extracted with ether, and the product worked up in the usual way, it was found that the ester had undergone complete alteration. It no longer yielded any appreciable quantity of Δ^8 -dihydromuconic acid on hydrolysis with dilute sulphuric acid, but was converted into the β -methoxyadipic acid described above. Similar effects were obtained with the corresponding ethyl esters. Further, the method by which muconic esters were obtained by the addition of the requisite quantity of alcoholic sodium alkoxide to $\beta\beta$ -dibromoadipic esters was useless when applied to the preparation of Δ^8 -dihydromuconic esters from β -bromoadipic esters; a considerable removal of the hydrogen bromide was effected, but the dihydromuconic ester underwent change so soon as produced.

The author desires to express his thanks to Professor J. F. Thorpe and Dr. C. K. Ingold for their interest in this work, and to the Chemical Society for a grant which has defrayed a considerable portion of the expense incurred.

CCCXCV.—*Experiments on the Synthesis of Substances Possessing the Ladenburg Formula, Part I. Associated Three-carbon Ring Systems.*

By ERNEST HAROLD FARMER.

WHEN, a few years ago, Beesley and Thorpe (T., 1920, 117, 591) synthesised a closed associated ring-system of the "cage" type, it seemed that this would be the first of a series of substances of similar nature. Since then no further example seems to have been obtained, although it is probable that many such compounds are capable of existence and there is one such structure, that represented by the Ladenburg formula, which is of particular interest in view of the part it took in the controversy concerning the constitution of benzene. The attention of the author was directed by Professor Thorpe towards the problem of synthesising a substance derived from the hydrocarbon represented by formula I, and many experiments have been made with this ultimate object in view.

In building up such a substance from non-cyclic materials two main processes are involved: the closing of four-carbon and of three-carbon rings. According as one or the other operation is first performed, it appeared that the process must necessarily proceed by way of a six-carbon skeleton of one of the types (A), (B), and (C). The consideration of these types in the light of

present knowledge concerning the difficulty of formation of four-carbon rings, the instability of three-carbon rings, and the tendency of associated ring-systems such as norcaradienecarboxylic acid to undergo isomeric change, made it obvious that for the present the

production and study of one or more of these intermediate six-carbon structures must be an aim in itself. Although the possibilities of each of these methods of procedure has been to some extent explored, the present paper deals mainly with the formation of substances of the type (C). It is impossible to forecast the ease or difficulty with which substances of this type may be converted by joining one of the pairs of carbon atoms denoted in the diagram

by the signs *, into substances of the type (B), or by union of both pairs into the "prism" structure (I). If figures for such tendencies in the carbon skeleton could be calculated on the lines of Ingold's "Figures of Formation" (T., 1921, 119, 305) such figures could scarcely apply in practice owing to the experimental necessity of introducing heavy, unbalanced, substituent groups. Further complications arise from the latter in the way of stereoisomerism.

In view of the ready formation of three-carbon rings from substituted glutaric acids, and the wealth of experimental detail concerning the process to be found in the literature, the substance which suggested itself as eminently suited to the present purpose was *s*.-ethanetetra-acetic acid, $(\text{CO}_2\text{H}\cdot\text{CH}_2)_2\text{CH}\cdot\text{CH}(\text{CH}_2\cdot\text{CO}_2\text{H})_2$ (II). All attempts, however, to synthesise this acid from such substances as muconic acid, β -bromoglutaric acid, and $\beta\beta'$ -dibromoadipic acid were unsuccessful. From the ester of the last acid, however, was obtained one of a class of substances which it was desired to examine in connexion with the synthesis of substances of type (B). The reaction between ethyl $\beta\beta'$ -dibromoadipate and ethyl sodiomalonate resulted mainly in the loss of hydrogen bromide by the former, the muconic ester produced subsequently undergoing further transformation, owing to the occurrence of an additive reaction of the Michael type; yet, when the reaction was carried out at a higher temperature with sodiocyanoacetic ester in place of the sodiomalonic ester, addition of the Michael type did not occur or only to an inappreciable extent. The main product was again muconic ester, but the subsidiary product, carboxycyanocyclopropanediacetic ester,* (III), was probably formed according to the scheme below. On boiling the cyclic ester with strong

hydrochloric acid, fission of the cyclopropane ring occurred, yielding a lactonic acid probably represented by (IV). In this connexion may be mentioned certain other cyclopropaneacetic acids which have been prepared in the course of the search for a suitable starting material for the preparation of tricyclohexane derivatives (type B). By bromination and esterification of methylmethanetriacetic acid (V), a monobrominated acid ester (VI) was obtained which on

* An analogous substance could not be obtained by the action of ethyl diazoacetate on ethyl Δ^8 -dihydromuconate.

3334 FARMER: EXPERIMENTS ON THE SYNTHESIS OF SUBSTANCES

treatment with concentrated aqueous caustic potash yielded the bridged acid (VII). Of the three stereoisomeric forms (two *meso*

and one racemic) which are theoretically possible for this substance, two were isolated in a state of purity, the third, which was probably present, being inseparable from small amounts of a gummy lactic acid probably represented by (VIII). In dealing with all such substances, the difficulty was not one of securing reaction of the desired type, but of obtaining the required products in adequate yield. Up to the present, this has only been achieved for materials required for the synthesis of substances of type (C).

Of the methods recorded in the literature for producing cyclopropane rings, there are three that lend themselves to the production of a double cyclic system; the addition of diazoacetic ester or diazomethane to such substances as benzene and fumaric ester has frequently been made use of, whilst in other cases the same result has been obtained by the action of sodiummalonic ester on the esters of $\alpha\beta$ -dibrominated or $\alpha\beta$ -unsaturated- α -brominated acids. The application of the diazoacetic ester reaction to muconic esters was unsuccessful, reaction proceeding only at high temperatures to yield viscous materials unrecognisable as products of the usual type. The employment of ethyl $\alpha\alpha'\beta\beta'$ -tetrabromoadipate was vitiated by the loss of bromine by reduction which resulted in the formation, amongst other products, of ethyl muconate and ethyl ethanetetra-carboxylate. When, however, the third method was used, addition of the required type proceeded smoothly. The formation of a cyclopropylcyclopropane system (IX) rather than

of a cyclopentadiene ring (X) under conditions precisely similar to those used by Perkin and Robinson (T., 1921, 119, 1292) for obtaining the corresponding saturated compound (XI) from ethyl $\alpha\alpha'$ -dibromoadipate, is in keeping with the failure of all the author's

attempts to obtain even traces of cyclopentadiene or cyclopentadienone derivatives from muconic acid. It seems remarkable that, although substances such as thiophen, pyrrole, and furan are readily obtained from 1:4-diketones, the preparation of their homocyclic analogues directly from butadiene derivatives presents great difficulty.

The preparation of isomeric methyl and ethyl dichloromuconates in quantity was described in a recent communication (this vol., p. 2544). Since the process of additive ring formation in each half of the halogenated muconic molecule almost certainly takes place in two stages, a Michael addition rendering free rotation possible, followed by ring formation, it is not surprising that the same

product is obtainable from two stereoisomerides. Thus the two methyl $\alpha\alpha'$ -dichloromuconates (probably representing *cis-cis*- and *trans-trans*-forms) yielded one and the same solid methyl cyclopropylcyclopropanehexacarboxylate, and the two ethyl dichloromuconates, one corresponding ethyl ester. These esters were beautifully crystalline substances and were produced in yield of about 25 per cent. They were not, however, the only substances formed. Whenever the reaction was carried out with one or other isomeride of either series, the appropriate solid ester was accompanied by an extremely viscous liquid isomeride. Although these liquids could readily be obtained in a state of chemical purity, their stereoisomeric homogeneity is doubtful. Addition of malonic residues to the chloromuconic system probably takes place on the same and on different sides of the plane of the double linkings in different molecules, yielding position isomerides of the types (XII) and (XIII) as well as stereoisomerides of both types. The deter-

mination of the configuration of the different isomerides, although of considerable interest and having an important bearing on the last stages of the synthesis of a closed associated ring system, yet offers in these esters and their corresponding hexacarboxylic acids very great experimental difficulty and has not been attempted at this stage of the investigation.

The solid methyl and ethyl hexacarboxylic esters (IX) yield on

hydrolysis with alkali a crystalline sodium salt from which the hexacarboxylic acid, $(\text{HO}_2\text{C})_3\text{C}_3\text{H}_2\text{C}_3\text{H}_2(\text{CO}_2\text{H})_3$, is easily obtained. This acid, which is procurable in very pure condition and in reasonable quantities, shows extraordinary stability towards bromine and alkaline permanganate. It loses carbon dioxide on heating above its melting point, but at the same time suffers considerable ring-fission. Heating with water in a sealed tube gives a better result, although in this case also some fission results and the difficulty of the economical separation of the products has not yet been satisfactorily surmounted. Nevertheless, specimens of the pure tetracarboxylic acid (XIV) have been obtained, but the configuration of the substance is not yet known. The further examination of the tetracarboxylic acids derived from both liquid

and solid esters with the object of isolating the form (XV) is now in progress and it is hoped to describe these substances more fully at a later date.

EXPERIMENTAL.

Action of Ethyl Sodiocynoacetate on Ethyl ββ'-Dibromoadipate.

Ethyl cycloPropane-1 : 1-dicarboxylate-2 : 3-diacetate.—The bromo ester and ethyl sodiocynoacetate (2 mols.) reacted quickly in cold alcoholic solution. The mixture was heated on a steam-bath for five minutes to complete the reaction, poured into water, and worked up in the usual way, the product consisting almost entirely of cyanoacetic and muconic esters; the amount of condensation was insignificant. In boiling solution, however, a much larger proportion of condensation product formed. This was obtained on fractionation as a colourless, rather viscous oil, b. p. 222°/21 mm. quite different from the substance resulting from an additive reaction of the Michael type, and on account of its properties must almost certainly be represented by formula III. The small yield of the compound, however, rendered its employment in quantity as a basis for further synthesis too expensive (Found C = 57.57; H = 6.56. C₁₆H₂₁O₆N requires C = 57.88; H = 6.75 per cent.).

Lactone of β -Hydroxybutane- $\alpha\delta$ -dicarboxylic- γ -acetic Acid (Formula IV).—Hydrolysis of the cyclic ester with concentrated hydrochloric acid was carried out before its cyclic nature was appreciated. Extraction of the acid solution with ether removed a quantity of gummy material only, but evaporation to dryness yielded a mixture of a solid acid and ammonium chloride. The former was extracted with ethyl acetate, and after recrystallisation from this solvent was obtained as a white, crystalline powder, m. p. 140°. The acid was isomeric with that derived from the product of Michael addition mentioned above (*vide T.*, 1922, 121, 2019), but was stable to alkaline permanganate. On titration with standard baryta solution, only two equivalents of the latter were neutralised and the end-point was of that indefinite character frequently associated with lactonic acids (Found: C = 47.57; H = 5.08. $C_9H_{10}O_6$ requires C = 47.52; H = 4.95 per cent.).

Diethyl Hydrogen α -Bromomethylmethanetriacetate (Formula VI).—The mono-bromination of the acid bromide of methylmethanetriacetic acid under conditions similar to those used by Beesley and Thorpe (*loc. cit.*, p. 610) for dibromination invariably led on subsequent esterification to a mixture of neutral and acidic esters. In no case was a specimen of the undoubted triethyl monobromo-ester isolated from the neutral portion; the latter usually consisted of a mixture of esters of the unbrominated and dibrominated acids. The acidic portion, on the other hand, consisted almost entirely of a diethyl hydrogen monobrominated ester, but its yield amounted to about only one-eighth of the total product. All attempts to improve the yield by adopting other conditions and methods of bromination failed. The acid ester which was separated from the neutral products by means of sodium carbonate solution was liberated by acidification and taken up in pure ether. From the well-washed ethereal solution, after drying and thorough removal of the solvent, the bromo-ester was obtained as a pale yellow oil (Found: Br = 24.1. $C_{12}H_{19}O_6Br$ requires Br = 23.6 per cent.).

3-Methyl-cyclopropane-1:2-dicarboxylic-3-acetic Acid (Formula VII).—To a concentrated aqueous solution of potassium hydroxide at 150°, 10 grams of the bromo-ester, mixed with an equal volume of alcohol, were added as quickly as possible and the reaction was allowed to subside. The product was cooled and acidified. Since extraction with ether removed only a small quantity of acid material, the solution was evaporated to dryness and the residue extracted with ether and acetone. The combined extracts yielded a yellow syrup which partly solidified on standing. The whole was dissolved in glacial acetic acid and the acid (m. p. 180–190°) that crystallised after several days was filtered off. Further small quantities of this

acid separated over a period of several weeks. It was recrystallised by dissolution in a small amount of water and addition of an equal volume of concentrated hydrochloric acid. On standing, colourless flakes separated; these melted at 194° with loss of steam (Found: $C = 47.40$; $H = 4.87$; M , tribasic, $= 201.8$. $C_8H_{10}O_6$ requires $C = 47.52$; $H = 4.95$ per cent.; $M = 202$).

The mother-liquor was mixed with dry chloroform, which precipitated a solid and an oil. After standing for some days, the solvent and oil were removed by suction and the solid acid was washed with dry ether. The acid, which was extremely soluble in water, crystallised from a mixture of acetic acid and chloroform as a white, crystalline powder, m. p. 216° (Found: $C = 47.48$; $H = 5.02$; M , tribasic $= 202$. $C_8H_{10}O_6$ requires $C = 47.52$; $H = 4.95$ per cent.; $M = 202$).

The viscous gum obtained from the filtrate could not be purified; it is almost certainly isomeric with the solid acids (above), but is not tribasic.

Action of Methyl Sodiomalonate on Methyl trans-trans-xx'.Di. chloromuconate.—The solid chloro-ester (1 mol.) was gradually added with shaking to a solution of methyl sodiomalonate (2 mols.) in methyl alcohol. Reaction soon set in, sodium chloride separating, and after a time (premature external heating causing the reaction to proceed with almost explosive violence) the mixture was heated on a steam-bath until the product was only feebly alkaline towards litmus (usually about two hours); although a slight deficit of sodium was usually employed, prolonged heating failed to remove the last trace of alkalinity. The cooled product was poured into water and shaken with ether, the solid ester that remained undissolved was removed, and the unwashed ethereal extract dried by standing for at least twelve hours over anhydrous sodium sulphate; the further considerable quantity of the solid ester that crystallised out on the sodium sulphate was recovered by decanting the ethereal solution and dissolving the sulphate in warm water. On evaporating the ether from the dry ethereal solution, a viscous, yellow oil was obtained. Extraction of the acidified aqueous liquor yielded a small quantity of a halogen-free acid ester, which was hydrolysed without further treatment.

Methyl cycloPropylcyclopropanehexacarboxylate (IX).—(a) *Solid form.* The crude solid ester was well washed with methyl alcohol and dry ether and then twice recrystallised from boiling methyl alcohol, in which it was only sparingly soluble. It was obtained in stout, well-formed, colourless prisms, m. p. 148° . The recrystallisation of this substance in quantities of more than a few grams offered difficulty owing to the slight solubility of the ester in all the

ordinary organic solvents. It was satisfactorily accomplished, however, by extracting the crude ester with benzene in a Soxhlet apparatus and removing from time to time the crystals which accumulated in the boiling solution. Yield about 25 per cent. (Found: C = 50.09; H = 5.29. $C_{18}H_{22}O_{12}$ requires C = 50.23; H = 5.12 per cent.).

(b) *Liquid form.* The oily ester (above) was almost completely freed from a little dissolved solid ester by cooling its solution in a fairly large quantity of methyl alcohol in a freezing mixture until no further solid would crystallise. The liquid ester recovered from the alcoholic solution was extremely stable and in spite of its high molecular weight could be distilled in small quantities at reduced pressure without decomposition. For adequate fractionation, a pressure not greater than 5 mm. was necessary. The pure ester, which probably represented more than one stereoisomeride, was obtained as a pale yellow liquid (b. p. $230^{\circ}/4$ mm.) of almost resinous consistency when cold. It was readily soluble in boiling methyl alcohol, but separated from fairly concentrated solution in this solvent on cooling (Found: C = 50.19; H = 5.17. $C_{18}H_{22}O_{12}$ requires C = 50.23; H = 5.12 per cent.).

A small quantity of material which had a somewhat lower boiling point than the above and contained halogen was usually obtained. This was accumulated and re-treated with methyl sodiomalonate.

Ethyl cycloPropylcyclopropanhexacarboxylate.—Solid and liquid forms of this ester were obtained by methods precisely similar to those used for the methyl esters. The solid form crystallised from alcohol in very perfect, colourless prisms, m. p. 96° (Found: C = 56.00; H = 6.56. $C_{24}H_{34}O_{12}$ requires C = 56.03; H = 6.61 per cent.). The liquid form of the ester possessed properties almost identical with those of the corresponding methyl ester and yielded a similar product on hydrolysis.

Action of Methyl Sodiomalonate on Methyl cis-cis- $\alpha\alpha'$ -Dichloromuconate.—When the lower-melting stereoisomeric methyl dichloromuconate (regarded as the *cis-cis*-form) was substituted for the *trans-trans*-form in the reaction with methyl sodiomalonate, the products were indistinguishable from those obtained with the latter form. The solid esters obtained in the two cases were identical and were produced in approximately equal yield; the liquid esters possessed similar properties and yielded very similar products on hydrolysis, but their complete identity is as yet uncertain.

cycloPropylcyclopropanhexacarboxylic Acid.—When the solid methyl or ethyl hexacarboxylate was heated for four hours with the exact theoretical amount of alcoholic sodium hydroxide, obtained by adding water to alcoholic sodium ethoxide, a white, crystalline,

sodium salt was obtained. This was filtered off and washed with alcohol. It dissolved in hot water and separated, on standing, in large, colourless, bevelled prisms which contained water of crystallisation. The latter was lost on heating at 130° ; the anhydrous hexa-sodium salt was a fine, white powder (Found: $\text{Na} = 28.5$, $\text{C}_{12}\text{H}_4\text{O}_{12}\text{Na}_6$ requires $\text{Na} = 28.9$ per cent.).

The hexacarboxylic acid was produced on acidification of an aqueous solution of the sodium salt, but owing to its extreme solubility in water and slight solubility in organic solvents it could not be extracted with ether. Evaporation to dryness of an aqueous solution containing even a small excess of hydrochloric acid appeared to cause considerable ring-fission. It was found best to saturate an aqueous solution of the sodium salt, maintained at a temperature below 0° , with hydrogen chloride. The acid was precipitated along with sodium chloride. The solid portion was removed, dried in an evacuated desiccator, and the acid extracted with ethyl acetate in a Soxhlet apparatus. The acid was purified by a further precipitation from aqueous solution with hydrogen chloride; it was thus obtained as a white, crystalline powder which melted at 197° with loss of carbon dioxide [Found: $\text{C} = 41.74$; $\text{H} = 3.01$; M (hexabasic) = 346. $\text{C}_{12}\text{H}_{10}\text{O}_{12}$ requires $\text{C} = 41.61$; $\text{H} = 2.84$ per cent.; $M = 346$]. The acid which remained dissolved in the hydrochloric acid solutions was recovered in the form of its insoluble barium salt.

The liquid ethyl and methyl hexacarboxylic esters on hydrolysis with alcoholic sodium hydroxide yielded similar sodium salts. The acid from each of these was liberated on acidification; a small portion was obtained on thorough extraction with ether, the remainder on evaporation to dryness and extraction of the residue. In each case the acid was a pale yellow syrup which contained a proportion of unsaturated material. There was little doubt that the syrups were similar mixtures of isomeric hexacarboxylic acids. Conversion into the very insoluble barium salt which these syrups yield and regeneration of the acid still gave the latter in a syrupy form and there still remained a proportion of unsaturated acid. Oxidation of the unsaturated portion by alkaline permanganate and precipitation of the saturated portion as the barium salt did not serve as a method of securing a reasonably pure product. The yield of material was excellent, but the complete purification at this stage was not accomplished.

cycloPropylcyclopropanetetrcarboxylic Acid.—The solid hexacarboxylic acid was readily decomposed by heating at 200° , but decarboxylation by this method was unsuitable, since the greater proportion of the material appeared to suffer ring-fission. A better

method was that of heating the acid with water in a sealed tube at 180° . No charring took place and the extent to which ring fission occurred was considerably reduced. The separation of the products, however, was exceedingly difficult owing to their similar solubilities and inferior powers of crystallisation. At present, though many methods for their economic separation have been attempted, reasonably pure specimens of a saturated tetracarboxylic acid only have been prepared. This substance, which crystallises from concentrated solution in a mixture of acetone and chloroform only with great difficulty and on long standing, was obtained in colourless, crystalline nodules, m. p. $105-107^{\circ}$. It was obtained by evaporating to dryness of the aqueous solution from the sealed tube. The bulk of the residue solidified after standing for some days. A partial separation of the admixed gummy material was effected by spreading on a porous tile; the remainder was removed by repeated recrystallisation (Found: C = 46.24; H = 4.21. $C_{10}H_{10}O_8$ requires C = 46.51; H = 3.87 per cent.). On titration with standard baryta solution, the acid neutralised rather less than four equivalents of alkali.

Stability of cycloPropylcyclopropane Derivatives.—The stability of cyclopropylcyclopropanhexacarboxylic acid is remarkable. Attempted bromination of the acid chloride of the solid form by heating on a steam-bath for two days with bromine—during a large part of the time the mixture was exposed to brilliant sunlight—led to little bromination either by substitution or by addition subsequent to ring-fission. On pouring the product into methyl alcohol, the bulk of the acid was recovered unchanged as its solid methyl ester. Small quantities of the acid could be left in contact with dilute alkaline permanganate at room temperature for several weeks without reduction occurring.

The specimens of the solid tetracarboxylic acid obtained did not decolorise permanganate, but gradual reduction of the first drop of the latter became noticeable after fifteen minutes.

Acknowledgment is made to the Chemical Society for a grant which has defrayed a portion of the cost of this research and to Professor J. F. Thorpe for his interest and advice throughout the work.

CCCXCVI.—*The Chemistry of the Glutaconic Acids.*
 Part XV. *Three-carbon Tautomerism in the*
cycloPropane Series. Part II.

•By FRANK ROBERT GOSS, CHRISTOPHER KELK INGOLD, and
 JOCELYN FIELD THORPE.

THE study of the isomerism of a glutaconic acid, in which the possibility of geometrical isomerism is excluded by ring formation, is of more than ordinary interest, because in such a case the evidence is clearer than any which has previously been obtained that in three-carbon tautomerism structural conditions may be encountered which cannot be interpreted by conventional space models. An instance of this kind was described in the preceding part of this series (Goss, Ingold, and Thorpe, this vol., p. 327), and in view of the fact that the examination of such compounds is likely to throw light on the nature of the valency by which the tautomeric hydrogen atom is attached to the organic molecule (Usherwood, this vol., p. 1718), every effort is being made to extend the former investigation, and to prepare other "test-case" substances.

The general conclusion which was drawn as a result of the former experiments was that whilst the cyclic glutaconic acid under examination exists in one isolable form having the "normal" structure (I), its reactions show that in solution it comes into equilibrium with a second, or "labile," modification (II). On the other hand, when the mobile hydrogen atom of each carboxyl group was replaced by an alkyl radicle (esterification), the tautomeric change, depending on the one remaining mobile hydrogen atom, became damped down to such an extent that three isomeric esters, the "normal," "labile," and "enol" modifications (formulae III, IV, and V), could be isolated as separate individuals and their interconversion studied experimentally.

In view of the fact that the results formerly obtained have been made use of in support or illustration of electrical theories, notably by Lowry (this vol., pp. 827, 2116), whose speculations regarding the acids and esters we have investigated pass quite beyond anything that, so far as we are aware, we have, as yet, experimentally demonstrated, it is desirable in referring to the above conclusions to state exactly what we wish the formulae given for the "normal" acid

and esters to imply. First, all experiments on the glutaconic acids, including this cyclic acid, combine to show that there is something in the constitution of these substances which conventional symbols do not explain, and that this "something" is connected with the mobile hydrogen atom of the system, because it disappears whenever that hydrogen atom is absent; we assume, therefore, that this structural peculiarity is connected with the mode of attachment of the mobile hydrogen atom to the rest of the molecule. Secondly, the investigation of the tautomeric esters (types III, IV, and V) clearly showed that after the mobile hydrogen atom had passed into the carboxyl group as in the enol modification (V), it could not return to the position which it takes up in the normal form (III) *directly*, but only by way of its position in the labile ester (IV), that is, at the α -carbon atom of the system, which forms a halting place in the two-stage migration; thus in the normal structure (III) the hydrogen atom is, in a certain sense, *further away* from the carboxyl

group than it is in the labile ester, in which it is directly attached to the α -carbon atom. Thirdly, as experiments on the identity of α - and γ -substituted glutaconic acids have shown, the mobile hydrogen atom in a normal acid or ester is situated symmetrically with respect to the two carboxyl groups. Beyond these three salient facts, there is nothing which can be regarded as proved with respect to normal three-carbon structure. The method of formulation adopted, typified by the following representation of glutaconic acid (VI), depicts each

of these three facts with a bare minimum of implied hypothesis, and in our view no zeal for a system can justify the introduction of formulæ which are in no sense proved, and are improper in so far as they imply more knowledge than any to which we can justly lay claim in the present state of the subject.

Constitution of the cycloPropene Acid: Two New Syntheses.

The constitution of the acid (I, II) rests at present on the following evidence:

- (i) Its formation from bromoisodehydracetic ester (VII), which

may be assumed to decompose as follows under the influence of alkali :

(ii) Its formation from $\alpha\alpha'$ -dibromo- β -methylglutaric ester (VIII) (Ingold, T., 1922, 121, 2687) :

(iii) Its additive properties, which characterise it as a monocyclic unsaturated acid with an $\alpha\beta$ -double bond (Goss, Ingold, and Thorpe, *loc. cit.*).

(iv) Its special properties showing that it is a typical mobile glutamic acid (*loc. cit.*).

(v) Oxidation of the esters by the ozone method to ethyl acetyl-oxaloacetate (IX) (*loc. cit.*).

(vi) Oxidation of the acid by alkaline permanganate to malonic acid (*loc. cit.*).

(vii) Reduction of the acids by hydrogen iodide to β -methylglutamic acid (X) (*loc. cit.*).

Although the accumulated weight of this evidence is sufficient to place the constitution of this acid beyond any reasonable doubt, we felt that in view of its remarkable properties and theoretical interest no effort should be spared to consolidate the grounds on which its structure is based. A notable lacuna in the chain of evidence lay in the absence of any direct connexion with known saturated compounds of the cyclopropane series, and some such connexion we have therefore endeavoured to establish.

Our first experiments with this object were directed towards the reduction of the acid to 3-methylcyclopropane-1 : 2-dicarboxylic acid (XI). Mild reducing agents, however, had no effect on the cyclopropene acid, and hydrogen iodide attacked, not the glutamic system, but the three-carbon ring, giving β -methylglutamic acid (X) as sole product (*loc. cit.*). We therefore turned to the converse

process, the introduction of a double linkage into the *cyclopropane* ring of the saturated acid (XI), and in this way we have succeeded in evolving two distinct new syntheses of the *cyclopropene* acid.

The *cyclopropane* acid (XI) can theoretically exist in three forms, a *trans*-form (XII), and two *cis*-forms (XIII and XIV), and, as these behave differently in the subsequent stages of the synthesis, their formation and orientation must first be described.

All three stereoisomeric acids are conveniently prepared by hydrolysis of the tri- and tetra-carboxylic esters (XV and XVI). The tricarboxylic ester is readily obtained by condensing the dibromide of ethyl crotonate with ethyl malonate and sodium ethoxide, and the tetracarboxylic ester by condensing acetaldehyde with malonic ester and treating the disodio-derivative of the dimalonic ester with bromine :

It will be noticed that the tetracarboxylic ester can have but one geometrical configuration, whilst two configurations are possible for the tricarboxylic ester. Moreover, whilst the tetracarboxylic ester might, on hydrolysis, give rise to all three dicarboxylic acids, the tricarboxylic ester, whatever its configuration, can at most yield two dicarboxylic acids, one of which must be the *trans*-acid (XII). It happens that in each case acid hydrolysis gives the theoretical number of isomerides.

The hydrolysis of the tricarboxylic esters has been carried out by Preiswerk (*Ber.*, 1903, **36**, 1085), who isolated a *cis*-acid, m. p. 108°, by means of its anhydride, but failed to obtain the *trans*-isomeride, m. p. 195°.

Kötz and Stalman (*J. pr. Chem.*, 1903, [ii], **68**, 158) hydrolysed the tetracarboxylic ester, but were unable to obtain a pure product. Actually the gum which they describe is a mixture of the three

isomerides, m. p. 195°, 132°, and 108°, which, after the gum has solidified, may readily be separated by fractional crystallisation.

Ingold (*loc. cit.*) described the two acids, m. p. 108° and 132°, as products regenerated from anhydrides obtained by the action of acetyl chloride on a mixture of the three isomerides, and from this it follows that the acid, m. p. 195°, must have the configuration represented by the *trans*-formula (XII), whilst the other two acids, m. p. 132° and 108°, are *cis*-acids to which the two remaining formulæ must be assigned.

As to which of these formulæ belongs respectively to each of the two *cis*-acids, the evidence is less direct. If, however, we accept Auwers and Wissebach's demonstration (*Ber.*, 1923, 56, [B], 715) of the *trans*-structure of ethyl crotonate, and assume that the usual *trans*-addition of bromine occurs in the formation of its dibromide, and further, that in the formation of the tricarboxylic ester (XV) the ring closure takes place without change of configuration (Perkin and E. Robinson, T., 1921, 119, 1395), then it follows that the configuration of the tricarboxylic ester must be such that only the acids (XII) and (XIV) can result from its complete hydrolysis. Since the two acids actually obtained are the *trans*-acid and the *cis*-acid, m. p. 108°, it follows that the acid, m. p. 132°, has the (*trans*)-*cis*-structure (XIII), and that the acid, m. p. 108°, has the (*cis*)-*cis*-structure (XIV). This method of reasoning cannot, of course, be regarded as conclusive; but as it leads to the particular allocation of formulæ which might have been anticipated from the relative melting points and solubilities of the acids, it may, perhaps, be accepted as providing a provisional solution to the stereochemical problem involved.

The *trans*-acid (XII), on bromination by means of bromine and phosphorus pentachloride, yields products which differ according to the conditions of the experiment. Rapid bromination leads to a dibromo-derivative which, since it is converted back into the original acid on reduction by sodium amalgam, must have the constitution expressed by formula (XVII). If, however, the bromination is carried out with caution at a lower temperature, the sole isolable derivative is the same dibromo-acid (XIX) that was previously described (Goss, Ingold, and Thorpe, *loc. cit.*) as the bromo-additive product of the cyclopropene acid. The formation of this bromo-acid appears at first sight difficult to interpret, but it is readily understood when it is recalled that the monobrominated acid (XVIII), which in any event must initially be formed, has previously been shown (Ingold, *loc. cit.*) to be an intermediate product in the formation of the cyclopropene acid (II) from ethyl $\alpha\alpha'$ -dibromo- β -methylglutarate. The excess of bromine present

under the experimental conditions employed would immediately convert the *cyclopropene* acid (II) into the dibromo-acid (XIX), and, as has already been shown (Goss, Ingold, and Thorpe, *loc. cit.*), this acid is stable and is not converted into a tribromo-derivative by excess of bromine under the conditions employed. Moreover, it has been shown (*loc. cit.*) that on reduction by sodium amalgam this dibromo-acid (XIX) passes into the *cyclopropene* acid (II), and hence the synthesis of this acid from the *trans-cyclopropane* acid is completed :

The two *cis*-acids may also be converted into the *cyclopropene* acid in the following manner. On bromination, each acid forms a dibromo-substitution product which loses hydrogen bromide, giving the bromocyclopropene acid (XX). This substance on dissolving in cold, dilute alkali undergoes spontaneous reduction to the *cyclopropene* acid (I, II), free hypobromite being liberated in the solution :

The bromocyclopropene acid (XX) was not isolated during the former research, but it was shown, notwithstanding, that in such an acid the tendency to acquire the hydrogen atom necessary for three-carbon tautomerism is such that spontaneous reduction would occur in cold, dilute alkalis with the liberation of free hypobromite (*loc. cit.*, pp. 332, 342) and the formation of the mobile *cyclopropene* acid (I, II). This happens, just as was anticipated.

Isomerism and Interconversion of the Esters.

The experiments previously described, relating to the three ethyl esters of the cyclopropene acid, led to the conclusion that these substances enter into a double reversible isomeric change of the following type :

The equilibrium favours the normal ester rather than the labile, and the labile rather than the enol, whilst the relative velocities of the changes are such that when the enol ester is prepared in a state of purity and then kept at the ordinary temperature, most of it is converted into the labile ester in the course of a few hours, and most of this passes into the normal ester after a few months. The first change occurs instantaneously, and the second in a few minutes or hours, in alcoholic sulphuric acid at 100°.

In sodium ethoxide solution a third reversible change, the formation and alcoholysis of the sodium derivative of the enol ester, takes place, and the resultant equilibrium is of the following type :

The figures are for the temperature 60°, and are those to which an extended study of these reactions has led. At this temperature the "rapid" equilibrium is established in seconds or at most a few minutes, whilst the "slow" equilibrium requires hours or at most a few days.

The equilibration of the methyl esters, either in the absence of reagents or in acid solution, resembles that of the ethyl esters, but the preponderance of normal ester is still greater; so much so that we were unable to determine the "normal-labile" equilibrium ratio with any approach to accuracy :

It was not found possible to examine the equilibration of the methyl esters in sodium methoxide solution at 60° owing to the fact that at this temperature the "normal" ester reacts with sodium methoxide to form an additive compound. At 20°, however, this reaction does not take place to an appreciable extent, and an examination of the interconversion at this temperature of the three esters and the sodio-ester was rendered possible by the fact that equilibration proceeds much more rapidly than in the ethyl ester

series. The "slow" reaction represented in the following scheme requires about fifteen hours for the complete establishment of equilibrium; the figures indicate the observed equilibrium ratios:

The sodio-methyl ester (XXI) is a yellow, crystalline substance similar in appearance and in many of its properties to the well-known yellow sodium compound of ethyl dicarboxyglutaconate (XXII). Both the sodio-ester and the enol-ester give colours with ferric chloride, whereas the normal and labile esters give no colour, excepting under conditions in which partial reconversion into the enol-ester is possible.

We believe that these experiments provide ample grounds for our contention that the position of the mobile hydrogen atom in the normal ester is such that a hydrogen atom replacing the sodium atom in the sodio-ester can only reach it by passing through a position on the α -carbon atom of the system.

Reactivity of the Normal Glutaconic Esters.

In collecting together all the evidence which seems to bear in any way on the constitution of the normal glutaconic esters, the remarkable fact emerges that no uniform relationship appears to subsist between the additive powers of the normal esters and their labile isomerides.

It has already been shown that the normal and the labile esters of the open-chain glutaconic acid series differ sharply in regard to their capacity to form additive products with ethyl sodiocyanoacetate (Thorpe and Wood, T., 1913, 103, 1579; Ingold and Thorpe, T., 1921, 119, 492). Whilst the labile esters react readily in the manner characteristic of $\alpha\beta$ -unsaturated esters, the reactions with the normal esters take place with great difficulty and give rise to products of 1:3-addition.

On the other hand, when the addition of ozone is considered, the normal esters are frequently the more reactive. Feist noticed that normal ethyl α -carboxy- β -phenyl- α -methylglutaconate absorbed ozone more readily than the corresponding labile ester (*Annalen*, 1922, 248, 45), and we have found a similar marked difference in the case of the normal and the labile ethyl ester of the glutaconic acid

which forms the subject of this communication, the normal ester absorbing ozone about three to five times as rapidly as the labile ester under corresponding conditions of temperature and dilution. On the other hand, the ethyl esters of $\alpha\beta$ -dimethylglutaconic acid differ in the opposite sense, the labile ester showing the greater additive power. In all these cases 1:2-addition, and not 1:3-addition, of ozone takes place.

Comparative experiments on the addition of bromine to the normal and the labile methyl ester of the *cyclopropene* acid have shown the labile ester to be the more reactive, although it may be doubted whether the difference in the velocity of absorption is sufficient to justify the assumption that addition takes place solely through the labile form, since the equilibrium ratio is so unfavourable to this modification. The addition is exclusively 2:3 (corresponding to 1:2-addition to an open-chain glutaconic ester), however, each ester yielding the same crystalline dibromide (XXIII) unaccompanied by any isomeride.

The addition of methyl alcohol to the same two methyl esters shows a similar interesting difference; but in this case the normal ester is the more reactive. Nevertheless, it forms a 2:3-addition product. The reagent employed is methyl alcoholic sodium methoxide, and although it does not attack the normal ester at an appreciable velocity in the cold, on warming for a few minutes an almost quantitative conversion into the additive product (XXIV) takes place. On the other hand, the labile ester, when heated with the same reagent under similar conditions, these being such as to preclude more than a very small conversion into the normal isomeride, yields practically no additive product, and, although it is impossible to avoid the formation of the sodio-ester (XXI) owing to the rapidity of the "labile-enol" equilibration, this sodio-ester and much unchanged enol-ester are the sole products obtained from the experiment.

These results do not, of course, preclude the possibility that the addition of methyl alcohol to the labile ester may take place directly, without intervention of the normal ester; they do, however, show that if any such direct additive reaction with the labile ester occurs at all, it does so much more slowly than the addition to the normal ester.

The facts summarised above are obviously insufficient for any

comprehensive generalisation bearing on the constitution of the normal form; but already it is clear that the relative additive powers of the normal and labile isomerides vary with the character of the addendum, and that more experimental data of this kind are required before conclusions can be drawn as to the types of reaction to which the normal form is prone. It is, however, desirable here to emphasise the general characters of the facts which have so far been established, first, because they point out a new direction from which evidence as to the nature of "normal" structure is to be sought, and secondly, because the impression, acquired from earlier experiments and expressed on several occasions, as to a generally lower reactivity in the normal isomerides, is now seen to require correction.

Finally, it is of interest to note that the reaction by which methyl alcohol is added to the normal ester when the latter is heated with methyl alcoholic sodium methoxide is reversible. The degree of reversibility is small, and in fact it could not be detected when the reaction was carried out under the usual conditions in methyl alcoholic solution. When, however, the methoxy-ester (XXIV) was treated with an ethereal suspension of sodium methoxide, a large elimination of methyl alcohol took place with the formation of the sodio-methyl ester (XXI) along with a smaller quantity of the sodium salt of the acid (XXV), produced by direct hydrolysis. Probably the great insolubility of the sodio-ester (XXI) in ether, and its smaller alcoholysis to the enol-ester in this solvent, combine to determine the extensive decomposition observed:

If the normal ester is taken as the starting point, the first reaction which occurs, when it is treated under the conditions described in the experimental portion of this paper with ethereal sodium methoxide, is that which results in the addition of methyl alcohol; and if the product be isolated before the slow "normal-labile" equilibrium has had time to establish itself, it is found to contain as much as 90 per cent. of the addition product; but so soon as the labile ester begins to be produced in appreciable amount it passes rapidly into the enol-ester and thence into the sodio-ester, which at once begins to precipitate from solution, and hence determine the eventual destruction of the whole of the methoxy-ester originally formed; or, at any rate, such of it as does not pass out of the sphere

of action by conversion into the insoluble sodium salt of the methoxy-acid (XXV).

EXPERIMENTAL.

(A) *Synthesis of 3-Methylcyclopropane-1 : 2-dicarboxylic Acid (Two Stereoisomeric Forms) by way of Ethyl 3-Methylcyclopropane-1 : 1 : 2-tricarboxylate.*

Ethyl Crotonate.—This ester was prepared by Wahl's method from ethyl α -bromobutyrate and diethylaniline (*Compt. rend.*, 1901, 132, 693), and no difficulty was experienced in obtaining Wahl's yield (50 per cent. of the theoretical), although Thorpe and Young (T., 1903, 83, 355) and Hope and Perkin (T., 1911, 99, 766) could not obtain a yield greater than 35 per cent. Hope and Perkin expressed the opinion that their small yield was largely accounted for by the formation of an additive product between the bromo-ester and the base, and the subsequent elimination of ethyl bromide to give the compound $\text{NPhEt}\cdot\text{CH}(\text{CO}_2\text{Et})\cdot\text{CH}\cdot\text{CH}_3$, and a similar opinion has been stated by Thorpe and Wood (T., 1913, 103, 1601). In our experiments, however, not only did the yield of ethyl crotonate amount to more than 50 per cent., but the recovery of unchanged ethyl α -bromobutyrate accounted for almost the whole of the remaining material.

One hundred grams of ethyl α -bromobutyrate were added to 150 grams of boiling diethylaniline and the boiling was continued for twenty-four hours. The excess of base was removed by treatment with dilute acid, and the esters were carefully fractionated. The yield of ethyl crotonate was 35 grams (60 per cent. of the theoretical), whilst 35 grams (35 per cent.) of ethyl α -bromobutyrate were recovered.

Ethyl $\alpha\beta$ -Dibromobutyrate.—It has been found that ethyl crotonate may be directly converted into the dibromo-ester by treatment with bromine in sunlight.

Ethyl crotonate (40 grams) and bromine (60 grams) dissolved in chloroform were left in full daylight for a week, and the product was washed with aqueous potassium hydrogen sulphite to remove the excess of bromine, dried with calcium chloride, and distilled. The yield of dibromo-ester, b. p. 100—110°/20 mm., was 90 grams (93 per cent. of the theoretical).

Ethyl 3-Methylcyclopropane-1 : 1 : 2-tricarboxylate (XV).—To a solution of sodium ethoxide prepared from 96 grams of sodium and 150 c.c. of ethyl alcohol, 72 grams of ethyl malonate were added, and then 53 grams of ethyl dibromobutyrate. The mixture was allowed to remain at the ordinary temperature for twenty-four hours, and then heated on the steam-bath for an hour, or until

neutral. It was poured into water and the oil extracted with ether. The extract was washed with water, dried with sodium sulphate, and evaporated, and the residue distilled. The yield of triethyl ester, b. p. 150—170°/20 mm., was 50 grams (96 per cent.).

trans-3-Methylcyclopropane-1 : 2-dicarboxylic Acid (XII).—The above ester (50 grams) was boiled with 300 c.c. of 20 per cent. hydrochloric acid for thirty hours under a condenser short enough to permit the escape of alcohol vapour, and the residue obtained on evaporation, esterified with ethyl alcohol and sulphuric acid. The portion of the ester which distilled between 120° and 140°/20 mm. was again boiled with 20 per cent. hydrochloric acid for two hours. On partial evaporation of the resulting solution, crystals of the *trans*-acid separated, and these were purified by crystallisation from ether or xylene, or by sublimation.

When pure, the *trans*-acid melts at 195°, and boils at 180°/20 mm. without decomposition, the distillate at once solidifying in the receiver (Found : C = 50.1; H = 5.5. $C_6H_8O_4$ requires C = 50.0; H = 5.6 per cent.). The acid does not decolorise cold alkaline permanganate.

(*cis*)-*cis*-3-Methylcyclopropane-1 : 2-dicarboxylic Acid (XIV).—When the filtrate from the *trans*-acid was completely evaporated, the residue solidified to a mass of crystals consisting of the *cis*-acid, m. p. 108°. This acid was identical in every way with that described by Preiswerk (*loc. cit.*) and Ingold (*loc. cit.*), and after crystallisation from benzene did not lower the m. p. of a genuine specimen. Like the *trans*-acid, this acid is stable to cold alkaline permanganate.

(B) *Synthesis of 3-Methylcyclopropane-1 : 2-dicarboxylic Acid (Three Stereoisomeric Forms) by way of Ethyl 3-Methylcyclopropane-1 : 1 : 2 : 2-tetracarboxylate.*

Ethyl Ethylidenemalonate.—We were unable to obtain more than a 25 per cent. yield of this ester by Knoevenagel's method (*Ber.*, 1893, **31**, 2587), and therefore turned to that of Komenos (*Annalen*, 1883, **218**, 15). By making certain modifications, Komenos's yield was considerably surpassed, and a satisfactory method of preparation obtained.

One hundred grams of ethyl malonate, together with 100 grams of acetic anhydride and 57 grams of acetaldehyde, were heated in a closed vessel for thirty hours at 100°, and the product was distilled under ordinary pressure until the thermometer registered 140°. The residue was then distilled under diminished pressure, and after collecting 30 grams of unchanged ethyl malonate, b. p. 90—113°/20 mm., 80 grams of ethyl ethylidenemalonate, b. p. 113—130°/20 mm. were obtained, the yield being 70 per cent. of the theoretical.

Ethyl Ethylidenedimalonate.—This was prepared by Kötze and Stalman's method (*loc. cit.*), with the introduction of certain modifications, for the most part suggested by Perkin's description of the preparation of the isomeric straight-chain compound (T., 1887, 51, 21; 1894, 65, 580, 950).

A solution of sodium ethoxide prepared from 12.5 grams of sodium and 190 c.c. of ethyl alcohol was poured into 300 c.c. of ether and mixed with 100 grams of ethyl malonate dissolved in 300 c.c. of ether. The mixture was stirred mechanically while 100 grams of ethyl ethylidenemalonate, dissolved in 300 c.c. of ether, were gradually run in. The stirring was continued for two hours, and the liquid shaken with dilute hydrochloric acid, dried, and distilled. The yield of dimalonate, b. p. 200—230°/20 mm., was 120 grams (57 per cent.).

Ethyl 3-Methylcyclopropane-1 : 1 : 2 : 2-tetracarboxylate (XVI).—This was prepared by an analogous modification of the method of Kötze and Stalman.

A solution of sodium ethoxide prepared from 15 grams of sodium and 220 c.c. of dry alcohol was poured into 500 c.c. of dry ether, and mixed with 100 grams of ethyl ethylidenedimalonate dissolved in 300 c.c. of dry ether. The mixture was stirred mechanically while 50 grams of dry bromine were added during three hours. The stirring was continued for a further hour, and the solution then washed with dilute potassium hydrogen sulphite, and water, and dried. The yield of tetra-ethyl ester obtained on evaporating the ether amounted to 80 grams (80 per cent.).

trans-3-Methylcyclopropane-1 : 2-dicarboxylic Acid (XII).—The above ester was hydrolysed by boiling with six times its weight of 20 per cent. hydrochloric acid for thirty hours, and the product obtained on evaporation esterified with ethyl alcohol and sulphuric acid. The distilled ester, b. p. 120—140°/20 mm., was re-hydrolysed by means of 20 per cent. hydrochloric acid, and the resulting solution concentrated. The crystals which separated were collected, purified, and identified as the *trans*-acid, m. p. 195°, exactly as described above.

(*trans*)-*cis-3-Methylcyclopropane-1 : 2-dicarboxylic Acid* (XIII).—The filtrate from the *trans*-acid on further evaporation yielded crystals, which after several alternate crystallisations from benzene and xylene, melted at 132°, and were identified as the *cis*-acid of this m. p. described by Ingold (*loc. cit.*). The identification was confirmed by a mixed melting-point determination. Like the *trans*-acid, this acid, m. p. 132°, is stable towards cold alkaline permanganate.

(*cis*)-*cis-3-Methylcyclopropane-1 : 2-dicarboxylic Acid* (XIV).—

This *cis*-acid, m. p. 108°, was deposited from the ultimate mother liquors of the preceding acid, but it can be separated from the accompanying *cis*-acid, m. p. 132°, only with considerable difficulty, and is best prepared by the method described in section (A).

(C) *Synthesis of the cycloPropene Acid from trans-3-Methylcyclopropane-1 : 2-dicarboxylic Acid.*

trans-1 : 2-Dibromomethylcyclopropane-1 : 2-dicarboxylic Acid (XVII).—The *trans*-cyclopropane acid (3.8 grams) was warmed with 12 grams of phosphorus pentachloride until hydrogen chloride ceased to be evolved. Small quantities of iron and iodine were then added, and the mixture was boiled for five minutes, and then maintained at 180° while 10 c.c. of bromine were added drop by drop. The absorption occurred immediately at first and with considerable violence, but moderated somewhat towards the end of the addition. Heating was continued for two minutes after the last drop of bromine had been added, and the excess was then removed by a rapid stream of dry air. The product was poured into water, and the mixture warmed until homogeneous, and then partly evaporated. The dibromo-acid thus obtained separated from hot water in needles, m. p. 282° (Found: Br = 53.3. $C_6H_6O_4Br_2$ requires Br = 53.0 per cent.).

Reduction of the 1 : 2-Dibromo-acid by Sodium Amalgam: Formation of the trans-cycloPropene Acid (compare Goss, Ingold, and Thorpe, *loc. cit.*, p. 340, footnote).—The dibromo-acid (0.38 gram) was dissolved in 5 c.c. of water and reduced with 10 grams of 1 per cent. sodium amalgam. The aqueous solution was acidified and extracted with ether. On drying and evaporating the ether, the *trans*-cyclopropane acid, m. p. 195°, was obtained in theoretical yield.

trans-2 : 3-Dibromo-3-methylcyclopropane-1 : 2-dicarboxylic Acid (XIX).—This bromination was carried out exactly like that described above, excepting that the temperature was maintained at 90–100° during the addition of bromine. The product was decomposed with water, and the homogeneous solution concentrated, when the 2 : 3-dibromo-acid, m. p. 244°, crystallised. It was identified by direct comparison, by a mixed melting-point determination, and by its behaviour towards reducing agents, with a specimen prepared by the addition of bromine to the cyclopropene acid (*loc. cit.*).

Reduction of the 2 : 3-Dibromo-acid by Sodium Amalgam: Formation of the cycloPropene Acid (I, II)—compare Goss, Ingold, and Thorpe, *loc. cit.*, p. 357.

(D) *Synthesis of the cycloPropene Acid from the Two cis-3-Methylcyclopropane-1:2-dicarboxylic Acids.*

1-Bromo-3-methyl- Δ^2 -cyclopropene-1:2-dicarboxylic Acid (XX).—This acid was formed when either of the *cis*-cyclopropane acids, m. p. 108° and 132°, was brominated at 180° by the method described in the preceding section. When the product was decomposed by water, the bromocyclopropene acid was immediately precipitated as an insoluble, crystalline powder. As the purification of this substance by recrystallisation was attended with difficulty owing to the insolubility of the acid in water and the usual organic solvents, it was prepared for analysis by precipitation with hydrochloric acid from a filtered solution of its sodium salt. Thus obtained, the acid forms a colourless powder, which melts at 138° with vigorous decomposition (Found: C = 32.6; H = 2.3; Br = 36.0. $C_5H_5O_4Br$ requires C = 32.6; H = 2.3; Br = 36.2 per cent.). As is described more fully below, this acid undergoes spontaneous reduction in the presence of cold dilute alkali with the formation of the cyclopropene acid and alkaline hypobromite. Indeed so readily does this reaction occur that attempts to obtain the equivalent of the acid by titration with carbonate-free sodium hydroxide proved ineffectual, 2—3 molecules of sodium hydroxide being neutralised, owing to the liberation of hypobromous acid during the titration.

Reduction of the Bromocyclopropene Acid by Cold Alkali. Formation of the cycloPropene Acid (I, II).—The bromo-acid 0.7 gram) was dissolved in 10 c.c. of 10 per cent. potassium hydroxide, and the solution kept for twelve hours at the ordinary temperature, and then acidified with hydrochloric acid and extracted with ether. The residue obtained on evaporation of the ether melted at 200° after crystallisation from xylene, and was identified as the cyclopropene acid (I, II).

(E) *Equilibration of the Normal, Labile, and Enol Methyl Esters.*

Equilibration in Methyl Alcoholic Solution.—Each of the three esters, when heated for several hours in methyl alcohol containing a small proportion of sulphuric acid, yielded a mixture of the normal, labile, and enol esters, the normal ester constituting practically the whole and the labile and enol esters being present in qualitative traces only.

Equilibration in the Presence of Sodium Methoxide.—A series of experiments, made with the object of examining the nature and speed of establishment of the equilibrium which obtains when any one of the three esters is treated with an equivalent of methyl alcoholic sodium methoxide, has led to the conclusion that equi-

oration is complete after fifteen hours at 15°, and that the two intermediate members of the series: normal ester \rightleftharpoons labile ester \rightleftharpoons enol ester \rightleftharpoons sodio-ester, are almost entirely absent, the mixture consisting of about 29 per cent. of the normal ester and 71 per cent. of the sodium compound.

It was not possible to examine the equilibration at 60° owing to the formation of the methoxy-compound described below.

Methyl Sodio-3-methyl- Δ^2 -cyclopropene-1:2-dicarboxylate (XXI).

—This substance, which was obtained in the course of the above experiments and in those described in the next section (F), is precipitated from its solution in methyl alcohol by warming, and is insoluble in ether and benzene. It forms a yellow powder, which is stable in dry air (Found: Na = 12.1. $C_8H_9O_4Na$ requires Na = 12.0 per cent.), but is extensively decomposed by water, forming the enol ester.

(F) *The Reversible Addition of Methyl Alcohol to the Normal Methyl Ester.*

Action of Methyl Alcoholic Sodium Methoxide on the Normal Methyl Ester.—The normal methyl ester (2 grams) was added to a solution of sodium methoxide prepared by dissolving 0.5 gram of sodium in 10 c.c. of methyl alcohol. The solution was warmed for a few minutes, poured into water, and extracted with ether. The yield of methyl 3-methoxy-3-methyl-cyclopropane-1:2-dicarboxylate (XXIV) (*loc. cit.*), p. 360, was nearly quantitative.

Action of Methyl Alcoholic Sodium Methoxide on the Labile Methyl Ester.—The labile methyl ester (2 grams) was added to a solution of sodium methoxide prepared from 0.5 gram of sodium and 10 c.c. of methyl alcohol. When the solution was warmed as in the preceding experiment, a precipitate consisting of the sodio-ester was formed. This was collected, and the filtered solution poured into water and extracted with ether. The residue obtained on evaporating the ether consisted entirely of unchanged labile ester.

Action of Methyl Alcoholic Sodium Methoxide on the Equilibrated Mixture of Esters.—Either the normal or labile ester (8.5 grams) was added to a solution of sodium methoxide prepared by dissolving 3 grams of sodium in 45 c.c. of methyl alcohol, and the mixture left for fifteen hours at the ordinary temperature to equilibrate. It was then warmed for a few minutes and the precipitated solid collected. The whole of the methoxy-methyl ester (1.8 grams) was found to be carried down with the sodio-ester (4.5 grams), and was separated from it by extraction with boiling benzene.

Prolonged Action of Methyl Alcoholic Sodium Methoxide on the Equilibrated Mixture of Esters.—The equilibrated solution was

prepared as in the preceding experiment, and then heated for eight hours, after which the sodio-ester, originally precipitated, had completely dissolved. The product obtained on adding water and extracting with ether consisted solely of the methoxy-ester.

Action of Methyl Alcoholic Sodium Methoxide on the Methoxy-ester.—In order if possible to detect the reversibility in methyl alcohol solution of the addition of methyl alcohol to the cyclopropene acid, the following experiment was carried out. The methoxy-ester (1.3 grams) was added to a solution of sodium methoxide prepared from 0.5 gram of sodium and 10 c.c. of methyl alcohol. The solution was heated on the steam-bath for one hour, and then poured into water and extracted with ether. Unchanged methoxy-ester was the sole recovered material. (As noted below, the retrograde reaction was realised by using an ethereal in place of a methyl-alcoholic solution.)

Action of Ethereal Sodium Methoxide on the Normal Ester.—The normal ester (5 grams), dissolved in 50 c.c. of dry ether, was added to an ethereal solution of sodium methoxide, prepared by dissolving 3 grams of sodium in 45 c.c. of methyl alcohol and adding 150 c.c. of ether. The solution was left over-night at the ordinary temperature, and the precipitated sodio-ester (0.5 gram) collected. The solution was washed with water, dried, and evaporated. The residue (1.5 grams) consisted of the methoxy-ester. The aqueous washings were acidified, and extracted with ether, and by this means 2 grams of the methoxy-acid (XXV) described below were obtained.

Prolonged Action of Ethereal Sodium Methoxide on the Normal or Labile Ester, or on the Methoxy-ester.—If either of the above esters is treated for a considerable time with ethereal sodium methoxide prepared as in the preceding experiment, the product consists almost entirely of the sodio-ester (XXI) and the methoxy-acid (XXV).

3-Methoxy-3-methylcyclopropane-1 : 2-dicarboxylic Acid (XXV).—This acid, which was obtained in the course of the experiments described above, and also by hydrolysis of the methoxy-ester (XXIV) was purified by crystallisation from xylene and was thus obtained as prisms, m. p. 158° (decomp.) (Found : C = 48.3; H = 6.0. $C_7H_{10}O_5$ requires C = 48.2; H = 5.8 per cent.).

On reduction by hydriodic acid it behaves like the ethoxy-acid (*loc. cit.*, p. 360) and yields normal β -methylglutaconic acid but no trace of any ketonic acid or lactone such as would be expected to arise from an α -methoxy-ring acid.

(G) *The Addition of Bromine to the Normal and Labile Methyl Esters.*

Comparative experiments on the velocity of addition of bromine to the normal and the labile methyl ester in chloroform solution at

the ordinary temperature showed that the labile ester absorbed bromine much more readily than the normal ester at small dilutions, whilst at greater dilutions the difference was in the same sense, but very much less marked.

Experiment at a Small Dilution.—Each ester (0.55 gram) was mixed with bromine (0.45 gram) in 10 c.c. of chloroform at 19°, the solution being maintained at this temperature by immersion in water. The decoloration proceeded very much more rapidly in the case of the labile ester and was complete in five to ten minutes, whilst in the case of the normal ester about three hours were required.

Methyl 2:3-Dibromo-3-methylcyclopropane-1:2-dicarboxylate (XXIII).—When the solutions obtained in the preceding experiments were evaporated, the residues solidified to colourless, silky needles which, without purification, melted at 76°. After crystallisation, they had the correct m. p. 77° (Jones, T., 1905, 87, 1064), and were identified as the above methyl ester by direct comparison with a genuine specimen.

We wish to thank the Chemical and Royal Societies for grants with the aid of which much of the expense of this investigation has been defrayed.

[Received, September 29th, 1923.]

CCCXCVII.—*The Tautomerism of Amidines. Part III.* *The Alkylation of Open-chain Amidines (continued).*

By FRANK LEE PYMAN.

It has long been recognised that unsymmetrical amidines containing a mobile hydrogen atom ($RN: CX \cdot NHR'$ or $RNH \cdot CX : NR'$) yield on alkylation a mixture of the two isomeric alkyl derivatives I and II in the cases where R and R' are similar in character, but

until quite recently it was believed that where the two groups differed in character only a single alkyl derivative was formed, and further that the alkyl derivative produced was that in which the alkyl group was attached to the less basic nitrogen atom. Earlier in the year one of these cases of alleged homogeneous alkylation was investigated (Pyman, this vol., p. 367, where previous references are given), and it was shown that the methylation of benzenylphenylmethylamidine (III or IV) by means of

methyl iodide gave, not only methylphenylamidobenzenylmethylimidine (V), but also a small proportion of dimethylamidobenzenylphenylimidine (VI). Two further cases of supposed homogeneous

alkylation of unsymmetrical open-chain amidines have now been investigated, and it has been found that benzenylphenylamidine (VII) reacts with methyl iodide to yield, not only methylphenylamidobenzenylimidine (VIII), as stated by von Pechmann (*Ber.*, 1897, **30**, 1782), but also to a small extent benzenylphenylmethylamidine (IX), whilst benzenylphenylbenzylamidine (X) reacts with

methyl iodide to yield, not only methylphenylamidobenzenylbenzylimidine (XI), as stated by Beckmann and Fellrath (*Annalen*, 1893, **273**, 1) and Lander (*T.*, 1903, **83**, 320), but also to a small extent methylbenzylamidobenzenylphenylimidine (XII). More

over, benzenylmethylamidine (XIII) reacts with methyl iodide to yield a mixture of the two isomeric monomethyl derivatives, methylamidobenzenylmethylimidine (XIV) and dimethylamidobenzenylimidine (XV), and benzenylbenzylamidine (XVI) similarly yields a

mixture of benzenylmethylbenzylamidine (XVII) and methylbenzylamidobenzenylimidine (XVIII). The constitutions of the methylated

benzenylmethylamidines were readily determined, for on distillation with 20 per cent. aqueous sodium hydroxide they were decomposed, with the formation of benzoic acid and the appropriate amines, for example,

The methylated benzenylbenzylamidines, however, proved to be stable to this reagent, but the constitution of one of the two monomethylated compounds, and therefore of the other also, was determined by reduction with sodium amalgam in alcoholic solu-

tion, a method devised by Beckmann and Fellrath (*loc. cit.*), when methylamine and dibenzylamine were obtained.

The products of methylation were worked up as completely as was practicable in all the above cases, a very large number of crystallisations as base, hydrochloride, hydriodide, or more usually picrate being necessary. In every case, there was always isolated, besides the mixture of the two monomethylated derivatives, some of the unchanged unmethylated amidine. The presence of the latter is due to reactions which in total effect may be represented by the equation

and give rise to a molecule of dimethylated product for each molecule of unchanged material. Where R or R' is hydrogen, the dimethylated product is a tertiary base which can be isolated, and here the observed yield is given in the following table, but in all other cases it is a quaternary salt which was not isolated, and in these cases (asterisked) the yield given is calculated from the amount of unchanged material in accordance with the above equation.

The numerical results were as follows:

Yields in percentage of theoretical of products obtained by the action of methyl iodide upon amidines $\text{NR}\cdot\text{CPh}\cdot\text{NHR}'$ or $\text{NHR}\cdot\text{CPh}\cdot\text{NR}'$.

		Products.				Total accounted for.	Ratio 1:2.
R.	R'	1. $\text{NMeR}\cdot\text{CPh}\cdot\text{NR}'$	2. $\text{NR}\cdot\text{CPh}\cdot\text{NMeR}'$	3. Unchanged.	4. Dimethyl- ated deriv- ative.		
I. Ph	Me	62.4	4.2	9.0	9.0*	84.6	15:1
II. Ph	CH_2Ph	88.8	2.5	1.0	1.0*	93.3	35:1
III. Ph	H	82.7	0.55	5.7	5.0	93.9	150:1
IV. Me	H	18.6	15.3	27.9	23.6	85.4	1.2:1
V. CH_2Ph	H	8.3	9.5	23.3	19.6	60.7	—

Before discussing the significance of the ratios in which the two isomeric monomethylated derivatives 1 and 2 are produced, an obvious criticism must be met. Clearly the dimethylated product 4 could be produced by the further methylation of either 1 or 2. Thus, in case III, if the whole of the dimethylated product had been produced by the further methylation of 2 and none of it from 1, the true relative proportions of 1 and 2 would be as 15:1 instead of as 150:1. It was necessary, therefore, to study the relative avidity of methylation of 1 and 2, and for this purpose a mixture of 1 mol. of each of the two isomerides methylphenylamidobenzoylimidine (VIII) and benzenylphenylmethylamidine (IX), dissolved in a little methyl alcohol to give a homogeneous

solution, was treated with 1 mol. of methyl iodide, when 33 per cent. of the first and 54 per cent. of the second were recovered unchanged. In view of the fact that the first compound is less readily separated from the mixture than the second, this result indicates that the rate of methylation of the two isomerides is somewhat similar, but that the isomeride produced in smaller quantity is actually methylated rather less readily than the other. The small yield of this compound is therefore not due to its preferential methylation.*

The production of two isomeric alkyl derivatives by the action of methyl iodide upon open-chain as well as upon cyclic amidines generally may now be regarded as established, and it becomes of interest to inquire whether the formation of the two isomerides is due to reaction of the amidine in two isomeric forms, for example, $\text{RN}:\text{CX}:\text{NHR}'$ and $\text{RNH}:\text{CX}:\text{NR}'$, or to reaction of the amidine in a single form which becomes methylated in two different ways, for instance, by direct addition to the tertiary nitrogen and by substitution of the imino-group.

Different interpretations of the formation of an alkyl derivative $\text{NR}:\text{CX}:\text{NR}'\text{Alkyl}$ by the action of an alkyl halide upon an unsymmetrical amidine capable of reacting in the tautomeric forms A and B have been given.

(A) $\text{NR}:\text{CX}:\text{NHR}'$

(B) $\text{NHR}:\text{CX}:\text{NR}'$

Von Pechmann (*Ber.*, 1897, **30**, 1781), Lander (*T.*, 1903, **83**, 320), and Cohen and Marshall (*T.*, 1910, **97**, 328), all of whom studied open-chain amidines, regard the formation of the above alkyl derivative as evidence that the amidine has reacted in the form A, that is to say, that the hydrogen atom has been replaced directly by the alkyl group.

Wheeler (*Amer. Chem. J.*, 1898, **20**, 481) and Young and Crookes (*T.*, 1906, **89**, 59), on the other hand, were led through their studies of partly cyclic amidines to the opposite view, that the amidine has reacted in the form B in the formation of the above alkyl derivative. Moreover, Pinner and Schwarz (*Ber.*, 1902, **35**, 2441) have shown that *N*-alkylglyoxalines—cyclic amidines—react with alkyl halides to give quaternary salts of 1:3-dialkylglyoxalines, and consequently that the second alkyl group has become attached to the nitrogen atom, which is doubly linked to carbon.

Comparison of the properties of amidines with those of iminoethers and acid amides led Burtles and Pyman (this vol., p. 363) to agree with the conclusions of Young and Crookes. Further work with open-chain amidines which do not contain a mobile hydrogen atom has confirmed our opinion. Thus, it is now shown (1) that methylphenylamidobenzylidene (VIII) reacts with methyl iodide to give methylphenylamidobenzylmethylidene (XIX), which was obtained in a yield of 61 per cent. of the theoretical, together with 13 per cent. of unchanged material and

presumably an equivalent amount of a quaternary dimethylated product; (2) that dimethylamidobenzylidene (XV) reacts with methyl iodide to give dimethylamidobenzylmethylidene (XX) in a yield of 64 per cent. of the theoretical, together with 9 per cent. of unchanged material, and again presumably an equivalent amount of the corresponding quaternary salt; and (3) that methylphenyl-

amidobenzylmethylidene (XIX) and dimethylamidobenzylphenylidene (VI) yield the same methiodide (XXI) when heated with methyl iodide. These results show clearly that the inter-

action of open-chain amidines with alkyl salts leads to the attachment of the alkyl group to the nitrogen atom, which is doubly linked to carbon, and lead to the conclusion that the formation of two isomeric alkyl derivatives by the action of methyl iodide upon open-chain amidines is due to the reaction of the amidine in two isomeric forms.

Reference will now be made to the relative yields of the pairs of isomeric monomethylated amidines. Previous investigators (Young and Crookes, *loc. cit.*; Cohen and Marshall, *loc. cit.*) have pointed out that the sole alkyl derivative isolated from the products of alkylation of amidines $\text{RN}\cdot\text{CX}\cdot\text{NHR}'$ or $\text{RNH}\cdot\text{CX}\cdot\text{NR}'$ (where R and R' differed in character) was that in which the alkyl group was attached to the less basic nitrogen atom. Moreover, a connexion between enolising power of a group R and the dissociation constant of the corresponding acid ($\text{R}\cdot\text{OH}$) in compounds of the formula $\text{X}\cdot\text{CO}\cdot\text{CH}_2\text{R} \rightleftharpoons \text{X}\cdot\text{C}(\text{OH})\cdot\text{CHR}$ has been pointed out by Claisen (*Ber.*, 1892, 25, 1763) and confirmed by K. H. Meyer (*Ber.*, 5 T 2

1912, 45, 2843). It seemed possible, therefore, that the relative basicity of the two amines $R\cdot NH_2$ and $R'\cdot NH_2$ might determine the proportion of the isomeric methyl derivatives produced on the alkylation of amidines of the above general formula. Examination of the figures given on p. 3361, however, shows that the relative basicity of the amines $R\cdot NH_2$ and $R'\cdot NH_2$ is not the sole factor in determining the relative yields of the two isomeric monomethylated amidines, for in each of the cases I, II, and III, where $R = Ph$, and $R' = Me, CH_2Ph$, and H , the nitrogen attached to phenyl is methylated to the greater extent, that is to say, $NMePh\cdot CPh\cdot NR'$ is produced to a greater extent than $NPh\cdot CPh\cdot NMeR'$, where the three bases $R'\cdot NH_2$ are stronger bases than aniline, whilst, on the other hand, by comparing the three cases it is observed that $NPh\cdot CPh\cdot NMeR'$ is produced in greater proportion the stronger the base $R'\cdot NH_2$ ($K = 50, 2.4, 1.8 \times 10^{-5}$ for $MeNH_2, CH_2Ph\cdot NH_2$, and NH_3 , respectively), and again in case IV, $NMe_2\cdot CPh\cdot NH$ is obtained in larger quantity than $NMe\cdot CPh\cdot NHMe$, methylamine being a stronger base than ammonia. Consideration of the products of methylation of benzenylbenzylamidine is omitted in view of the fact that they could not be isolated even approximately quantitatively.

This investigation is being continued and extended to include some types of partly cyclic amidines and a full discussion of the results is reserved for a later communication. In the meantime, it may be pointed out that the results obtained hitherto harmonise with the assumption that the relative yields of the two monomethyl derivatives obtained by the action of methyl iodide upon amidines, open-chain or cyclic, of the general formula $NR\cdot CX\cdot NHR'$ or $NHR\cdot CX\cdot NR'$ (in cyclic amidines R and R' are linked together) depend upon the polar characters of the groups R and R' , which influence the result in two directions.

The most important effect appears to be the influence of positive groups (such as phenyl) on the position of the double linking; the well-known isomeric changes of $\beta\gamma$ - to $\alpha\beta$ -unsaturated acids, and of β -phenylpropylene into α -phenylpropylene suggest that benzenylphenylmethylamidine reacts preferably in the form A rather than in the form B, which is consistent with the preferential

formation of $NMePh\cdot CPh\cdot NMe$ on treatment with methyl iodide, since it has been shown above that this reagent methylates the nitrogen atom which is doubly linked to carbon.

The subsidiary effect appears to be the influence of the groups R and R' on the polarity of the nitrogen atoms. Thus, 4(or 5)-

methylglyoxaline yields with methyl iodide the 1:4- and 1:5-dimethyl derivatives in the proportion of 2:2:1 (Pyman, T., 1910, 97, 1814; 1922, 121, 2616) and is thus regarded as reacting to the extent of some 70 per cent. as 5-methylglyoxaline (XXII), and 30 per cent. as 4-methylglyoxaline (XXIII). In the predominant

form, namely, as 5-methylglyoxaline, the polarity of the tertiary nitrogen atom induced by the methyl group is positive, and that of the secondary nitrogen atom negative.

Methylation of 5(or 4)-nitro-4(or 5)-methylglyoxaline gave 5-nitro-1:4-dimethylglyoxaline and 4-nitro-1:5-dimethylglyoxaline in the proportions of 233:1. Here, the parent compound is reacting almost wholly as 4-nitro-5-methylglyoxaline (XXIV) in which the induced positive polarity of the tertiary nitrogen atom and the

induced negative polarity of the secondary nitrogen atom are greatly enhanced as compared with the case of 5-methylglyoxaline.

The methylation of benzenylmethylamidine is similar to that of 4(or 5)-methylglyoxaline, $\text{NMe}_2 \cdot \text{CPh} \cdot \text{NH}$ and $\text{NMe} \cdot \text{CPh} \cdot \text{NHMe}$ being produced in quantities which indicate that the original

amidine is reacting to the greater extent in the form $\text{H}_3\text{C}^+ \cdot \text{N}^- \cdot \text{CPh} \cdot \text{NH}_2$, where again the polarity of the doubly linked nitrogen atom induced by the methyl group is positive.

EXPERIMENTAL.

Methylation of Benzenylphenylamidine.—Benzenylphenylamidine was prepared by the action of benzanilide iminochloride upon aniline (von Pechmann, *Ber.*, 1897, 30, 1782) in poor yield, only 16 grams of the pure compound being obtained from 100 grams of benzanilide. It crystallised from alcohol in rosettes of spikes, which melted at 115–116° (corr.). Von Pechmann (*loc. cit.*) gives 112°, and Bernthsen and Szymanski (*Ber.*, 1880, 13, 918), who describe the substance as indefinitely crystalline, 114.5–115°.

Seventeen grams of pure benzenylphenylamidine were dissolved

in 34 c.c. of methyl iodide by gentle warming and kept over-night. The excess of methyl iodide was then removed, the residue dissolved in hot water and added to a solution of 20 grams of picric acid in 800 c.c. of hot water. A large crop (34 grams) of crystalline picrates was deposited, and further crops were obtained from the mother-liquor. These were purified by fractional crystallisation from alcohol, and gave 29.95 grams of pure methylphenylamido-benzonylimidine picrate (A), melting at 184° (corr.) (von Pechmann gives 184°), and 1.75 grams of pure methylphenylamidobenzonylmethylimidine picrate (D), melting at $174-176^{\circ}$ (corr.). All remaining crops of picrates and their mother-liquors were then combined and converted into a mixture of bases (3.3 grams), which on treatment with ether deposited 0.67 gram of nearly pure benzenylphenylamidine (C) melting at $112-114^{\circ}$. The filtrate was deprived of ether and converted into picrates, when on fractionation, further quantities of A (1.55 grams) and D (0.2 gram) were isolated in a pure state. From the mother-liquors the bases were then regenerated and amounted to 1.25 grams. On treatment with ether, this product deposited 0.15 gram of crude C, m. p. $86-90^{\circ}$, and after removing the ether, it was digested with warm light petroleum, when another 0.15 gram of crude C, melting at $80-90^{\circ}$, remained undissolved. The filtrate from this deposited, on cooling, 0.15 gram of crude benzenylphenylmethylamidine (B), which gave 0.1 gram of the nearly pure base, melting at $132-133^{\circ}$ after crystallisation from alcohol. After a further crystallisation from alcohol, this compound melted at 135° (corr.), alone or mixed with a specimen prepared by the action of benzomethylamide iminochloride upon aniline, whilst its picrate melted at $169-170^{\circ}$ (corr.), alone or mixed with the picrate of the synthetic base. The final mother-liquor gave 0.8 gram of an oily base, which gave a difficultly separable mixture of picrates and was rejected. The yields in percentage of the theoretical are given in the table on p. 3361.

Methylation of Methylphenylamidobenzonylimidine (1 Mol.) and Benzenylphenylmethylamidine (1 Mol.) with Methyl Iodide (1 Mol.).—10.5 Grams each of methylphenylamidobenzonylimidine (A) and benzenylphenylmethylamidine (B) were heated on the water-bath with 5 c.c. of methyl alcohol, when a clear solution resulted. To this, 7.1 grams of methyl iodide were added through a reflux condenser, when gentle ebullition took place. The mixture was kept for two days, and then mixed with water and ether, when 4.2 grams of crude B remained undissolved, whilst a further quantity of 1.7 grams of the same base separated on concentrating the ethereal solution. The ethereal mother-liquor was combined with the product obtained by basifying the aqueous extract and extracting

with ether, and the resulting oily bases were converted into the picrates and crystallised fractionally from alcohol, when 11.6 grams of the picrate of methylphenylamidobenzylmethylimidine (D) and 3.6 grams of the picrate of A were obtained in a nearly pure state. All the mother-liquors from the crystallisation of the picrates were then combined and the bases were regenerated, when 7 grams of oil were obtained, which deposited 0.6 gram of crude B on the addition of light petroleum. The bases from the mother-liquor were again converted into picrates and gave further quantities of A and D.

Finally, there were obtained in a pure state 5.65 grams of B, that is, 53.8 per cent. of the quantity taken, 7.15 grams of the picrate of A equivalent to 32.6 per cent. of the quantity taken, and 11.65 grams of D, that is, 51.4 per cent. of the theoretical yield based upon the quantity of methyl iodide employed. There remained a quantity of oily base which gave no more of B on treatment with light petroleum, and on conversion into the picrate gave a mixture of crystals which could not be separated further.

Methylation of Methylphenylamidobenzylimidine.—Von Pechmann (*Ber.*, 1897, 30, 1782) states that the above base on heating with methyl iodide yields methylphenylamidobenzylmethylimidine, which melts at 56°,* but does not state the yield.

Three grams of pure methylphenylamidobenzylimidine, which melted at 84–85° (corr.) (von Pechmann gives 85°), were dissolved in 6 c.c. of methyl iodide. The solution became first ice-cold and then gradually warm. After keeping for two days, when it had become partly crystalline, the excess of methyl iodide was removed, and the bases regenerated and converted into picrates. On fractional crystallisation from alcohol, there were obtained in a pure state 3.9 grams of methylphenylamidobenzylmethylimidine picrate, melting at 174–176° (corr.), and 0.8 gram of methylphenylamidobenzylimidine picrate, melting at 184° (corr.). These yields amount to 60 and 13 per cent. of the theoretical, respectively, and allowing for 13 per cent. of quaternary salt, corresponding to the unchanged material, account for 86 per cent. of the material employed.

* In Part II (this vol., p. 370), it was recorded that methylphenylamidobenzylmethylimidine melted at 65–66° (corr.), 10° higher than the temperature given by von Pechmann. The identity of the base melting at 65–66° was confirmed at the time by re-conversion into the picrate which melted at 174–176° (corr.), but unfortunately no specimen of the base was preserved. The base has since been prepared on several occasions from the picrate melting at 174–176° (corr.) and always found to melt at 56° as stated by von Pechmann.

Methylation of Methylphenylamidobenzenylmethylimidine and Dimethylamidobenzenylphenylimidine.—Each of the above bases was digested with excess of methyl iodide for several hours on the water-bath under reflux, and thus converted quantitatively into a crystalline *methiodide* which, after drying at 100°, melted at 176–178° in each case. After recrystallisation from water, each product melted at 177–179° (corr.) after drying at 100°, and a mixture of the two melted at the same temperature. The product from either source forms colourless prisms which are readily soluble in hot, but sparingly soluble in cold water, and very easily soluble in methyl alcohol [Found: (A) in salt from $\text{NMePh}\cdot\text{CPh}\cdot\text{NMe}$; (B) in salt from $\text{NMe}_2\cdot\text{CPh}\cdot\text{NPh}$; loss at 100° (A) 1.6; (B) 1.1; on material dried at 100°, I = (A) 34.4; (B) 34.7. $\text{C}_{16}\text{H}_{19}\text{N}_2\text{I}$ requires I = 34.8 per cent.].

Methylation of Benzenylphenylbenzylamidine.—Benzenylphenylbenzylamidine was prepared by the action of benzanilide iminochloride upon benzylamine (2 mols.) according to Beckmann and Fellrath (*loc. cit.*), when a yield amounting to 63 per cent. of the theoretical of the pure base melting at 100° (corr.) was obtained.

Forty grams of benzenylphenylbenzylamidine were dissolved in 40 c.c. of methyl iodide by gentle warming. After keeping for about ten minutes, crystallisation commenced, causing gentle ebullition. The mixture was kept for two days and the crystalline product purified by crystallisation from methyl alcohol, when 52.55 grams of methylphenylamidobenzenylbenzylimidine hydriodide (X) were obtained pure, melting at 232–233° (corr.). The syrupy hydriodides remaining were converted into the bases, which were mixed with light petroleum, when 0.4 gram of unchanged benzenylphenylbenzylamidine was deposited in a nearly pure state; it melted at 100° after softening from 95°, and its melting point was not depressed by admixture with known material.

The bases soluble in light petroleum were converted into hydrochlorides, and the hydrochlorides extracted from aqueous solution by means of chloroform. The chloroform residue was dissolved in very little absolute alcohol, mixed with a little absolute ether, and inoculated with methylbenzylamidobenzenylphenylimidine hydrochloride (Y), prepared by the action of benzanilide iminochloride upon methylbenzylamine (Beckmann and Fellrath, *loc. cit.*), when 1.0 gram of this salt separated in a pure state, melting at 206–207° (corr.), alone or mixed with the material obtained by the direct method. On converting the residue from the filtrate into hydriodides, a further 0.6 gram of X was obtained, and the mother-liquors from this were converted into hydrochlorides and gave another 0.2 gram of Y.

The yields are thus 88.8 per cent. of X, 2.5 per cent. of Y (ratio 35 : 1), and 1 per cent. unchanged.

Methylphenylamidobenzenylbenzylimidine was liberated from the pure hydriodides and melted at 89–90° (corr.). Beckmann and Fellrath (*loc. cit.*) give 90.5°; Lander (*loc. cit.*) 89–90°.

Methylbenzylamidobenzenylphenylimidine was prepared from the hydrochlorides obtained (1) by the action of benzanilide iminochloride on methylbenzylamine, and (2) by the methylation of benzenylphenylbenzylamidine. Both specimens and a mixture of the two melted at 63–65° (corr.). Beckmann and Fellrath (*loc. cit.*) give 67°.

Benzenylmethylamidine.—The hydrochloride of this base was first prepared by Wheeler (*Amer. Chem. J.*, 1898, 20, 481) by the interaction of the hydrochloride of benziminoethyl ether and aqueous methylamine, and described as colourless needles, which were not extremely soluble in water and contained Cl = 20.75 per cent. This analysis was evidently carried out with the dried salt, which requires Cl = 20.8 per cent.

This salt may be obtained in yields not exceeding about 30 per cent. of the theoretical either by Wheeler's method, or by the action of methyl iodide upon benzamidine, or by the action of ammonia upon the iminochloride of benzomethylamide. It may be prepared readily and in excellent yield by the following method: To a solution of 23 grams of sodium in 400 c.c. of absolute alcohol, 67 grams of methylamine hydrochloride were added, and the mixture was shaken occasionally during one hour. The turbid liquor was then poured on to 140 grams of benziminoethyl ether hydrochloride, and the mixture well shaken and placed in a bath of cold water. After keeping over-night, sodium chloride was separated by filtration and washed well with alcohol. The filtrate and washings were then evaporated to dryness, and the residue crystallised from water, when 130 grams of pure benzenylmethylamidine hydrochloride were obtained, that is, 83 per cent. of the theoretical yield.

Benzenylmethylamidine hydrochloride crystallises from water in colourless needles, which contain 2H₂O, and after drying at 100° melt at 222–223° (corr.) [Found: loss at 100° = 17.8, 17.6; N (by Kjeldahl's method) = 14.0; Cl = 16.8. C₈H₁₀N₂.HCl.2H₂O requires H₂O = 17.4; N = 13.5; Cl = 17.2 per cent.]. On combustion, the substance gave rise to volatile products which passed through the combustion tube largely unchanged, so that estimations of carbon and hydrogen by this method were variable and worthless.*

* Other halide salts of amidines, namely, dimethylamidobenzenylmethylimidine hydriodide and benzenyldibenzylamidine hydrochloride, behaved similarly on combustion.

The *picate* crystallised from alcohol in woolly needles which were anhydrous and melted at $130-132^{\circ}$ (corr.) (Found: C = 45.8, 46.1; H = 4.0, 3.9. $C_8H_{10}N_2, C_8H_9O_7N_3$ requires C = 46.3; H = 3.6 per cent.). The base was obtained as an oil which did not crystallise after keeping for five weeks.

Methylation of Benzenylmethylamidine.—Fifty grams of benzenylmethylamidine hydrochloride (containing $2H_2O$) were mixed with aqueous sodium hydroxide, and the base was extracted with chloroform. The chloroform residue was mixed with 50 c.c. of methyl iodide, when a vigorous reaction took place with the evolution of heat. The mixture was at first cooled in running water and subsequently warmed for a few minutes under reflux, when a partly crystalline product was obtained. On the addition of about 20 c.c. of methyl alcohol, 17.4 grams of crude dimethylamidobenzenylmethylimidine hydriodide were collected. From the filtrate, the bases were regenerated, converted into hydrochlorides, and crystallised, when 10 grams of crude benzenylmethylamidine hydrochloride were obtained. The bases regenerated from the hydrochloride mother-liquor by means of sodium hydroxide and chloroform were next converted into *picates*, which were fractionally crystallised from alcohol so long as crops of the two benzenyldimethylamidine *picates* continued to separate. The *picates* in the mother-liquors were then converted into hydrochlorides, when a further quantity of benzenylmethylamidine hydrochloride separated. The mother-liquors gave on treatment with sodium iodide a further small crop of the trimethylamidine hydriodide, and the filtrate from this was worked up for the bases which it contained, and these were converted into the *picates* and fractionally crystallised. The operations of crystallisation as hydrochloride, hydriodide, and *picate* were repeated on the remaining material.

The *picates* were purified by recrystallisation from alcohol and the hydrochloride and hydriodide from water, when there were obtained in a pure state 16.95 grams of dimethylamidobenzenylimidine *picate*, 13.92 grams of methylamidobenzenylmethylimidine *picate*, 13.95 grams of benzenylmethylamidine hydrochloride, and 16.6 grams of dimethylamidobenzenylmethylimidine hydriodide, these yields being 18.6, 15.3, 27.9, and 23.6 per cent. of the theoretical, respectively, and amounting in all to 85.4 per cent.

In two previous experiments in which the total material was less satisfactorily accounted for, starting from 20 and 100 grams of benzenylmethylamidine hydrochloride, the yields of the four products in the above order were 18.4 and 16.8, 9.8 and 11.3, 18.4 and 22.0, 23.4 and 18.8 per cent. of the theoretical respectively.

Dimethylamidobenzylimidine picrate crystallises from alcohol in deep yellow, diamond-shaped or hexagonal plates, which sinter from 122° and melt sharply at 134° (corr.). It is anhydrous (Found: C = 47.4; H = 4.0. $C_9H_{12}N_2 \cdot C_6H_3O_7N_3$ requires C = 47.8; H = 4.0 per cent.).

The *hydrochloride* crystallises from absolute alcohol in colourless prisms, which are anhydrous and melt at 252–253° (corr.). It is very easily soluble in water or alcohol (Found: Cl = 18.8. $C_9H_{12}N_2 \cdot HCl$ requires Cl = 19.2 per cent.). The base was obtained as an oil which did not crystallise. After keeping for six weeks, the oil deposited benzamide in large crystals and had a strong odour of a volatile amine.

A quantity of the hydrochloride was distilled with an excess of 10 per cent. aqueous sodium hydroxide, and the volatile amines were collected in hydrochloric acid. On evaporating this solution to dryness, there remained a mixture of chlorides which were separated by means of chloroform. The insoluble portion was insoluble in absolute alcohol, and infusible, and proved to be ammonium chloride (Found: Cl = 66.1. Calc., Cl = 66.3 per cent.). The portion soluble in chloroform melted at 155–165°, but after crystallisation from absolute alcohol, formed deliquescent plates, melting at 170°, and consisted of dimethylamine hydrochloride (Found: Cl = 42.7. Calc., Cl = 43.5 per cent.).

Methylation.—Eight grams of dimethylamidobenzylimidine hydrochloride were mixed with aqueous sodium hydroxide and the base was collected by means of ether. After removing the solvent, the residue was cooled and mixed with 8 c.c. of methyl iodide. The mixture gradually became warm, and soon crystallised almost explosively. After adding a few c.c. of methyl alcohol, the crystals were collected and recrystallised from water, when 7.8 grams of dimethylamidobenzylmethylimidine hydriodide (M) were obtained in a pure state, melting at 258–262° (corr.), alone or mixed with a specimen prepared by the methylation of benzylmethylamidine. From the mother-liquors, the bases were regenerated and crystallised as picrates, when 4.45 grams of dimethylamidobenzylimidine picrate was obtained in a pure state, melting at 134° (corr.) after sintering earlier. Finally, the base from the residual picrates was converted into hydriodides, when a further quantity of 0.2 gram of M hydriodide was obtained in a pure state.

The yield of M is thus 63.6 per cent. of the theoretical, whilst 8.9 per cent. of the original base was recovered unchanged.

Methylamidobenzylmethylimidine crystallised from ether in colourless, elongated plates which melt at 80–81° (corr.). It is fairly easily soluble in water and very easily soluble in alcohol,

ether, chloroform, or benzene (Found: loss in a vacuum = 5.2. $C_9H_{12}N_2 \cdot \frac{1}{2}H_2O$ requires $H_2O = 5.7$ per cent. Found: in dried base, C = 72.8; H = 8.1. $C_9H_{12}N_2$ requires C = 73.0; H = 8.1 per cent.).

The *picrate* crystallises from alcohol in stout, yellow rods, which are anhydrous and melt at $171-172^\circ$ (corr.) (Found: C = 47.7, 47.5; H = 4.4, 4.0. $C_9H_{12}N_2 \cdot C_6H_3O_7N_3$ requires C = 47.8; H = 4.0 per cent.).

The *hydrochloride* crystallises from absolute alcohol in colourless spikes which are anhydrous and melt at $255-256^\circ$ (corr.) (Found: Cl = 19.3. $C_9H_{12}N_2 \cdot HCl$ requires Cl = 19.2 per cent.).

A quantity of the hydrochloride was distilled with an excess of 10 per cent. aqueous sodium hydroxide, and the volatile amines were collected in hydrochloric acid. On evaporating this solution to dryness, there remained a residue wholly soluble in absolute alcohol and yielding only traces to chloroform, which consisted of nearly pure methylamine hydrochloride. After crystallisation from absolute alcohol, this salt melted at 228° and was found to contain Cl = 52.4 (Calc., Cl = 52.6 per cent.).

Dimethylamidobenzylmethylimidine hydriodide crystallises from water in colourless needles which are anhydrous and melt at $258-262^\circ$ (corr.). It is sparingly soluble in cold water (Found: I = 43.8, 43.7. $C_{10}H_{14}N_2 \cdot HI$ requires I = 43.8 per cent.).

The *picrate* crystallises from alcohol in long plates which soften from 136° and melt at 138° (corr.) (Found: C = 48.8; H = 4.9. $C_{10}H_{14}N_2 \cdot C_6H_3O_7N_3$ requires C = 49.1; H = 4.3 per cent.). The base was obtained as an oil which did not crystallise after keeping for five weeks.

A quantity of the hydriodide was distilled with an excess of 10 per cent. aqueous sodium hydroxide, and the volatile amines were collected in hydrochloric acid. On evaporating this solution, there remained a residue which was wholly soluble in alcohol, but could be separated by means of chloroform. The insoluble portion was identified as methylamine hydrochloride by its melting point, 226° , after crystallisation from absolute alcohol, and by analysis of the chloroplatinate (Found: Pt = 41.0. Calc., Pt = 41.3 per cent.). The portion soluble in chloroform was identified as dimethylamine hydrochloride by conversion into the chloroplatinate and analysis (Found: Pt = 39.0. Calc., Pt = 39.0 per cent.).

Benzylbenzylamidine.—Benzylbenzylamidine may be obtained in the form of the hydrochloride in poor yield by the process described by Hofmann and Gabriel (*Ber.*, 1892, 25, 1585). An improved yield is obtained by the following method.

Thirty grams of benziminoethyl ether hydrochloride were mainly

dissolved in 100 c.c. of warm absolute alcohol. The solution was quickly cooled and mixed with 34 grams of benzylamine, when the temperature rose to about 40°. The imino-ether salt dissolved and benzenylbenzylamidinium hydrochloride slowly crystallised out. After keeping over-night, 18.5 grams of this salt, melting at 229°, were collected, and the mother-liquor was acidified with dilute hydrochloric acid and concentrated to remove alcohol, when it deposited various crops of sparingly soluble hydrochlorides melting between 210° and 160°, and eventually benzylamine hydrochloride. The sparingly soluble hydrochlorides melting at about 160° readily gave on crystallisation from water a salt, melting at 180—181° (corr.), which is probably benzenyldibenzylamidinium hydrochloride, $\text{CPh}(\text{N}\cdot\text{CH}_2\text{Ph})\cdot\text{NH}\cdot\text{CH}_2\text{Ph}\cdot\text{HCl}$, judging from its method of formation, and analysis of the salt and the corresponding picrate, but crystallisation of the hydrochlorides melting at about 210° did not readily effect a separation. The whole of the crude benzenylbenzylamidinium hydrochloride was therefore converted into the picrate and crystallised from alcohol, when 51.5 grams of the pure salt were obtained, that is, 72 per cent. of the theoretical yield.

Benzenyldibenzylamidinium picrate crystallises from alcohol in stout, prismatic needles, which are anhydrous and melt at 169—170° (corr.) (Found: C = 54.3; H = 3.9. $\text{C}_{14}\text{H}_{14}\text{N}_2\cdot\text{C}_6\text{H}_3\text{O}_7\text{N}_3$ requires C = 54.7; H = 3.9 per cent.).

From this, the pure base melting at 77—78° (corr.) and hydrochloride melting at 227—229° (corr.) were prepared; Hofmann and Gabriel (*loc. cit.*) give the melting points 77—78° and 222—225°, respectively.

The mother-liquors of the above picrates deposited some *benzylamine picrate*, which crystallised from alcohol in prismatic needles, softening from 190° and melting at 198—202° (corr.), alone or mixed with a specimen prepared from the two components.

Benzenyldibenzylamidinium hydrochloride crystallises from water in large prisms, which are anhydrous and melt at 180—181° (corr.). It is readily soluble in hot, but sparingly soluble in cold water (Found: Cl = 10.6. $\text{C}_{21}\text{H}_{20}\text{N}_2\cdot\text{HCl}$ requires Cl = 10.5 per cent.). The base was not decomposed when boiled with 10 per cent. aqueous sodium hydroxide.

The *picrate* crystallises from alcohol in needles which are anhydrous and melt at 146—147° (corr.) (Found: C = 61.0; H = 4.4. $\text{C}_{21}\text{H}_{20}\text{N}_2\cdot\text{C}_6\text{H}_3\text{O}_7\text{N}_3$ requires C = 61.2; H = 4.3 per cent.).

Methylation of Benzenylbenzylamidinium.—Thirty-five grams of the base were mixed with 35 c.c. of methyl iodide, and a vigorous reaction took place after keeping for a short time. The bases regenerated from the product were converted first into hydro-

chlorides, when 7.8 grams of benzenylbenzylamidine hydrochloride, melting at 227—229°, separated from aqueous solution, and then into picrates, when there separated from alcoholic solution in the course of a few days about 4 grams of crude methylbenzylamido-benzenylimidine picrate. After several weeks, the mother-liquor deposited a quantity of crude methylbenzylamidobenzenylmethyl-imidine picrate, and, on the removal of this, crude benzenylmethylbenzylamidine picrate crystallised from the mother-liquor. After a long series of fractional crystallisations from alcohol, quantities of the three picrates were obtained in the pure state, but the methylbenzylamidobenzenylimidine picrate frequently separated in crusts or warty masses contaminated with benzenylbenzylamidine picrate; in order to purify mixtures of this nature, it was necessary to remove the latter base as hydrochloride, and then reconvert the residual bases into picrates. The yields of pure products isolated are given in the table on p. 3361.

Methylbenzylamidobenzenylimidine picrate crystallises from alcohol in elongated prisms which are anhydrous and melt at 156—158° (corr.) (Found: C = 55.4, 55.4; H = 4.4, 4.3. $C_{18}H_{16}N_2C_6H_3O_7N_3$ requires C = 55.6; H = 4.2 per cent.).

The *hydrochloride* crystallises from dilute hydrochloric acid in clear, well-formed prisms, which contain $\frac{1}{2}H_2O$ and after drying at 100° soften from 176° and melt at 179—180° (corr.). It is easily soluble in water (Found: in air-dried salt, H_2O = 2.8; in dried salt, Cl = 13.3. $C_{15}H_{16}N_2.HCl.\frac{1}{2}H_2O$ requires H_2O = 3.3 per cent. $C_{15}H_{16}N_2.HCl$ requires Cl = 13.6 per cent.). The base did not crystallise. It was not decomposed by boiling with 20 per cent. aqueous sodium hydroxide, and was only slowly attacked by sodium amalgam in alcoholic solution, when ammonia, identified as hydrochloride, was the only product identified with certainty, although some benzylamine appeared to be formed.

Benzenylmethylbenzylamidine crystallises from ether in balls of microscopic needles, which melt at 71—73° (corr.). It is anhydrous, almost insoluble in water or light petroleum, very readily soluble in alcohol, and readily soluble in ether (Found: C = 80.1; H = 7.1. $C_{15}H_{16}N_2$ requires C = 80.3; H = 7.1 per cent.). It was not decomposed by boiling 20 per cent. aqueous sodium hydroxide. The hydrochloride did not crystallise.

The *picrate* crystallises from alcohol in fine needles which are anhydrous and melt at 118—122° (corr.) (Found: C = 55.6; H = 4.3. $C_{15}H_{16}N_2C_6H_3O_7N_3$ requires C = 55.6; H = 4.2 per cent.).

Reduction.—0.5 Gram of the above base was dissolved in 50 c.c. of absolute alcohol, mixed with 50 grams of 2.5 per cent. sodium

amalgam, and warmed gently for two hours, volatile amines being collected in hydrochloric acid. Aqueous sodium hydroxide was then added to the alcoholic solution, and the alcohol was distilled into the hydrochloric acid. The distillate was evaporated to dryness, mixed with aqueous sodium hydroxide, and extracted with ether (E). It was then distilled into dilute hydrochloric acid, when the solution gave on evaporation methylamine hydrochloride, which, after crystallisation from absolute alcohol, melted at 228°, alone or mixed with a known specimen. The ethereal extract (E) was used to extract the original alkaline solution, and evaporated, the residue yielding with hydrochloric acid a quantity of elongated plates which melted at 260° (corr.), alone or mixed with dibenzylamine hydrochloride, of which a pure specimen melted in the same bath at 261° (corr.).

Methylbenzylamidobenzenylmethylimidine picrate crystallises from alcohol in glistening, golden leaflets which are anhydrous and melt at 119–120° (corr.) (Found: C = 56.6; H = 4.4. $C_{16}H_{18}N_2 \cdot C_6H_3O_7N_3$ requires C = 56.5; H = 4.5 per cent.).

The author is indebted to Mr. I. E. Balaban, M.Sc.Tech., for carrying out the analyses recorded in this paper.

CCCXCVIII.—*Bromonitrocoumarins and their Reaction with Alkalis.*

By BIMAN BIHARI DEY and KARNAD KRISHNA ROW.

SOME time ago, it was shown by one of us (Dey, T., 1915, 107, 1618) that 1-methyl-4:3- β -naphthapyrone, when warmed with aqueous alkali, formed an acid which could be crystallised from hot alcohol without undergoing any change. In spite of its remarkable stability, this acid was regarded as the coumarinic acid, and the *cis*-configuration was assigned to it mainly on the ground that its 2-chloro- and 2-bromo-derivatives behaved with hot alkalis in a very different manner from other similarly substituted coumarins. Whilst the latter lost a molecule of halogen acid under these conditions and formed the coumarone or naphthafuran derivatives, the corresponding halogen-substituted β -naphthapyrones yielded extremely stable chloro- and bromo-acids by the addition of the elements of water. This extraordinary behaviour was therefore interpreted as a direct consequence of the *cis*-structure of these chloro- and bromo-acids, in which the halogen atom was remote

from the phenolic group, the view being advanced that the general reaction by which 3-halogen-substituted coumarins were transformed into coumarone derivatives could take place only through the intermediate formation of the *trans*- or coumaric acid, whereas if a stable *cis*- or coumarinic acid intervened, the elimination of the halogen acid and the consequent closing of the coumarone ring would be difficult, if not impossible. The following scheme explains the changes involved in the two cases :

β -Naphthapyrone and its derivatives have been found to provide the only exceptions to the general rule, and therefore it seemed desirable to obtain an explanation of this singular reaction by studying the conditions under which the formation of such stable coumarinic acids would be possible. As the few coumarinic acids that had hitherto been isolated in a comparatively stable condition were those derived from nitrocoumarins (Miller and Kinkelin, *Ber.*, 1889, **22**, 1706; Clayton, T., 1910, **97**, 1407), the presumption seemed to be reasonable that the introduction of halogen atoms into the pyrone ring in these substances would give rise to compounds which might react with alkalis in a manner analogous to β -naphthapyrone, and yield stable *cis*-acids containing halogen in the side chain. Although our expectations in this direction have not been realised to the extent desired, the results obtained have proved to be of significance in their bearing on the general question of isomerism of the coumarinic and coumaric acids.

The action of bromine on 6-nitrocoumarin appears to have been investigated by Taege (*J. pr. Chem.*, 1891, [ii], **43**, 1543), who obtained a dibromonitrocoumarin melting at 271°, in which the positions of the bromine atoms were not determined. Later, Dhar (T., 1920, **117**, 1000) prepared a monobromo- and a dibromo-nitrocoumarin melting at 215° and 220°, respectively.

We were unable to reproduce Taege's compound, and we found

that on treating 6-nitrocoumarin with bromine, substitution occurred simultaneously in the pyrone and benzene rings with the formation of a dibromo-derivative melting at 215°. Attempts to prepare the monobromo-derivative by this method were unsuccessful, a mixture being invariably obtained which was extremely difficult to separate, even if an insufficiency of the halogen had been used. The monobromonitrocoumarin was, however, readily obtained pure by the nitration of 3-bromocoumarin; it melted at 215°, and yielded on further bromination the above-mentioned dibromo-compound melting at the same temperature. The latter was converted, on oxidation, into a monobromonitrosalicylic acid melting at 222° which, on treatment with bromine in boiling aqueous solution, lost carbon dioxide, 2:6-dibromo-4-nitrophenol (m. p. 143°) being produced. The bromine atoms had therefore occupied positions 3 and 8 in the coumarin ring. The sequence of changes is shown in the scheme :

Similarly, 4:7-dimethylcoumarin yielded, on nitration and bromination, the 3:8-dibromo-6-nitro-derivative, whilst 4-methyl-1:2- α -naphthapyrone gave the 3-bromo-6-nitro-derivative, melting at 291°, which was also prepared either by the bromination of 6-nitro-4-methyl- α -naphthapyrone or by the nitration of 3-bromo-4-methyl- α -naphthapyrone.

These bromonitrocoumarins are practically insoluble in alcohol, and dissolve only sparingly in boiling glacial acetic acid, but are more readily soluble in hot pyridine or nitrobenzene, which are convenient media for crystallising them. They are insoluble in aqueous sodium carbonate, but gradually dissolve in cold dilute caustic alkalis, the solutions being of a deep orange or red colour. On acidification at 0°, the free coumarinic acids slowly separate in the crystalline form. The freshly precipitated substances dissolve almost completely in cold aqueous sodium carbonate,

but quickly lose this property on warming, or even when they are left in contact with water for a few hours, owing to their being largely reconverted into the coumarins. The action of cold alkalis on these bromonitrocoumarins seems therefore to have the effect of merely opening up the pyrone ring and forming the sodium salts of the coumarinic acids. On warming the alkaline solutions, however, the sodium coumarinates slowly undergo change: sodium bromide is eliminated and the nitrocoumarilic acids are produced, the sodium salts of which usually separate on cooling, owing to their sparing solubility. The change, however, can be completed only on prolonged boiling, for on acidifying a solution of 3:8-dibromo-6-nitrocoumarin which had been boiled with caustic soda solution for half an hour and cooled, a mixture of the coumarinic and the coumarilic acid was precipitated; they were separated by warming the mixture with dilute hydrochloric acid, when the coumarinic acid was converted into the coumarin and thus rendered insoluble in sodium carbonate.

The disilver salts of the coumarinic acids which were obtained as deep red precipitates on carefully neutralising the cold alkaline solutions with dilute nitric acid and adding silver nitrate, were more stable than the free acids and could be preserved unchanged at the ordinary temperature for more than a day, provided they were kept in the dark. On treating the silver salts with warm dilute nitric acid, the original coumarins were quantitatively regenerated. If, however, these salts were warmed with water or alcohol or exposed to sunlight, they gradually changed into a mixture of silver bromide and the silver bromonitrocoumarilates, the course of the transformation being easily followed by the rapid change in colour of the silver salts from deep red to light grey. This change of the silver salts on exposure to light is therefore obviously analogous to what takes place on heating the sodium coumarinates, and the two reactions can be best understood by assuming that the unstable salt of the coumarinic or the *cis*-acid has been slowly transformed into the stable salt of the coumaric or the *trans*-acid with the consequent elimination of sodium or silver bromide. The mechanism of the changes may be represented as shown on p. 3379.

Attempts to prepare the coumarinic esters by treatment of the dry silver salts in ethereal suspension with ethyl iodide were unsuccessful, the ethyl esters of the coumarilic acids being the only products isolated. As the conversion of a *cis*-compound into its *trans*-isomeride has frequently been observed to be preceded by the formation of an additive compound with the reagent bringing about the change (compare Biilmann, *Annalen*, 1912,

388, 259), the probability of the alkyl iodide having played such a part in the above reaction seems to deserve consideration.

EXPERIMENTAL.

3-Bromo-6-nitrocoumarin (Formula II).—Eight grams of 3-bromocoumarin, prepared by Perkin's method (T., 1871, 24, 37), were treated in cold glacial acetic acid (30 c.c.) solution with a mixture of fuming nitric acid (6 c.c.) and glacial acetic acid (10 c.c.). After one hour, concentrated sulphuric acid (20 c.c.) was added, and the solution heated on the water-bath for some time, when pure 3-bromo-6-nitrocoumarin crystallised; further quantities of a slightly impure product were obtained on dilution of the mother-liquor (Found: Br = 29.38. Calc., Br = 29.62 per cent.).

α -Bromo-5-nitrocoumarinic Acid, $\text{NO}_2 \cdot \text{C}_6\text{H}_3(\text{OH}) \cdot \text{CH} : \text{CBr} \cdot \text{CO}_2\text{H}$.—The bromonitrocoumarin (2 grams) was shaken at the ordinary temperature with 10 per cent. caustic potash (50 c.c.) until it completely dissolved. The deep orange solution was cooled in ice and carefully acidified with dilute hydrochloric acid, when the coumarinic acid, mixed with a small amount of the coumarin itself, crystallised. The product was freed from the unchanged coumarin by treating it with cold dilute aqueous sodium carbonate and acidifying the rapidly filtered solution; the coumarinic acid, thus obtained in an almost pure condition, melted with sudden decomposition at 197–198°, being reconverted into the coumarin.

The acid was too unstable to purify by crystallisation from a solvent, and changed rather rapidly into the coumarin even on standing at the ordinary temperature (30°).

The *silver* salt was obtained as a heavy, orange-yellow precipitate on adding silver nitrate to a neutral solution of the sodium coumarinate (Found : Ag = 42.71. $C_9H_4O_5NBr_2Ag_2$ requires Ag = 43.03 per cent.).

The freshly prepared silver salt regenerated the bromonitrocoumarin on acidification with nitric acid at the ordinary temperature, but when it was dried and kept in a desiccator, it gradually changed in colour and became nearly white at the end of twenty-four hours; on acidifying the product with dilute nitric acid, a mixture of silver bromide and nitrocoumarilic acid was obtained, from which the latter was extracted with boiling dilute alcohol.

Action of Ethyl Iodide on Silver Bromonitrocoumarinate.—A suspension of the fresh dry silver salt (10 grams) in anhydrous ether (100 c.c.) and ethyl iodide (6 grams) was shaken mechanically for four hours, the ether then allowed to evaporate, and the residue extracted thrice with warm absolute alcohol. Dilution with water precipitated a solid ester, which after two crystallisations from 30 per cent. alcohol separated in colourless plates, m. p. 153° (Found : N = 6.46. $C_{11}H_9O_5N$ requires N = 6.0 per cent.).

4-Nitrocoumarilic Acid, $NO_2 \cdot C_6H_3 \begin{smallmatrix} \diagup O \\ \diagdown CH \end{smallmatrix} \cdot C \cdot CO_2H$.—A solution of 3-bromo-6-nitrocoumarin (5 grams) in a minimum of 90 per cent. alcohol was boiled under reflux with aqueous caustic potash (10 grams in 25 c.c.) for 3 to 4 hours; on cooling, *potassium 4-nitrocoumarilate* crystallised in colourless needles. The acid, liberated from this salt as a white, gelatinous precipitate by hydrochloric acid, and crystallised twice from hot dilute acetic acid, formed needles melting and decomposing at 274–275°. The colourless *silver* salt was analysed (Found : Ag = 34.3. $C_9H_4O_5NAg$ requires Ag = 34.4 per cent.).

The *ethyl* ester, prepared by the hydrogen chloride method, crystallised in colourless plates, m. p. 153°, and was identical with the preceding ester.

3:8-Dibromo-6-nitrocoumarin (Formula I).—Five grams of 6-nitrocoumarin were heated with a solution of bromine (12 grams) in glacial acetic acid (25 c.c.) and a trace of iodine for four hours. The dibromo-derivative, which separated out almost completely on cooling, was recrystallised several times from boiling glacial acetic acid, in which it dissolved rather sparingly. It separated in clusters of hard, colourless needles, m. p. 215° (Found : Br = 45.34. $C_9H_2O_5NBr_2$ requires Br = 45.84 per cent.).

2-Bromo-4-nitrosalicylic Acid.—Three grams of 3:8-dibromo-6-nitrocoumarin were dissolved by heating with 6 grams of sodium hydroxide (20 per cent. solution), the solution was cooled to the

ordinary temperature (32°), diluted to 100 c.c., and treated slowly with a solution of potassium permanganate (5 grams), the oxidation being completed by boiling for an hour. The precipitated manganese dioxide was washed with hot water, and the combined filtrate and washings, after concentration, were acidified. The bulky, white precipitate was washed with cold water and crystallised once from boiling water. The pure acid melted with sudden decomposition at 222° (Found: Br = 30.50. $C_7H_4O_5NBr$ requires Br = 30.53 per cent.).

The *ethyl* ester, prepared in the usual way, crystallised in white needles, m. p. 219°.

Action of Bromine on 2-Bromo-4-nitrosalicylic Acid.—Saturated bromine water was added to the acid in boiling aqueous solution until it no longer decolorised. Carbon dioxide was evolved and crystals separated, which were deposited from alcohol in prisms melting at 143°, and were identified with 2:6-dibromo-4-nitrophenol, prepared by direct bromination of *p*-nitrophenol.

3:8-Dibromo-6-aminocoumarin was obtained by reduction of the nitro-compound with stannous chloride in acid alcoholic solution, the separated stannichloride being decomposed with boiling dilute aqueous sodium acetate. The amine separated from hot xylene in bright yellow needles, m. p. 237° (Found: N = 4.16. $C_9H_5O_2NBr_2$ requires N = 4.39 per cent.).

3:α-Dibromo-5-nitrocoumarinic Acid (Formula III).—The dibromonitrocoumarin (3 grams) was shaken with 20 c.c. of 10 per cent. sodium hydroxide until almost the whole of the solid had dissolved, the filtered, deep orange-red solution was acidified at 0°, and the pale yellow, crystalline precipitate quickly dissolved in sodium bicarbonate solution and reprecipitated at a low temperature. The washed acid, dried on porous tile, formed a cream-coloured, crystalline powder which began to sinter at 188° and melted with sudden evolution of gas at 196–197°. The residue melted at 212–213°, alone or mixed with the pure dibromonitrocoumarin. The free acid was too unstable to purify further by crystallisation from any solvent, and slowly changed into the coumarin even on standing at the laboratory temperature, as was shown by its becoming insoluble in cold sodium bicarbonate solution.

The *silver* salt was obtained as an orange-red precipitate on adding silver nitrate to a carefully neutralised solution of the acid (Found: Ag = 36.45. $C_9H_3O_5NBr_2Ag_2$ requires Ag = 37.16 per cent.).

6-Bromo-4-nitrocoumarinic Acid (Formula in accordance with IV).—Freshly prepared silver 3:α-dibromo-5-nitrocoumarinate was converted by dilute nitric acid at 0° largely into the free acid,

mixed with a little of the coumarin. When warmed, however, with water, or when kept in a desiccator for two days, the silver salt changed into a light grey powder, composed mainly of silver bromonitrocoumarilate and silver bromide. After acidification, the free acid was extracted with boiling water and obtained in colourless needles, m. p. 253—254° (Found: Br = 27.71. $C_9H_4O_5NBr$ requires Br = 27.97 per cent.).

The same acid was obtained directly from the dibromonitrocoumarin by boiling with 25 per cent. caustic soda, filtering the precipitated sodium salt, acidifying with dilute hydrochloric acid, and crystallising the curdy precipitate from boiling water.

The sodium salt of this acid is much more sparingly soluble than the potassium salt and can be crystallised readily from hot water (Found: Na = 7.53. $C_9H_3O_5NBrNa$ requires Na = 7.46 per cent.).

The ethyl ester, prepared in the usual way, crystallised from alcohol in soft, colourless needles, m. p. 156° (Found: Br = 25.13. $C_{11}H_8O_5NBr$ requires Br = 25.47 per cent.).

Action of Ethyl Iodide on Silver 3 : α -Dibromo-5-nitrocoumarinate.—Five grams of the freshly precipitated, dry silver salt were shaken with 4 grams of ethyl iodide and 50 c.c. of anhydrous ether for two hours. The ether was evaporated at the ordinary temperature, and the residue treated with boiling alcohol; the extract deposited white needles melting at 156°, alone or mixed with the preceding ester.

3 : 8-Dibromo-6-nitro-4 : 7-dimethylcoumarin,

was prepared by brominating 6-nitro-4 : 7-dimethylcoumarin in glacial acetic acid solution in the presence of a trace of iodine. Colourless, stout prisms melting at 224° were obtained which were practically insoluble in alcohol or ether and dissolved very sparingly in boiling acetic acid (Found: Br = 41.98. $C_{11}H_7O_4NBr_2$ requires Br = 42.44 per cent.).

It dissolved slowly in cold dilute sodium hydroxide solution with a deep red colour, but the precipitate obtained on acidification in the cold consisted almost entirely of the unchanged coumarin. The free coumarinic acid could not be isolated in the pure state, but the pure disilver salt was precipitated on adding silver nitrate to the carefully neutralised solution of the coumarin in alkali.

6-Bromo-4-nitro-2 : 5-dimethylcoumarilic Acid,

—The sodium salt of this acid crystallised on boiling a solution

of the bromonitrodimethylcoumarin with 25 per cent. caustic soda for two hours; it was dried at 100° (Found: Na = 7.1. $C_{11}H_7O_5NBrNa$ requires Na = 6.84 per cent.). The free acid crystallised from dilute alcohol in colourless needles, melting and decomposing at 263—264°.

3-Bromo-6-nitro-4-methyl-1 : 2- α -naphthapyrone,

—6-Nitro-4-methyl- α -naphthapyrone (5 grams), dissolved in glacial acetic acid (100 c.c.), was boiled with bromine (1.5 c.c.) and a trace of iodine until the evolution of hydrogen bromide ceased. The precipitated solid was washed with hot glacial acetic acid and crystallised twice from nitrobenzene, yellow needles being obtained melting at 291—292°.

The same product was obtained on nitrating 3-bromo-4-methyl- α -naphthapyrone in the usual way. It was practically insoluble in the ordinary organic solvents, but dissolved to some extent in hot pyridine and more readily in boiling nitrobenzene, which are convenient media for crystallisation (Found: Br = 23.78. $C_{14}H_8O_4NBr$ requires Br = 23.94 per cent.).

3-Bromo-6-amino-4-methyl-1 : 2- α -naphthapyrone was prepared by the reduction of the nitro-compound with alcoholic stannous chloride. It crystallised from hot absolute alcohol in long, orange-yellow needles, m. p. 222° (Found: N = 4.96. $C_{14}H_{10}O_2NBr$ requires N = 4.6 per cent.). The acetyl derivative crystallised from dilute alcohol in colourless, silky needles, m. p. 287—288°.

Action of Cold Alkali on 3-Bromo-6-nitro-4-methyl- α -naphthapyrone.—The bromonitro- α -naphthapyrone slowly dissolved in cold 10 per cent. aqueous caustic soda to form a deep red solution. The pale yellow precipitate obtained on acidification at a low temperature was largely composed of the unchanged coumarin, from which the free coumarinic acid was extracted with cold sodium bicarbonate in the usual way. The acid was very unstable and passed rapidly into the bromonitronaphthapyrone even on shaking with water, as was shown by its becoming insoluble in sodium carbonate solution after some time. When freshly prepared, it decomposed with sudden evolution of gas near 245° in the manner characteristic of coumarinic acids, and left a solid residue which melted at 290—291°. The silver salt was obtained as a deep red, heavy precipitate on adding silver nitrate to the neutral solution of the coumarinic acid (Found: Ag = 37.92.

requires Ag = 38.15 per cent.).

4-Nitro-2-methyl- α -naphthafuran-1-carboxylic Acid,

—3-Bromo-6-nitro-4-methyl- α -naphthapyrone (2 grams) was heated with a solution of potassium hydroxide (4 grams in 4 c.c. of water) and alcohol (40 c.c.) for four hours. The alcohol was distilled off, and the thick sludge of crystalline potassium salt washed with a little cold alcohol and dissolved in cold water. The gelatinous, white precipitate obtained on acidifying the filtered solution crystallised from boiling dilute alcohol in colourless needles melting and decomposing at 277°. The sodium salt was rather sparingly soluble and separated almost immediately on neutralising the acid with 2N-sodium carbonate (Found: Na = 8.13. $\text{C}_{18}\text{H}_9\text{O}_5\text{NNa}$ requires Na = 7.86 per cent.).

The ethyl ester, prepared by the hydrogen chloride method, separated from the cooled solution in white needles, which, after two crystallisations from alcohol, were obtained pure and melted sharply at 152°.

The same ester was obtained by the action of ethyl iodide on the dry silver bromonitronaphthacoumarinate, the experiment being carried out in the same way as in the case of the dibromo-nitrocoumarin described above.

PRESIDENCY COLLEGE, MADRAS.

[Received, October 1st, 1923.]

CCCXCIX.—*Diazo-transformations of Amino-coumarins and Aminonaphthapyrones.*

By BIMAN BIHARI DEY and HARIDAS DALAL.

It is not possible to introduce a halogen atom directly into the benzenoid part of the coumarin molecule, because the substitution occurs in the lactone ring, which is more susceptible to attack. Thus, by the halogenation of coumarin, Perkin (this Journal, 1871, 24, 37) obtained a monochloro- and a monobromo-derivative containing the halogen in the pyrone ring; the isomeric derivatives with the halogen in the benzene nucleus were prepared synthetically by the action of acetic anhydride on the sodium salts of the corresponding halogenated salicylaldehydes. Similar results have been recorded by Seidel (*J. pr. Chem.*, 1898, [ii], 57, 495), Simonis and Wenzel (*Ber.*, 1900, 33, 1961), and also, in the case of several hydroxy-coumarins, by Fries and Lindemann (*Annalen*, 1914, 404, 65), who showed that under normal conditions no derivatives could be obtained in which the halogen had been exclusively substituted for hydrogen atoms in the benzene ring. Compounds of

the latter class, of which only a few are described in the literature, have hitherto been prepared, usually in poor yields, by indirect processes such as the application of Perkin's reaction to halogenated salicylaldehydes, or the condensation of halogen-substituted phenols with malic acid and acetoacetic ester (Pechmann).

The diazo-transformation of aminocoumarins, which are readily obtained by the nitration and reduction of coumarins, does not appear to have been employed to any extent in the preparation of these *Bz*-substituted coumarins. Our attention was first directed to the subject in the course of a determination of the positions of the halogen atoms in certain chloro- and bromo- α -naphthapyrones, which were subsequently prepared in good yields from the corresponding amines. The reaction was therefore investigated more fully and the results were applied in several cases to the orientation of substituents in coumarin derivatives.

Aminocoumarins behave like substituted benzenoid amines, the lactone ring having no influence on the course of the diazo-transformations (compare Morgan and Micklethwait, T., 1904, 85, 1233). Some of these diazo-derivatives are extraordinarily stable; for example, a solution of 4-methyl- α -naphthapyrone-6-diazonium sulphate retains in full its power of coupling with β -naphthol or aniline even after standing at the laboratory temperature (32°) for two weeks. 6-Aminocoumarin, 6-amino- α -naphthapyrone, and some of their alkyl homologues gave excellent yields of the corresponding chloro-, bromo-, and iodo-derivatives on the usual treatment; in several cases, the products were identified with compounds obtained by Perkin's reaction. The cyano-derivatives, which were also prepared in the usual way, exhibited the general characteristics of aromatic nitriles and were hydrolysed with ease to coumarincarboxylic acids. They also condensed with ethyl alcohol under the influence of dry hydrogen chloride to form the corresponding imino-ethers. When the imino-ether hydrochloride obtained from 6-cyanocoumarin was carefully heated under reduced pressure, it was quantitatively transformed into *coumarin-6-carboxylamide*:

The reaction furnishes a simple method for the preparation of the acid amides of the coumarin series.

Coumarin-6-carboxylamide forms a white, insoluble silver salt which, like silver benzamide, reacts in the tautomeric form, as it is converted on digestion with cold ethyl iodide into the free imino-ether:

The direct action of halogens on certain alkylcoumarins and naphthapyrones was also studied in the course of the present investigation. When 4:7-dimethylcoumarin is chlorinated or brominated, the first halogen atom to enter attaches itself to the pyrone ring in accordance with the usual rule. This is proved by (1) the behaviour of the compounds with alcoholic potash, which removes the halogen atom with the formation of 2:5-dimethylcoumarilic acid, (2) the identity of the monochloro-derivative and the product of condensation of *m*-cresol and ethyl α -chloroacetoacetate (Dey, P., 1914, 30, 38). On further chlorination, a dichloro-derivative is produced which loses a molecule of hydrogen chloride and yields a monochlorodimethylcoumarilic acid when treated with boiling alcoholic potash in the usual way. The second atom of chlorine is therefore evidently attached to the benzene ring. Its position was determined in two ways, (1) by the preparation of the same compound from 6-amino-4:7-dimethylcoumarin by the diazo-transformation and further chlorination of the product, (2) by its synthesis from 6-chloro-*m*-cresol and ethyl α -chloroacetoacetate as shown in the following scheme :

Chlorination of 4-methyl-1:2- α -naphthapyrone is analogous to that in the previous case. The first product is a monochloro-derivative in which the halogen has entered position 3 in the pyrone ring, the substance being identical with the compound obtained by the condensation of α -naphthol with ethyl α -chloroacetoacetate; alcoholic potash converts it into 2-methyl- α -naphthafuran-1-carboxylic acid (Hantzsch and Pfeiffer, *Ber.*, 1886, 19, 1303). On further chlorination, a dichloro-derivative is obtained, the 6-position of the second chlorine atom being established, as in the previous case, by preparing the same compound from diazotised 6-amino-4-methyl- α -naphthapyrone and cuprous chloride and subsequent chlorination.

EXPERIMENTAL.

6-aminocoumarin (2 grams) in 4*N*-hydrochloric acid (25 c.c.) was diazotised and, after one hour, added gradually to an ice-cold solution of cuprous chloride (2 grams) in concentrated hydrochloric acid (15 c.c.). The mixture was shaken for a few minutes and then gradually heated on the water-bath until effervescence ceased. The precipitate obtained on cooling was washed with very dilute caustic soda solution and with water, dried, and extracted with hot alcohol. Recrystallisation from rectified spirit gave a mass of pale yellow needles, m. p. 163° (Clayton, T., 1908, 93, 2022, gives m. p. 162°), weighing 1.7 grams (75 per cent. of the theoretical) (Found: Cl = 20.06. Calc., Cl = 19.67 per cent.).

6-Bromocoumarin was prepared in a similar way. The yield of the recrystallised product, m. p. 160° (Perkin, T., 1871, 24, 41), was 1.3 grams or 47 per cent. (Found: Br = 35.27. Calc., Br = 35.56 per cent.).

6-Iodocoumarin.—The ice-cold diazo-solution prepared from 6-aminocoumarin (2 grams) was slowly treated, with constant stirring, with a solution of potassium iodide (2.5 grams) in 20 c.c. of water. A yellow, crystalline mass formed after a short time, which gradually turned brown owing to separation of iodine. After the usual heating on the water-bath, the product was treated with a few crystals of sodium bisulphite until the colour became light yellow, cooled, filtered, and crystallised twice from absolute alcohol, 6-iodocoumarin (1.5 grams) being obtained in fine, colourless needles, m. p. 165° (Seidel, *J. pr. Chem.*, 1898, [ii], 57, 496, gives m. p. 164°) (Found: I = 46.43. Calc., I = 46.69 per cent.).

6-Cyanocoumarin.—This compound was prepared from the diazotised amine (4 grams) and a solution of cuprous cyanide potassium cyanide, 8 grams, crystallised copper sulphate, 7 grams, water, 40 c.c.) at 50°. A yellow, crystalline deposit soon formed which turned reddish-brown towards the end of the operation. The mixture was heated to 100° and the solid collected after twelve hours, dried, and extracted repeatedly with boiling rectified spirit. The crystals which were first deposited were pale brown, but two crystallisations from 50 per cent. alcohol furnished long, colourless needles, m. p. 220°. The yield was 2.6 grams (Found: C = 70.5; I = 3.44; N = 8.16. C₁₀H₅O₂N requires C = 70.2; H = 2.92; N = 8.18 per cent.).

Coumarin-6-carboxylic Acid.—6-Cyanocoumarin was warmed with 70 per cent. sulphuric acid until effervescence ceased. The flocculent precipitate which formed on pouring the product into cold water was dissolved in dilute sodium carbonate solution and reprecipitated with acid. It was deposited from dilute alcohol in fine, colourless needles, m. p. 268°. Störmer and Oetker (*Ber.*, 1904, **37**, 194) who prepared it by oxidation of the aldehyde, gave the same melting point (Found: C = 62.67; H = 3.19. Calc., C = 63.15; H = 3.15 per cent.). The free acid is sparingly soluble in hot water, and the aqueous solution of the sodium salt exhibits a pale blue fluorescence.

The *ethyl* ester was obtained from the acid in the usual way, but was more conveniently prepared by saturating a solution of the cyanocoumarin in excess of cold absolute alcohol with dry hydrogen chloride. After twelve hours, the solution was poured into cold water. The precipitate, crystallised once from 50 per cent. alcohol, formed soft, white needles, m. p. 130°, the yield being almost theoretical (Found: C = 65.7; H = 4.98. $C_{12}H_{10}O_4$ requires C = 66.1; H = 4.59 per cent.).

Chloride of Coumarin-6-carboxylic Acid.—The acid (2 grams) was boiled under reflux with phosphorus trichloride (5 c.c.) and phosphorus pentachloride (1 gram) until the solution became clear. The excess of phosphorus chloride was distilled off and the residue poured over crushed ice. A dark oil separated which quickly solidified. It was dried on porous tile, and crystallised from a minimum of boiling chloroform. The substance began to shrink at 175° and melted completely at 182° (Found: Cl = 16.64. $C_{10}H_5O_3Cl$ requires Cl = 17.02 per cent.).

The *anilide*, prepared by warming the above acid chloride and aniline together for a minute, separated from glacial acetic acid in shining crystals melting at 194° (Found: N = 5.0. $C_{16}H_{11}O_3N$ requires N = 5.28 per cent.).

Coumarin-6-formiminoether Hydrochloride,

—6-Cyanocoumarin (2 grams) was made into a thin cream with absolute alcohol (45 c.c.) and the mixture saturated with dry hydrogen chloride at 0°. The flask was loosely corked and left over-night at the laboratory temperature; about 60 c.c. of dry ether were then added with vigorous shaking. The crystals that separated after some time were washed with ether, and dried in

a vacuum over lime. The hydrochloride was readily soluble in cold water (Found : Cl, by titration with $N/10$ -silver nitrate, = 14.5. $C_{12}H_{12}O_3NCl$ requires Cl = 14.00 per cent.).

The free *imino-ether* was obtained in fine, glistening needles by the action of ammonia on the aqueous solution of its hydrochloride. It melted at 135° and was very soluble in alcohol (Found : N = 6.43. $C_{12}H_{11}O_3N$ requires N = 6.45 per cent.).

Coumarin-6-carboxylamide.—The imino-ether hydrochloride (2 grams) was heated in a 50 c.c. distilling flask connected to the water-pump. At 170 – 180° , long, white needles began to sublime. The temperature was gradually raised to 200° and at the end of the reaction the product was digested with alcohol and the extract filtered and evaporated to dryness. The residue was crystallised from hot water, colourless prisms, m. p. 203° , being obtained with the aid of animal charcoal. The pure product weighed 0.9 gram (Found : N = 7.27. $C_{10}H_7O_3N$ requires N = 7.41 per cent.).

Preparation of the Imino-ether from the Silver Salt of the Amide.—The silver salt, which was obtained as a white, granular precipitate on adding silver nitrate to an aqueous solution of the amide, was dried on porous tile and boiled with excess of ethyl iodide under reflux for three to four hours. The liquid was evaporated on the water-bath, and the residue crystallised twice from dilute alcohol. The product melted at 134 – 135° , alone or mixed with the imino-ether (m. p. 135°) prepared above.

Coumarin-6-formamidine Hydrochloride, $C_9H_5O_2 \cdot C(NH_2) \cdot NH_2 \cdot HCl$.—The imino-ether hydrochloride was triturated with alcoholic ammonia until nearly the whole of the solid dissolved. The filtered solution was evaporated in a vacuum at the ordinary temperature, the residue treated with hydrochloric acid, and the solid crystallised from a little dilute hydrochloric acid, when a mass of woolly needle, separated, which became waxy and translucent at 130° , and melted to a clear liquid at 170 – 171° .

6-Chloro-4 : 7-dimethylcoumarin.—This compound, prepared from diazotised 6-amino-4 : 7-dimethylcoumarin and cuprous chlorides crystallised from absolute alcohol in pale yellow prisms, m. p. 210° , the yield being almost quantitative (Found : Cl = 17.21. $C_{11}H_9O_2Cl$ requires Cl = 17.02 per cent.).

6-Cyano-4 : 7-dimethylcoumarin, obtained in poor yield from the 3-amino-compound in the usual way, crystallised from acetic acid in soft, buff-coloured needles, m. p. 286° .

3-Chloro-4 : 7-dimethylcoumarin.—The required amount of dry chlorine, generated from potassium permanganate and hydrochloric acid, was passed into a boiling solution of the coumarin in glacial acetic acid. Magnificent, prismatic needles separated from

the cold solution. These contained acetic acid of crystallisation, which was lost on exposure to the air. The resulting powder, recrystallised from alcohol, gave long, colourless needles, m. p. 134° (Found: Cl = 16.89. $C_{11}H_9O_2Cl$ requires Cl = 17.02 per cent.).

2:5-Dimethylcoumarilic acid, prepared from the above monochloro-derivative, crystallised in thin needles melting at 218°. The silver salt was prepared (Found: Ag = 36.36. $C_{11}H_9O_3Ag$ requires Ag = 36.36 per cent.).

3:6-Dichloro-4:7-dimethylcoumarin was prepared by saturating with chlorine a warm glacial acetic acid solution of either 3-chloro- or 6-chloro-4:7-dimethylcoumarin, and being very sparingly soluble, separated in the crystalline form. Recrystallisation from excess of boiling glacial acetic acid gave long, prismatic needles, m. p. 216° (Found: Cl = 28.98. $C_{11}H_8O_2Cl_2$ requires Cl = 29.21 per cent.).

The same compound was synthesised by Pechmann's method as follows: 6-chloro-*m*-cresol (7 grams) and ethyl α -chloroacetate (8 grams) were treated at 0° with concentrated sulphuric acid (10 c.c.), and the mixture, having been left over-night at the laboratory temperature (30°), was poured into 300 c.c. of cold water. The solid that separated was crystallised several times from hot alcohol, and prismatic needles were obtained, which weighed more than 2 grams, melted at 216°, and did not depress the melting point of the preceding compound.

4-Chloro-2:5-dimethylcoumarilic Acid.—The potassium salt of this acid separated out on boiling the dichloro-compound mentioned above with excess of alcoholic potash under reflux for three hours; it was crystallised from the minimum amount of hot water (Found: K = 14.61. $C_{11}H_8O_3ClK$ requires K = 14.5 per cent.). The free acid crystallised from dilute acetic acid in felted needles melting with decomposition at 264–265°.

6-Amino-1:2- α -naphthapyrone, $NH_2 \cdot C_{10}H_5 < \begin{smallmatrix} O-CO \\ CH:CH \end{smallmatrix}$ —A boiling alcoholic solution of stannous chloride (9 grams) and concentrated hydrochloric acid (8 c.c.) containing a little metallic tin was slowly treated with the 6-nitronaphthapyrone (2 grams). The mixture having been boiled under reflux for an hour and cooled, 10 c.c. of concentrated hydrochloric acid were added, and, after a few hours, the crystalline stannichloride was collected, washed with a little concentrated hydrochloric acid, and boiled with sodium acetate solution (10 grams in 500 c.c.). The amine, which separated as a yellow powder after twelve hours, was purified by crystallisation from alcohol, golden-yellow needles, m. p. 193°, being obtained (Found: N = 6.58. $C_{13}H_9O_2N$ requires N = 6.64 per cent.). The amine formed a sparingly soluble hydrochloride, nitrate, and sulphate which crystallised well from hot water.

The *acetyl* derivative, prepared by boiling the amine with acetic anhydride containing a drop of pyridine for a minute, crystallised from alcohol in colourless needles, m. p. 216° (Found: N = 5.32. $C_{15}H_{11}O_3N$ requires N = 5.53 per cent.). The *benzoyl* derivative formed colourless prisms, m. p. 239° .

6-Chloro-1:2- α -naphthapyrone.—As the aminonaphthapyrone hydrochlorides are very sparingly soluble in water, diazotisation of the 6-amino-compound was effected by alternately adding the powdered amine and sodium nitrite to ice-cold hydrochloric acid. The mixture having been kept in the cold for two hours with occasional shaking, the almost clear solution was filtered and added slowly to the cold cuprous chloride solution; the crystalline precipitate obtained was treated in the usual way. Crystallised from glacial acetic acid, the product gave light yellow, prismatic needles, m. p. 106° (Found: Cl = 15.0. $C_{13}H_7O_2Cl$ requires Cl = 15.4 per cent.).

6-Chloro-4-methyl-1:2- α -naphthapyrone.—The amine (2 grams) was diazotised in the manner described above and treated with cuprous chloride. The product crystallised from alcohol in lustrous yellow needles, m. p. 212° (yield 1.5 grams) (Found: Cl = 14.3. $C_{14}H_9O_2Cl$ requires Cl = 14.51 per cent.).

6-Bromo-4-methyl-1:2- α -naphthapyrone crystallised from acetic acid in brown, prismatic needles, m. p. 210° (Found: Br = 27.4. $C_{14}H_9O_2Br$ requires Br = 27.68 per cent.).

6-Iodo-4-methyl-1:2- α -naphthapyrone, obtained in the usual way in almost theoretical yield, separated from alcohol in pale yellow, silky needles, m. p. 212° (Found: I = 38.47. $C_{14}H_9O_2I$ requires I = 38.8 per cent.).

6-Cyano-4-methyl-1:2- α -naphthapyrone crystallised from alcohol in yellow needles, m. p. 273° (Found: N = 5.88. $C_{15}H_9O_2N$ requires N = 5.96 per cent.).

4-Methyl-1:2- α -naphthapyrone-6-carboxylic acid was prepared by hydrolysing the cyano-compound with warm 70 per cent. sulphuric acid. It was deposited from dilute alcohol in clusters of colourless needles, m. p. 215° .

3-Chloro-4-methyl-1:2- α -naphthapyrone.—Dry chlorine, generated from 4 grams of potassium permanganate, was passed into a boiling glacial acetic acid (50 c.c.) solution of the methylnaphthapyrone (6 grams). Crystals of the monochloro-derivative soon began to appear and filled the liquid on cooling. A single crystallisation from acetic acid yielded flat prisms melting at 225° , alone or mixed with a specimen of the 3-chloro-compound prepared from α -naphthol and α -chloroacetoacetic ester (Found: Cl = 14.94. $C_{14}H_9O_2Cl$ requires Cl = 14.51 per cent.).

3:6-Dichloro-4-methyl-1:2- α -naphthapyrone was prepared by

chlorinating either the 3-chloro-derivative described above or the 6-chloro-compound obtained by the diazo-reaction from the corresponding amine. It was practically insoluble in alcohol, but could be crystallised from a large quantity of boiling acetic acid, which deposited prismatic needles, m. p. 258° (Found: Cl = 24.97, $C_{14}H_8O_2Cl_2$ requires Cl = 25.45 per cent.).

CCCC.—*The Freezing-point Curves of Binary Mixtures of some Substituted Acetanilides.*

By GLYN OWEN.

DURING the course of an investigation of the halogenation of anilides the freezing-point curves of the following systems were studied:

- (a) Aceto-2 : 4-dichloroanilide and aceto-2-chloro-4-bromoanilide.
- (b) Aceto-2 : 4-dibromoanilide and aceto-2-chloro-4-bromoanilide.
- (c) Aceto-4-chloro-2-bromoanilide and aceto-2-chloro-4-bromoanilide.
- (d) Aceto-2 : 4-dichloroanilide and aceto-4-chloroanilide.

Many binary mixtures of aromatic derivatives have been studied and examples of solid solution and polymorphism recorded. As far as anilides are concerned, mixtures of *o*- and *p*-monochlorinated anilides were investigated by Orton and Jones (T., 1909, 95, 1059) and by Orton and King (T., 1911, 99, 1381); they observed the frequent entry of polymorphic phenomena into the diagrams of thermal equilibrium. Also Orton and Reed state (T., 1907, 91, 1546), referring to trihalogenated isomeric anilines and anilides, that "the melting-point curves of such mixtures are nearly but not quite straight lines."

The results for systems (a), (b), and (c) show that the freezing points lie on continuous curves that are concave to the concentration axis and are without maxima or minima (Fig. 1); they indicate that in each case a continuous series of mixed crystals is formed and that the components are isomorphous. These four substances crystallise in large rhombs, which appears to be the stable form; an unstable form that is needle-shaped separates initially on crystallisation and changes on standing to the rhombic form. This polymorphism of anilide crystals has been investigated by determinations of the solubility curves by Chattaway and Lambert (T., 1915, 107, 1773) and by Chattaway and Clemo (T., 1916, 109, 89).

Mixed-crystal curves similar to the above have not been observed for anilides, save as mentioned above, but have been recorded for

pairs of isomorphous benzene derivatives such as *p*-dichloro- and *p*-dibromo-benzene by Küster (*Z. physikal. Chem.*, 1904, 50, 65). It was found that the freezing-point curve was without maximum and minimum, continuous, and concave to the concentration axis. Terwogt also found (*Z. anorg. Chem.*, 1905, 47, 203) that the freezing-point curves for the system iodine-iodine monobromide-bromine were of a similar form. Many examples have been recorded among alloys.

FIG. 1.

- I. Freezing-point curve for the system
aceto-2 : 4-dibromoanilide and aceto-2-chloro-4-bromoanilide.
II. Freezing-point curve for the system
aceto-4-chloro-2-bromoanilide and aceto-2-chloro-4-bromoanilide.

Somewhat different mixed-crystal curves have been observed for other binary systems in which the components differ only by the replacement of one halogen atom by another, for example, chloro- and bromo-cinnamaldehydes (Küster, *Z. physikal. Chem.*, 1891, 8, 589).

The freezing-point curve of aceto-2 : 4-dichloroanilide and aceto-4-chloroanilide is of the regular eutectic type, with a eutectic point at 127.6°, where the molar concentration of aceto-4-chloroanilide is 38.1 per cent. The times of eutectic arrests have not yet been fully studied, but trial experiments indicated the probable absence of any appreciable amount of solid solution. When mixtures of this pair were first melted and then frozen in a capillary tube, a

material was obtained on very slow cooling which had a freezing point about 10° below the normal value. The phenomenon could not be reproduced when larger amounts of material were used in a wide tube. It was due probably to the separation of the aceto-4-chloroanilide in a monotropic modification. For aceto-4-bromoanilide, Remmers (*Ber.*, 1874, 7, 348) recognised a second crystalline form, which was goniometrically measured by Mugge (*Z. Kryst. Min.*, 1880, 4, 332) and examined by Chattaway and Lambert (*loc. cit.*). The same phenomenon in the capillary melting point tube had been noticed previously with mixtures of aceto-4-chloroanilide and aceto-2-chloroanilide by Orton and Jones (*loc. cit.*; compare the three monotropic monochloroacetic acids of Pickering, T., 1895, 67, 1895, and the *o*- and *p*-chlorobenzanilides of Orton and King, T., 1911, 99, 1381).

Preparation of Materials.—Aceto-2-chloro-4-bromoanilide was prepared by chlorinating aceto-4-bromoanilide with chloramine-T and hydrochloric acid (compare Orton and King, T., 1911, 99, 1377). The preparation of aceto-2:4-dibromoanilide and aceto-4-chloro-2-bromoanilide is a matter of some difficulty. Chattaway's method was used (T., 1916, 109, 92), but bromination at 30° in 70 per cent. acetic acid with bromine in 100 per cent. excess and an equivalent amount of sodium acetate gives as good results in a shorter time; bromination at 70° is more advantageous, only fifteen minutes' heating being necessary.

Each material was recrystallised at least three times from alcohol and always finally from acetic acid. Before use, they were powdered and heated to a temperature just below their melting points to eliminate traces of occluded solvent. Each mixture was made up by very thorough grinding of the weighed components, practically the whole amount of each mixture was used for the determination, a milligram or so being kept for the seeding, so that no appreciable error due to incomplete mixing occurred.

Apparatus.—This was of the general Beckmann form. The mixture under examination was contained in a thin-walled test-tube (14 cm. \times 1 cm.), bearing the thermometer and the thin glass hand-stirrer, which was enclosed in an air jacket immersed in sulphuric acid in a boiling tube 4.5 cm. in diameter and of sufficient length to ensure the whole of the thread being below the level of the acid, so as to avoid stem correction. Heat was supplied by a micro-burner, regulated by a screw clip, at the base of a long, cylindrical hood. The bath liquid was stirred by a steady stream of dried air from a water-blower. The whole apparatus was carefully screened from air currents. Anschütz thermometers graduated in $1/5^{\circ}$ were used; by employing a reading-microscope, $1/20^{\circ}$ was easily estimated.

Observation of Freezing Points.—Following Kremann (*Monatsh.*,

1904, 25, 1230), the mean of the freezing points determined by heating the solid and by cooling the liquid was taken as the true freezing point of the mixture; errors due to superheating and supercooling thus tended to balance each other. It is important that the tube containing the mixture be placed in the bath when the temperature is but a few degrees below the freezing point of the mixture (compare McKie, T., 1918, 113, 799).

As a preliminary, the mixture was fused to ensure complete mixing; at the same time an approximate value of the freezing point was obtained. The freezing point was then observed during slow cooling, the mixture being seeded at frequent intervals and very thoroughly stirred. At about 0.2° to 0.4° below the freezing point a shower of crystals appeared and the freezing point was very sharply indicated. The temperature was then raised and the "freezing point" (that is, the temperature at which the last crystals disappeared) found by heating the mixture. The rate of heating was such that about ten minutes elapsed while the temperature was being raised from a degree below the freezing point to the freezing point (using 1—1.5 grams of material). These observations were repeated and finally a heating curve and a cooling curve were constructed.

Freezing Points of the Anilides used.—Aceto-4-chloroanilide; 172.5° (Kurbatow, *Annalen*, 1874, 182, 98); 173 — 175° (Collet, *Bull. Soc. chim.*, 1899, [iii], 21, 69); 175° (Hentschel, *Ber.*, 1897, 30, 2645); 179° (Orton and Jones, *loc. cit.*). The value found in this work was 179.0° .

Aceto-2 : 4-dichloroanilide : 143° (Lehmann, *Jahresbericht.*, 1882, 363). The value found in this work was 144.1° .

Aceto-2-chloro-4-bromoanilide : 151° (Chattaway and Orton, *Ber.*, 1900, 33, 2398). The value found was 151.4° .

Aceto-4-chloro-2-bromoanilide : 137° (Chattaway and Orton, *loc. cit.*). The value found was 134.6° .

Aceto-2 : 4-dibromoanilide : 146° (Remmers, *Ber.*, 1874, 7, 348); Chattaway and Orton, *Ber.*, 1899, 32, 3578). The value found was 144.7° . In the case of the last two substances, five recrystallisations from various solvents did not change the values. These freezing points have lately been confirmed independently in this laboratory.

Results.—The following table, which gives the freezing points for two mixtures of aceto-2 : 4-dichloroanilide and aceto-2-chloro-4-bromoanilide, exemplifies the readings obtained in an experiment.

Molar percentage of acetodichloroanilide.	F. p. ₁ .		F. p. ₂ .		Mean value.
87.34	144.7°	144.75°	144.05°	144.05°	144.3 (8)°
	144.65°	144.7°			
58.56	146.1°	146.05°	145.55°	145.55°	145.8 (3)°
	146.1°				

The column F.P.₁ gives the freezing points as determined by observing the fusion and the heating curve: the column F.P.₂ gives the freezing points as determined by observing the solidification and the cooling curve.

The following were the mean values obtained for the various mixtures:

System (a). x = molar percentage of acetodichloroanilide.							
x	5.90	11.94	23.27	28.94	33.70	39.62	44.37
F. p.	150.75°	150.05°	148.85°	148.35°	147.7°	147.3°	146.8°
x	49.83	54.78	58.56	64.69	69.22	73.96	77.90
F. p.	146.4°	146.05°	145.8°	145.4°	145.1°	145.0°	144.75°
x	82.38	87.34	91.66	94.50	95.79	96.60	99.20
F. p.	144.5°	144.35°	144.35°	144.25°	144.3°	144.2°	144.15°

A few of the last mixtures in this system were made up, not in the usual way, but by direct weighing in the apparatus; this method was inconvenient, but was unavoidable in those cases as the weights of one component were very small.

System (b). x = molar percentage of acetodibromoanilide.							
x	9.16	17.61	22.09	26.72	30.14	35.81	41.85
F. p.	150.4°	149.75°	149.1°	148.7°	148.25°	147.65°	147.25°
x	45.87	52.01	55.94	61.22	66.35	71.47	77.07
F. p.	146.85°	146.35°	146.09°	145.73°	145.43°	145.22°	145.0°
x	82.08	87.28	93.30				
F. p.	144.85°	144.75°	144.60°				

System (c). x = molar percentage of aceto-4-chloro-2-bromoanilide.							
x	15.37	24.17	31.73	39.23	44.08	49.90	54.20
F. p.	148.3°	146.3°	144.85°	143.35°	142.25°	141.25°	140.25°
x	63.81	69.77	74.52	80.69	84.96	89.94	92.13
F. p.	138.75°	137.85°	137.05°	136.45°	135.93°	135.45°	135.15°

System (d). x = molar percentage of aceto-4-chloroanilide.							
x	95.68	91.54	90.75	82.42	78.42	73.26	68.12
F. p.	176.1°	173.7°	173.3°	167.7°	165.5°	162.2°	156.9°
x	64.07	59.46	55.60	49.88	44.43	36.53	39.31
F. p.	153.8°	149.6°	146.3°	140.5°	136.0°	129.1°	129.1°
x	33.82	28.56	22.70	11.17			
F. p.	130.1°	132.4°	135.3°	140.1°			

The curves for the systems (b), (c), and (d) are shown in Figs. 1 and 2. The freezing-point curve for the system (a), for which the readings are given in the above table, has been omitted, as it is very similar to the freezing-point curve for the system (b).

The form of the cooling curves for the mixed-crystal systems indicates that the *solidus* is very close to the *liquidus*; this thermal method, however, lacks the necessary delicacy to fix the position

of the *solidus* curves for the mixed-crystal systems under consideration.

FIG. 2.

Freezing-point curve for the system
aceto-2:4-dichloroanilide and aceto-4-chloroanilide.

Summary.

(1) The freezing-point curves for the binary mixtures (a) aceto-2:4-dichloroanilide and aceto-2-chloro-4-bromoanilide, (b) aceto-2:4-dibromoanilide and aceto-2-chloro-4-bromoanilide, and (c) aceto-4-chloro-2-bromoanilide and aceto-2-chloro-4-bromoanilide show that a continuous series of mixed crystals is formed by each pair.

(2) The freezing-point curve for the binary system aceto-2:4-dichloroanilide and aceto-4-chloroanilide has a eutectic point at a concentration of 38.1 per cent. of aceto-4-chloroanilide and a temperature of 127.6°, and gives no indication of the formation of mixed crystals.

The investigation of the binary systems of isomeric and similarly orientated aromatic derivatives is being pursued.

I wish to express my thanks to Prof. K. J. P. Orton, F.R.S., for suggesting this work and for his kind advice and criticism.

I wish also to express my indebtedness to the Department of Scientific and Industrial Research and to the University of Wales for grants which have enabled me to carry out this work.

UNIVERSITY COLLEGE OF NORTH WALES,
BANGOR.

[Received, October 8th, 1923.]

Van Der Waals Memorial Lecture.

DELIVERED ON NOVEMBER 8TH, 1923.

By DR. JAMES HOPWOOD JEANS, Sec. R.S.

JOHANNES DIDERIK VAN DER WAALS, whose services to science we commemorate this evening, was born at Leyden on November 23rd, 1837. The circumstances of his youth were such that he was unable to take advantage of the educational opportunities offered by the University of his native town until he was more than thirty years of age. Not before the age of thirty-five did he write the thesis which gained him his doctor's degree. It rarely happens that the first dissertation of even the most brilliant young man of science makes much of a mark in the scientific world. There is perhaps only one instance of its making so great a mark that its title has become one of the commonplace phrases of scientific language—I mean the dissertation of Van der Waals "On the Continuity of the Liquid and Gaseous States."

This dissertation, first published in 1873, opened a chapter in the history of science which is not yet closed. The underlying ideas have proved so fruitful that they not only provided work for Van der Waals himself during the forty years of his active scientific life, but are even to-day providing work for a very large proportion of the Dutch school of physical chemistry. Even if he had published nothing else in his whole life, this dissertation would have secured for Van der Waals a noteworthy place among the founders of the Kinetic Theory of Matter.

Four years after the attainment of his doctor's degree, Van der Waals was appointed Professor in the University of Amsterdam, the town which henceforth was to be his home until his death on March 8th of the present year. Here he taught successfully and began to exert his great influence on the development of Dutch physics: a large part of the Dutch physics of to-day, if tracked down to its ultimate source of inspiration, will lead us back to the class-room of Van der Waals at Amsterdam. More than this, the distinctive quality of modern Dutch physics—and it has a very distinctive quality of its own—is precisely the quality imparted by the early work of Van der Waals.

In due course he became closely associated with the Amsterdam Royal Academy of Sciences, acting as General Secretary from 1896 until 1912, when both his bodily and mental powers began to fail. His influence here was enormous; in the words of one who knew him well, Prof. Kamerlingh Onnes: "For twenty-four years

he was the soul of the Board. Here as everywhere else he showed a never-failing unselfishness and a high conception of duty. We owe to him the modern form of the Proceedings and their English translation which he directed, both with an incomparable energy. The great efforts he bestowed on these periodicals have been well rewarded by the effect their stimulating influence had on Dutch science."

Van der Waals tells us that his choice of a subject for his doctor's dissertation arose out of his interest in a certain quantity which appears in Laplace's theory of capillarity, namely, "the molecular pressure exerted by a liquid bounded by a plane surface on the unit of this surface," or, as we should say to-day, the "internal pressure" in a liquid. He explains that as it appeared to him impossible to determine this pressure by direct experiment, he tried to deduce it from theoretical considerations, an attempt which led to his establishing the connexion between the gaseous and liquid states.

The first problem which confronted him was that of the nature of the forces between molecules. Speculation as to the nature of the molecules themselves, or rather of the ultimate indivisible units of matter, goes back into the mists of antiquity, but speculation as to the forces between these units scarcely goes further back than Newton. Newton seems to have thought that the expansive property of a gas could perhaps be explained in terms of repulsive forces between the various molecules, but showed that Boyle's law could only be satisfied if the particles repelled one another with a force which varied inversely as the distance. In Proposition 23 of the second book of the "Principia" he proves that "If a fluid be composed of particles mutually flying each other, and the density be as the compression, the centrifugal forces of the particles will be reciprocally proportional to the distances of their centres." He adds "But whether elastic fluids do really consist of particles so repelling each other is a physical question. We have here demonstrated mathematically the property of fluids consisting of particles of this kind, that hence philosophers may take occasion to discuss that question."

The birth of the Kinetic Theory of Gases led to an eclipse of speculations of this kind, but in any case, as Maxwell pointed out, the law of forces varying as the inverse distance is quite an impossible one; under this law the forces from the distant parts of a mass would preponderate over those from the contiguous parts and the pressure of a gas, for given density and temperature, would not be the same as we passed from one vessel to another, or even as we passed from one part to another of the same vessel.

Thus we have a logical chain of proof that the expansive property of gases cannot be attributed to repulsions between its molecules.

In discussing the forces between molecules, Van der Waals takes his stand on the experimental evidence of the Joule-Thomson effect. If we open the tap of a cylinder of compressed gas, we know that the issuing gas is intensely cold. The usual explanation assigns the cooling to the work done by the emergent gas in driving back the surrounding air against its own pressure. This, however, is not quite the whole story. When Joule and Kelvin replaced the tap by a porous plug and allowed the gas very slowly to leak out into a vacuum, they still found a small cooling—only a fraction of a degree for most gases, although rather more for carbon dioxide. If the molecules of a gas repelled one another as imagined by Newton, each molecule as it passed through the pores of the plug would be accelerated by the repulsions of the molecules behind it, so that the emergent gas would have a higher molecular velocity than the gas in the cylinder, and so would show a heating. The fact that it actually shows cooling disposes of the hypothesis of forces of repulsion and indicates the existence of forces of attraction. On this evidence, Van der Waals concludes that particles of matter "must always show attraction," and it is necessary to search for the reason why "particles of matter attracting one another and only separated by empty space do not fall together." This reason, he says, is to be found "in the motion of the molecules themselves, which must be of such a nature that it opposes a diminution of volume, and causes a gas to act as if there were repulsive forces between its particles."

These are, of course, the ordinary conceptions of the kinetic theory of gases. Maxwell and others had already obtained a proof, in terms of these conceptions, of the equation

$$pv = \alpha T \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

in which v is the volume of a gas at pressure p and absolute temperature T , and α is a particular constant for a particular mass of gas. Their proof is based upon a study of the molecular motions in a gas, but by the time the final equation is reached, practically all trace of the assumed molecular structure has disappeared, so that it is immaterial whether the molecules are massive or light, round or square, large or small, although it is essential that, when packed as closely together as they will go, they should occupy only an infinitesimal volume in comparison with the volume v of the gas. The gas-constant α depends on the number of molecules present, but is totally independent of the mass of a single molecule. Van der Waals requires for his purpose a more refined

picture of the molecular motion, and so endows his molecules with two distinct additional physical properties. In the first place, he supposes them to be all similar spheres, each of diameter σ , so that the total volume b_1 occupied by all the N molecules in the gas is given by $b_1 = \frac{1}{2}N\pi\sigma^3$. When b_1 is not assumed to be infinitesimal in comparison with v , it is found that the former equation (1) must be replaced by

$$p(v - 4b_1) = \alpha T \quad . \quad . \quad . \quad (2)$$

so that the volume corresponding to a given temperature and pressure is now greater by $4b_1$ than that given by the former equation.

The numerical multiplier 4 occurs as a consequence of Van der Waals having assumed his molecules to be spherical; had he assumed some other shape, a different multiplier would have appeared in his equation.

Next, in accordance with his principle that "matter must always show attraction," he assumes every molecule to exert an attractive force on every other molecule within a certain range. The forces on a molecule in the interior of the gas act indiscriminately in all directions, so that their resultant is negligible, but the forces on a molecule in the surface all have a component directed towards the interior. Thus the outermost layer of gas is attracted to the main mass with a force which must, of course, vary as the square of the density, or, what is the same thing, inversely as the square of the volume. When allowance is made for this force, the equation becomes

$$\left(p + \frac{a}{v^2}\right)(v - 4b_1) = \alpha T \quad . \quad . \quad . \quad (3)$$

an equation which is known all the world over as "Van der Waals's equation."

The replacement of v by $v - 4b_1$, leading to equation (2), resulted merely in a gas at a given temperature and pressure occupying a volume greater by $4b_1$ than that predicted by the simple equation (1). But the replacement of p by $p + a/v^2$ results in a much more fundamental change; when we attempt to calculate from equation (3) the volume corresponding to a given temperature and pressure, we find ourselves confronted by a cubic equation. Since a cubic equation may have either one or three real roots, it appears that a mass of matter at given temperature and pressure may exist in either one or three possible states. In the former case, the possible state is the gaseous one; when three states are possible, the state of highest volume is found to be the gaseous state, the state of intermediate volume is readily seen to be

mechanically unstable, and so cannot be observed experimentally, whilst the state of least volume is identified by Van der Waals with the liquid state. We need not pause to recapitulate the justification for this identification: it will suffice to say that it has never been challenged.

Van der Waals explains that his equation "cannot be pushed to the extreme limit of condensation of matter." For instance, corresponding to volumes v less than $4b_1$, which are of course perfectly possible physically, the equation predicts that either p or T must be negative. At very low temperatures, the equation predicts that p must be negative even at volumes greater than $4b_1$. Indeed, it is easy to see, from the way in which it is derived, that the equation can only be strictly true for gaseous states in which the departure of the gas from the "ideal" condition of infinite rarity is slight. In other words, the replacement of v by $v - 4b_1$, and of p by $p + a/v^2$, is only strictly accurate when the effect of each of these replacements is small. This consideration at once disposes of all hope of the equation giving an exact picture of the behaviour of a substance in the liquid state—indeed, for practically all liquids $v - 4b_1$ is negative, and the equation if strictly interpreted leads to an absurdity right away.

Thus although the equation is based on sound physical conceptions, it is mathematically incomplete, and there is a certain element of luck in its predicting the liquid state at all. Nevertheless, as the luck has been found to hold as regards qualitative predictions in the liquid state, there is at least a reasonable hope that it may to some extent hold as regards quantitative predictions as well.

Van der Waals seems to have realised quite clearly these limitations to the permissible use of his equation. Consequently it was only "with apprehension" that he strained his equation by attempting to calculate the values of the critical constants of carbon dioxide from the values of a and $4b_1$ yielded by a study of the departures of the behaviour of carbon dioxide from Boyle's law in states not far removed from the "ideal" state. That the attempt was remarkably successful is a matter of past history; instead of recapitulating past history here, let us rather re-examine the problem in the light of more modern experimental knowledge.

It is obvious on general grounds that as a gas passes from a state of rarity to one of high compression the product pv must increase, on the whole, above the value predicted for it by the simple law of Boyle. To take only one, and that the most obvious, illustration, a gas heated to above its critical temperature can support an infinite pressure without its volume becoming zero, so that the product pv becomes infinite at very high pressures,

in place of remaining finite as predicted by Boyle's law. The equation of Van der Waals predicts that pv will increase in this way and, if strained in the way already explained, it further predicts the precise increase to be expected in pv over that predicted by Boyle's law.

At the critical point in particular, Van der Waals's equation predicts that pv will be $2\frac{1}{2}$ times as great as the value given by the simple law of Boyle. This factor of increase is the same for all gases: it might at first have been thought that the factor would vary from one gas to another, depending on the values of a and b_1 , but the critical point also varies from one gas to another, and the two variations just cut one another out—indeed, a moment's reflection shows that they necessarily must, for the predicted ratio of increase, 2.67, being a pure number cannot depend on b_1 , which is a volume, or on a , which is of the physical dimensions of a pressure multiplied by the square of a volume.

Van der Waals had noticed that the ratio of increase for carbon dioxide was substantially greater than his predicted value 2.67, and the same proves to be true for all gases. The following table gives some trustworthy values for this ratio:

Gas.	Ratio of increase.	Authority.
Oxygen	3.419	Kamerlingh Onnes, Dorsman, and Holst.
Nitrogen	3.421	
Argon	3.424	
Xenon	3.605	Patterson, Cripps, and Whytlaw-Gray.
Carbon dioxide	3.61	Berthelot, S. Young.
Methane	3.67	Berthelot.
Carbon tetrachloride	3.68	S. Young.
Benzene	3.71	"
Stannic chloride	3.75	"
Bromobenzene	3.78	"
Chlorobenzene	3.81	"

Prof. Young some years ago expressed the conviction that the ratio would prove to be about 3.7 for all substances that attained the critical point without chemical change, and this prediction appears to be fairly well fulfilled. But the prediction is far removed from that of Van der Waals's equation—for not a single gas is the ratio in the neighbourhood of 2.67.

The fault does not lie so much with Van der Waals's equation as with the illegitimate use which has been made of it. When Van der Waals wrote a/v^2 for the cohesive force between the main gas and its outermost layer, he assumed the density in this outermost layer to be the same as in the main gas, an assumption which obviously fails when the cohesive force is comparable with the whole pressure of the gas, as it is by the time the critical point

is reached. It is, however, easy to allow mathematically for the effect of this diminished density on the efficacy of the cohesive force. We find that instead of replacing p in Boyle's law by $p + a/v^2$ (the procedure of Van der Waals), we must replace it by $pe^{\frac{a}{\alpha T v}}$, and so obtain the "equation of state" in the form

$$pe^{\frac{a}{\alpha T v}}(v - 4b_1) = \alpha T,$$

as suggested by Dieterici in 1898.

This equation, as can easily be shown, coincides precisely with that of Van der Waals throughout the range of small compression, but as we reach substantial compressions the equations diverge, so that finally, at the critical point, Dieterici's equation predicts for the ratio of increase of pv the value $\frac{1}{2}e^2$ or 3.695, a value which agrees extraordinarily well with what is observed. To make the matter quite clear, let me repeat that Dieterici's equation is based on precisely the same physical conceptions as that of Van der Waals, but is a mathematically more perfect expression of these conceptions—it is Van der Waals's equation generalised mathematically so as to apply to regions of substantial compression.

It should be added that although Dieterici's equation is strikingly successful in predicting the ratio of increase of pv at the critical point, it is somewhat less successful in predicting the actual values of the critical pressure, volume, and temperature separately. The following table of observed critical volumes will exemplify this:

Gas.	Critical volume v_c .	$v_c/4b_1$.
Hydrogen	0.00269	2.80
Air	0.00392	1.89
Carbon dioxide	0.00424	1.86
Argon	0.00328	1.41

Dieterici's equation predicts that the quantity $v_c/4b_1$, tabulated in the last column, should be equal to 2 for all gases; on the other hand, Van der Waals's equation requires that the quantity should have the uniform value 3 for all gases, a prediction which is still further from the truth.

The discovery of his equation of state opened one great chapter in the scientific life of Van der Waals; a second was opened seven years later with the discovery of the "law of corresponding states." The equation of state of Van der Waals, as we have seen, involves two constant quantities, namely b_1 , which depends on the size of the molecules, and a , which depends on the intensity of their cohesive forces, in addition to the "gas-constant" α , which depends merely on their number. The significance of such an equation is best exhibited by drawing the isothermal curves which

it predicts on a diagram on which p and v the pressure and volume are taken as rectangular axes. Such a drawing is shown in Fig. 1.

A drawing of this kind is made by computations from the equation which it represents, and we cannot compute values from Van der Waals's equation until we know the values of a and b_1 for the particular gas concerned. But if we draw a whole series of diagrams of this kind corresponding to different values of a and b_1 , we shall find that they are all precisely similar except for differences

FIG. 1.

in horizontal and vertical scales. This is not a consequence of any special mystic quality inherent in Van der Waals's equation; it is a necessary property of any equation whatever, which, like Van der Waals's equation, contains two and only two independent constants in addition to the gas-constant α —for instance, it is equally true of Dieterici's equation.

Thus the consequence of Van der Waals having endowed his molecules with two, and only two, distinct physical properties (apart from their mass), represented by his constants a and b_1 , is that the isothermals for all gases are the same except only for

differences in horizontal and vertical scale. And even this difference disappears if we draw our diagram, not in terms of the absolute units of a cubic centimetre of volume, a dyne of pressure, and a degree of temperature, but in terms of the special units of the critical volume, critical temperature, and critical temperature of the particular gas under consideration. When these latter units are used, the isothermals are the same for all gases. This is in effect the "law of corresponding states," although it is usually expressed in a different form. It is not a chemical or a physical law, but a mathematical law, or rather it expresses a mathematical consequence of the assumption that the gas-molecules of different gases differ apart from their mass in only two respects, namely, their size and their cohesive powers.

Thus the extent to which the law of corresponding states is true provides a test of the degree of truth of Van der Waals's fundamental assumption that molecules differ in only these two respects from one another. Every chemist and every physicist knows that the law of corresponding states is somewhere near to being true, but everyone who has worked specially at the subject knows further that it is not very near. We have had evidence already this evening of its imperfections. If the law had been strictly true, the value of $v_c/4b_1$ tabulated in the last column of Table II would be precisely the same for all gases: in actual fact this value is just about twice as great for hydrogen as for argon. Thus the molecules of hydrogen and argon are not built on the same model except for differences in mass, size, and cohesive power. We know enough about the molecules of hydrogen and of argon to have made this statement on quite other grounds than the failure of the law of corresponding states: we know that the molecules differ in at least one further respect—they differ in atomicity and so, presumably, in shape.

We have seen that if a molecule could be specified by two constants in addition to its mass, the equation of state would contain two constants in addition to the gas-constant and the law of corresponding states would be strictly true. The imperfection of the two-constant specification is not only shown directly by the partial failure of the law of corresponding states, but is further shown indirectly by the number of three-, four-, and even five-constant formulæ which have been introduced in the search for accurate equations of state. We shall return to some of these in a moment; for the present let us leave this aspect of the problem with the remark that in Van der Waals's original equation the two constants had quite definite physical meanings, and were suggested by definite physical properties of the molecule; the same is not true,

so far as I am aware, of any of the more complex equations of state which have been suggested. For this reason Van der Waals's equation must be regarded as possessing a permanency such as cannot be achieved by any of the more elaborate equations of state at present in existence.

Let us now try to probe a bit more deeply into the physical meaning of the "size" and "cohesive force" of gases. Van der Waals supposes that the cohesive force is necessarily positive: "particles of matter must always show attraction." If so, where does this universal cohesive force originate? It cannot originate in gravitational attraction; a simple calculation shows that this is far too small to enter into the question at all. If particles of matter always show attraction, it is clearly to the electrical structure of matter that we must look for an explanation of this attraction. Now a molecule of gas is an electrically neutral structure: the aggregate of its positive charges is exactly equal to that of its negative charges. If two molecules had each of them an excess of negative charge, they would of course repel one another; if each had an excess of positive charge, they would still repel; if they are each electrically neutral, the resultant force is, at any rate at the first glance, as likely to be positive as negative. There is so far no indication of the supposed necessity for all particles to attract.

The arrangement of the electric charges in all molecules is of a somewhat special type, for a molecule is made up of atoms, and in every atom, so far as we know, the positive charges are crowded together at the centre whilst the negative charges circulate in the outer regions. Is the preponderant attraction in some way a consequence of this special type of arrangement? No, for a quite general mathematical theorem, generally known as Gauss's Theorem, shows that the *average* force emanating from a whole molecule, or other electrically neutral structure, is zero. The average is best taken by averaging the radial force over any sphere we please which completely encloses the molecule, but it is equally permissible to average the normal force over any other surface provided only that it completely encloses the molecule. In whatever way the average is taken, the theorem makes it clear that there can be no preponderance of attraction over repulsion. Thus when two molecules are placed in juxtaposition, their orientation being selected at random, they are just as likely to repel as to attract. The argument, as we have so far sketched it out, is, it is true, concerned only with electrostatic forces, but it is readily seen that the electromagnetic forces also are as likely to be repulsive as attractive.

To get the true explanation of the preponderance of attractive forces, we have to descend into the depths of statistical mechanics. An exact solution to the problem of molecular motions shows that there will, in actual fact, be a real preponderance of attractive forces. The reason, which is found to depend only on general mechanical principles, is briefly (and somewhat incompletely) as follows. Imagine that in a certain brief interval, one thousand molecules flying about through the gas, pass so near to one thousand other molecules that the forces between them become appreciable—in the terminology of the Kinetic Theory of Gases, a thousand "encounters" take place. At the beginning of each encounter, the orientation may be supposed arranged at random, so that the intermolecular forces are as likely to be repulsive as attractive. Thus we may suppose that in five hundred encounters, the force is initially repulsive whilst in the other five hundred it is initially attractive. But the difference between the two types of encounter is not limited to a mere difference of sign. In a repulsive encounter, the molecules speedily drive one another away; the repulsive forces lessen the duration of the encounter. In an attractive encounter the reverse is the case, so that on the average an attractive encounter lasts longer than a repulsive one. Hence at any given instant of time there will be more attractive encounters than repulsive encounters in being—the "birth-rate" of the two types of encounters is the same, but the "expectation of life" for the attractive encounter is much the greater. Thus at any given instant of time the force exerted by a gas on its outermost layer is one of attraction, as supposed by Van der Waals; but this attraction is, so to speak, much more of an abstruse mathematical theorem, and much less of an inherent property of matter, than Van der Waals imagined.

In a gas the duration of an encounter is at best very brief, and the net attractive force resulting from inequalities in the durations of these encounters cannot be very great. In liquids, on the other hand, encounters are far more frequent and also more lasting; the repulsive encounters are so soon over that they may perhaps almost be neglected. Thus the net attraction is of an altogether higher order of magnitude than in a gas. The effect, which results only in a slight correction to the gas-pressure in a gas, gives rise to the phenomena of surface tension and capillarity in a liquid. Finally, in a solid, each atom is in a permanent attractive "encounter" with its neighbour, and we have the still more powerful forces of cohesion.

As, increasing the temperature, we pass in succession through the solid, liquid, and gaseous states, we find the duration of

encounters ever lessening, until finally, at infinite temperature, the duration of an encounter is zero. It is true that the number of encounters per unit time is infinite, but the difference between the duration of an attractive and a repulsive encounter may now legitimately be neglected, and we find that the resultant force of attraction vanishes altogether at infinite temperatures.

Thus, to fit in with our present view of its meaning, Van der Waals's a ought to be a function of the temperature. We can go further and say, as the result of a brief calculation, that at high temperatures it ought to vary approximately as the inverse of the absolute temperature T . The range of temperature over which Van der Waals compared his equation with observation was so limited that he was not led to suspect any variation of a with temperature: moreover, such variation would have been entirely inconsistent with his preconceived view as to the origin of a —namely, the attractive force permanently inherent in every molecule for every other molecule. But as soon as Clausius and Sarrau attempted to fit Van der Waals's equation to the extended observations of Amagat on carbon dioxide, the dependence of a on the temperature became manifest, and Clausius was led to suggest the equation

$$\left(p + \frac{a'}{T(v+c)^2}\right)(v - 4b_1) = \alpha T,$$

which, except for the replacement of v by $v + c$ in the denominator in the first term, is identical with Van der Waals's equation in which a is made to vary inversely as the absolute temperature. Although this equation is successful with the isothermals of carbon dioxide, and partly also with those of oxygen, nitrogen, and ethylene, it is far less successful in its application to certain other gases. Thus the equation does not express final truth any more than the earlier equation of Van der Waals.

I ought, perhaps, to add that when Clausius tried still further to improve the equation of state, he found it necessary to replace a , not by a'/T , as in the above equation, but by $a''/T^n - a'''T$. This quantity does not even approximately vary inversely as the temperature—indeed at high temperatures it increases directly as the temperature and is negative. Nevertheless, I think our explanation of the physical significance of a can stand; it seems likely that in the expression I have just written down the term a''/T^n represents the a of Van der Waals, whilst the rebellious term $a'''T$ is not cohesive at all but represents part of his $4b_1$.

To see how this can be, let us replace the $4b_1$ of Van der Waals by $b + b'$, where b and b' are any small quantities, limited only

by the condition that their sum shall be equal to $4b_1$. The original equation of Van der Waals can now be written in the form

$$\left(p + \frac{a}{v^2}\right)(v - b - b') = \alpha T.$$

If, as we are entitled to do, we neglect products of the small quantity b' by the other small quantities a and b , this equation transforms by simple algebra into

$$\left(p + \frac{a - b'\alpha T}{v^2}\right)(v - b) = \alpha T.$$

The interpretation of Clausius's term— $a'''T$ is now clear; a'' is the same as $b'\alpha T$, and the term in a''' merely represents taking a bit off the $4b_1$ correction and adding it to the a correction. Thus the a''' of Clausius does not originate out of the cohesive force at all, but out of the finite size of the molecules, as is indeed suggested *a priori* by the algebraic sign which it is found necessary to attach to it.

The true cohesive force represented by the term a'/T in the simpler of the two equations of Clausius, and by the term a''/T in his more complex equation, still falls off at some *inverse* power of the temperatures. At very high temperatures, the cohesive force disappears altogether, the reason being, as we have already seen, that in each molecular encounter the force is just as likely to be repulsive as attractive. At very low temperatures, on the other hand, the cohesive force increases almost beyond measure, the reason being that molecular encounters of repulsive type are exceedingly transitory, whilst those of attractive type last very long by comparison. At low temperatures and low volumes, the term a/v^2 may easily become very large in comparison with p —the liquid state. If we neglect p entirely, Van der Waals's equation gives

$$v = 4b_1 + \frac{\alpha v^3}{a} T,$$

an equation which gives a qualitative explanation of the heat-expansion of a liquid. The actual value predicted for the coefficient of expansion is, of course, not accurate: we have no right to strain Van der Waals's equation by using it in these regions at all. But we may notice that our equation attributes the temperature expansion to the heat-motions of the molecules as represented by the factor αT , and there is no reason to doubt that in the main this is the true cause.

Van der Waals supposed his second constant b_1 to originate in

the finite size of the molecules. That this is substantially the true explanation cannot be doubted; we can determine the size of gaseous molecules in a variety of ways, and they all, including the determination from the observed value of b_1 , lead to the same result. For instance, the size of a hydrogen molecule, assumed for simplicity to be spherical, can be determined independently from the three phenomena of viscosity, conduction of heat, and diffusion—the radius of the supposed sphere comes out, by each of the three methods, to be 0.68×10^{-8} cm. The value calculated from the observed value of b_1 is 0.64×10^{-8} cm. It is inevitable that this latter value should differ somewhat from that deduced from the three other methods, for the assumption that the hydrogen molecule may be treated as spherical is bound to introduce some error. But the agreement is sufficiently close to show that the quantity measured by b_1 is in effect the size of the molecule, and if we take the mean of the two quantities just mentioned, namely 0.66×10^{-8} to represent the radius of the hydrogen molecule, we find that the size of the hydrogen atom must be that of a sphere of radius $1/\sqrt{2}$ times this, or 0.53×10^{-8} cm. But what precisely is the “size” which is found in this way?

When we speak of the size of, say, a billiard-ball, we speak of a volume which is clearly marked out in space, and which, moreover, cannot be changed to any great extent by any agencies which are likely to be applied to it. But when we speak of the size of a hydrogen atom there is no such definiteness of meaning. A normal hydrogen atom consists of two electric charges each of infinitesimal size at a distance apart equal to 0.53×10^{-8} cm. These two charges can scarcely be said to occupy a volume at all; they rather occupy a finite piece of a line, or perhaps, if we take into account that one is describing an orbit about the other, a flat disk. Yet a study of hydrogen in the solid state shows that each atom occupies a volume somewhat larger than that of a sphere of radius 0.53×10^{-8} cm., and the value just calculated for the observed size of the hydrogen atom in a gas shows that each atom of hydrogen reserves for itself a volume just about equal to that of a sphere of radius 0.53×10^{-8} cm. In each case, the space is as definitely reserved against the encroachment of other atoms or molecules as though it were occupied by matter of almost infinite hardness, although, as is shown by experiments on the scattering of α - and β -particles, free electrons can pass clear through this space as though it were entirely free from matter.

The extreme “hardness” of the atom or molecule—in spite of its wholly invertebrate structure—receives a ready explanation from the quantum theory. We know from the researches of Bohr

that an infinite number of orbits are theoretically possible for the electron of the hydrogen atom, but that, except in the intense bombardment of the electric arc or in the high temperatures of stellar atmospheres, all atoms are in actual fact in the state in which the electrons describe the orbits of the smallest radius permissible, or, to put it still more shortly, all atoms are in the state of minimum energy. Thus no conceivable force can cause the hydrogen atom, or any other atom, to shrink to dimensions below those of its normal state. When a body yields readily to the application of force we describe it as "soft"; when even a considerable force results only in a slight yielding we call it "hard"; when a body exhibits a total inability to yield at all we can only describe it as "infinitely hard." Clearly the atom must be put in the last of these three categories, so that the quantum theory takes us back to the infinitely hard atoms of Democritus and Lucretius.

On the purely experimental side this infinite hardness is put in evidence by the beautiful experiments of Franck and Hertz. Electrons having velocities up to about 1.3×10^8 cm. a second are projected so as to collide with atoms of mercury vapour and are found to rebound with precisely their initial velocities, just as though the mercury atoms were billiard balls of infinite hardness. It is true that as soon as the velocity of impact exceeds the velocity just mentioned, the incident electrons are found to lose energy on impact; this, as is readily shown from a study of the radiation which is now emitted, does not arise from any imperfection in the hardness of the mercury atoms, but merely from the fact that electrons incident with this velocity yield it up in taking the first step towards breaking up the atom of mercury: to be more precise, they push the outermost electrons into orbits of higher total energy, and so of greater radius, than those that they occupy when the atom is in its normal state. Thus there is experimental as well as theoretical justification for describing an atom as infinitely hard.

The determination of the shape to be assigned to these infinitely hard atoms is a more difficult, and a far more speculative, matter. Apart from considerations of the quantum theory, the hydrogen atom consists merely of two infinitesimal point-charges. The quantum theory justifies us in replacing these, at least in so far as the "normal" state of the hydrogen atom is concerned, by an incompressible line of length 0.53×10^{-8} cm., having the two point-charges at its ends. And, as this line is in rapid rotation about one of its two ends, it is only a slight step onwards to regard the normal hydrogen atom as an incompressible disk of radius

0.53×10^{-8} cm. If we further suppose that this disk, the orbit of the negative electron, is continually changing its orientation in space, we speedily step to the conception of the hydrogen atom reserving for itself, or perhaps clearing for itself, a spherical volume having precisely the required radius of 0.53×10^{-8} cm. I do not think that there is any very direct evidence for the view that the disk-shaped atom clears a spherical space for itself by continual changes of its plane in space, but the view provides us at least with a simple and perfectly possible picture of the mechanism by which a disk of radius 0.53×10^{-8} cm. can keep for itself a sphere of the same radius.

The question is one of more than incidental importance. Some physicists are apt to think that a congeries of Bohr atoms, with their apparently soft, flabby texture, cannot give us the hardness and precision of structure observed in, say, a metal crystal. But this point of view disregards the hardness and precision introduced into the atom by the intangible fetters of the quantum theory. The nature of these fetters we do not in the least understand, but we now recognise that they bind the electrons in an atom down to definite orbits with so much definiteness and precision that no force in creation can cause, say, the electron of the hydrogen atom to describe an orbit of radius less than 0.53×10^{-8} cm.

It is only because of these unrelenting fetters and because of the "infinite hardness" with which these fetters endow it, that the atom has a permanent existence. If the atom were not infinitely hard, the continual hammering of successive molecular encounters would cause the atom to shrink bit by bit into configurations of ever lower and lower energy, until finally the whole structure would dissolve into radiation through the positive and negative charges rushing together and annihilating one another. Nothing but the b_1 of Van der Waals stands between us and rapid annihilation, just as nothing but his a stands between us and immediate disintegration: it is then fortunate that the existence both of a and of b_1 can be established on firm theoretical grounds.

Time does not permit me to discuss the later work of Van der Waals, such as, for instance, his work in connexion with the Phase rule. Even as regards his earlier work, I have elected to fill up my allotted hour in testing the foundations of the structure rather than in exploring the superstructure. My choice has been dictated by the feeling that now above all is the time when the foundations of all physical and chemical theory need to be examined in the light of our recently acquired knowledge of the ultimate structure and mechanism of matter. The importance of adding further to the structure is as nothing compared with the importance of making

sure that the whole structure is not built on sand. If I have helped you realise that the great work of Van der Waals can still be regarded as based on sure foundations, I have, perhaps, done the best service which was within my power to the memory of a great man of science.

NOTES.

An Improved Filter-pump. By KENNETH CLAUDE DEVEREUX HICKMAN.

THE degree of vacuum created by an ordinary venturi water pump may be considered to depend on the following factors :

FIG. 2.

- (1) The velocity of the water at the jets.
- (2) The relative size of the injector and receiver jets, and the amount of expansion in the base of the latter.
- (3) The degree of turbulence between the air and water.
- (4) The retarding effect of the walls of the pump.

In the present design, factor (4) is removed and (2) accurately controlled. The ratio between the capacities of the jets (x) and (y), Fig. 2, showing diagrammatically the ordinary filter-pump, is as $D_v^2 - D_r^2$, requiring great accuracy in manufacture. Care is especially necessary because the jet area given to the water must be greater than that allowed for the less viscous air, this small quantity being determined by the difference of two square numbers.

In the filter-pump shown in Fig. 1, the air is sucked from a central jet (a) the area of which can be determined by inspection or measurement. The water jet is formed by an annulus existing between the constricted walls of the pump and the central air-jet. Providing that the annulus is larger than a certain minimum, it is unimportant how much water is passed, the vacuum efficiency of the pump, with regard both to the suction and to the volume dealt with, remaining the same. Errors in construction can only cause slight extravagance in the water used. The design ensures a maximum turbulence between the air and water, satisfying factor (3) above, and the air being in contact with moving water only, factor (4) is abolished.

The pump may be made to deal with small volumes of air, giving good vacuum, off low water pressures; or a large capacity and medium or good vacuum may be obtained with heavy pressures. In the first case, jet (*a*) should be 1 mm. in external diameter, and the pump constriction at the annulus 3 mm. in internal diameter. In the second instance, (*a*) may be $2\frac{1}{2}$ mm. and the annulus $3\frac{1}{2}$ —4 mm. Other variations will suggest themselves for specific purposes. The pump is especially useful where it is desired to suck water instead of air; a very wide central jet is employed.

According to a modification, a second jet can be arranged to carry water into the centre of (*a*) so that double pumping effect is produced.

The device has been tested repeatedly and found to give rapid and complete evacuation.—IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, SOUTH KENSINGTON. [Received, November 3rd, 1923.]

A Laboratory Water Motor. By KENNETH CLAUDE DEVEREUX
HICKMAN.

SMALL water motors are unsatisfactory because of their excessive speed and tendency to leak. The accompanying sketch shows a simple slow-speed motor affording a good turning moment.

A cylindrical vessel, *A*, is fitted with a wide overflow tube, *BB'*, and a jet, *C*. A central tube, *D*, acts as a bearing for a spindle, *H*, carrying a large vane, *E*, recessed at *F* to clear the jet *C*. When working, water accumulating in *A* is rotated slowly by that issuing from the jet at high velocity, and the vane moves with the water. The system acts as an automatically variable gear, centrifugal force maintaining within *A* a small quantity of water at greater velocity or a larger amount at a lower speed, at will. When it is desired to remove the propeller, *K*, from any vessel, the spindle carrying the vane is lifted without disturbing the body of the motor.

FIG. 1.

It will be seen that, according to this design, the jet rotates a body of water, the water in turn moving the vane. The jet does not play on the vane.—IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, SOUTH KENSINGTON. [Received, October 31st, 1923.]

A Thermostat Refrigerator. By KENNETH CLAUDE DEVEREUX
HICKMAN.

THE mercury- and gas-operated thermostat, whilst satisfactory for ordinary use, becomes unmanageable at room temperature and valueless if it is required to keep the bath colder than the laboratory.

The following simple piece of apparatus has been used to maintain a bath at $15^{\circ} (\pm 0.05^{\circ})$ in summer and winter with only a

minor adjustment for the alternate seasons. By a modification, which, however, slightly impairs the sensitivity, variations due to the passage from summer to winter are automatically compensated.

The apparatus consists essentially of a toluene-mercury expansion bulb, *A, B, C*, working in conjunction with a head, *D*, a water-bath, *H*, and a coil of metal pipe, *N*, immersed in the thermostat. When working with the room temperature lower than the thermostat, the water in *H* being heated by a burner, a slow stream of tap water enters the head *D* at *F*, and normally passes

FIG. 1.

FIG. 2.

away by *E, E''* into *H*, which then overflows via *M* and *L* into the coil *N*, warming the latter.

When the bath reaches the required temperature, mercury rises in *E*, and the water takes the alternative path, *G G''*, whence it conveys heat from *H* through *K* to the sink.

In summer, *H* is packed with ice and the position of the tubes *G'', E''*, is altered to *G', E'*. The path of the water can be traced by reference to the figure. When the thermostat becomes too hot, ice-water overflows through *L, M* to the coil, *N*.

A modified head is shown in Fig. 2. The water entering at *W*

has a choice of three paths via *X*, *Y*, or *Z*. *X* conveys water to a heated bath, *Y* to the sink, and *Z* to an ice-bath, the delivery pipes terminating in ascending order as shown. The water then passes from the hot or cold reservoir into the thermostat coil in the manner previously described.—IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, SOUTH KENSINGTON. [Received, October 31st, 1923.]

Sulphur Dioxide as an Oxidising Agent. By WILLIAM WARDLAW and NORMAN DARBY SYLVESTER.

COMPARISON of the results of a recent investigation (this vol., p. 969) with those obtained in researches on the constitution of sulphur dioxide solutions has led to a new conception of the oxidation process.

According to Schaefer (*Z. anorg. Chem.*, 1918, **104**, 212), only a fraction of the sulphur dioxide dissolved in water is transformed into the true acid; even in 0.002*N*-solution sulphur dioxide hydrate, $\text{SO}_2 \dots \text{OH}_2$, can still be optically detected. Sulphur dioxide dissolves without change of constitution in sulphuric acid of concentration exceeding 10*N*; in 4*N*-acid, it is present principally as the hydrate, whilst in concentration above 4*N*, gradual dehydration takes place with formation of sulphur dioxide molecules in increasing numbers. Large quantities of sulphur dioxide hydrate are present in the low concentrations of sulphuric acid.

The facts that sulphur dioxide is a more active oxidising agent in the higher concentrations of sulphuric acid (Wardlaw and Sylvester, *loc. cit.*), which contain increasing quantities of non-ionised constituents, and that its action is relatively slow lead to the conclusion that possibly the action is not ionic but molecular. The difficulty with which sulphur dioxide reacts at the ordinary temperature shows that in the gaseous state it is not a strong reducing agent. Consideration of its typical reducing actions leaves little doubt that it functions best as a reducing agent in aqueous solution where there is a maximum possibility of ionisation. There are many reactions which reveal gaseous sulphur dioxide as an oxidising agent at comparatively low temperatures. The oxidation of tervalent molybdenum sulphate in 10*N*- and 15*N*-sulphuric acid was found to proceed beyond the quadrivalent stage (Wardlaw and Sylvester, *loc. cit.*). In those experiments sulphur dioxide was present as the dissolved gas (compare Schaefer, *loc. cit.*) and must have reacted as such. However, in lower acid concentration, where both the hydrate $\text{SO}_2 \dots \text{OH}_2$ and the non-ionised acid H_2SO_3 were present, oxidation still took place, and

therefore it seems probable that in addition to molecular sulphur dioxide the other non-ionised constituents may function as oxidising agents.

The formation of a hydrate of sulphur dioxide, if we accept the formula suggested by Rankine and Smith (*Proc. Physical Soc.*, 1922, 35, 33) will occur as follows :

The peroxide group thus produced will, in contact with a suitable reducing agent, give rise to an oxidising reaction. Otherwise it will assume the more stable configurations

A reaction in which sulphur dioxide functions as an oxidising agent can be represented thus :

The initial reduction product of the sulphur dioxide and its hydrate is probably the hypothetical sulphonylic acid, which by further reactions can give rise to hyposulphurous or the thionic acids. When sulphur is precipitated as the result of an oxidation by sulphur dioxide, it may be considered as the end product of a series of unstable intermediate substances.—THE UNIVERSITY, EDGBASTON, BIRMINGHAM. [Received, July 9th, 1923.]

The Reaction between p-Dibromobenzene and Magnesium. By
HERBERT SHEPPARD PINK.

As Grignard reagents of the type $\text{C}_6\text{H}_4(\text{MgX})_2$ could probably be utilised for the production of many interesting compounds, including bridged-ring aromatic hydrocarbons, the action of magnesium on *p*-dibromobenzene has been studied.

When a solution of *p*-dibromobenzene (1 mol.) in anhydrous ether is treated with magnesium (2 atoms), the product is almost wholly magnesium *p*-bromophenyl bromide, $\text{C}_6\text{H}_4\text{Br} \cdot \text{MgBr}$; about one-half of the magnesium cannot be brought into solution.

When the reaction was carried out at room temperature, heat was developed and a viscous, brown oil soon commenced to separate which gradually covered the metal and stopped the reaction after about one-third of the magnesium had disappeared. Vigorous

agitation then caused the reaction to recommence, but even after prolonged shaking more than one-half of the original quantity of magnesium was unchanged. From the product, after treatment with ice and dilute acid, bromobenzene, *p*-bromophenol, *p*-dibromobenzene, and *pp'*-dibromodiphenyl were isolated; thus there was no evidence of the formation of a Grignard reagent of the desired type.

In a similar experiment, carried on for a longer time and with mechanical stirring throughout, very little more than one-half of the magnesium passed into solution and the brown oil was produced as before; the product after treatment with water gave traces of benzene (indicating the formation of a di-Grignard compound), *p*-dibromobenzene, and *p*-bromophenol, but consisted almost entirely of bromobenzene and *pp'*-dibromodiphenyl. The viscous, brown oil is insoluble in ether, but as soon as the ethereal layer is decanted and the oil washed with ether, it becomes very viscous and begins to solidify at the surface. When heated on the water-bath, it gives a considerable quantity of ether and the colourless solid residue, decomposed with ice and dilute acid, yields a very little benzene together with bromobenzene, *pp'*-dibromodiphenyl, and a large proportion of magnesium bromide.

It appears, therefore, that the oil consists principally of magnesium bromide—formed by the action of magnesium *p*-bromophenyl bromide on *p*-dibromobenzene—the Grignard compound $C_6H_4Br \cdot MgBr$ (combined with ether), and *pp'*-dibromodiphenyl.

Attempts to prepare the di-Grignard compound by carrying out the reaction at -10° with vigorous stirring were also unsuccessful, although a larger proportion of magnesium passed into solution and there was no separation of the oil described above; after treatment of the product with ice and dilute acid, bromobenzene and a trace of *p*-bromophenol together with a very little benzene were obtained, but the product was practically free from *p*-dibromobenzene and *pp'*-dibromodiphenyl.

In boiling ethereal solution the results were substantially the same as those obtained at room temperature; the brown oil was again produced and after treatment with water only traces of benzene were obtained. The principal organic product was *pp'*-dibromodiphenyl.

From these results it may be concluded that at low temperature the formation of magnesium *p*-bromophenyl bromide is practically quantitative, but that at a higher temperature this compound reacts with unchanged *p*-dibromobenzene to give *pp'*-dibromodiphenyl. An attempt was therefore made to obtain the desired product by first treating *p*-dibromobenzene (1 mol.) with magnesium

(1 atom) at -17° , and when all the metal had disappeared, adding more magnesium to the boiling solution of magnesium *p*-bromophenyl bromide. Very little magnesium, however, was dissolved, and when decomposed with water the product contained only a very small proportion of benzene. In another experiment, the ether from the prepared solution of magnesium *p*-bromophenyl bromide was evaporated, pure benzene added, and the mixture boiled with some fresh magnesium and a few drops of dimethyl aniline; there was, however, no appreciable diminution in the quantity of the metal.

The author is indebted to Prof. Kipping, F.R.S., for suggesting this work.—UNIVERSITY COLLEGE, NOTTINGHAM. [Received, October 18th, 1923.]

Action of Hydrazine Hydrate on Phenanthraquinone. By
SIKHIBHUSHAN DUTT and NIRMAL KUMAR SEN.

PHENANTHRONE was readily obtained as follows. Ten grams of phenanthraquinone, suspended in 100 c.c. of absolute alcohol and treated with 3 grams of hydrazine hydrate, dissolved, the colour of the solution changing through various shades of green and blue to lemon-yellow, nitrogen being evolved, and heat developed. After twenty-four hours, the reaction mixture was poured into dilute hydrochloric acid, the brown, crystalline precipitate collected, unchanged phenanthraquinone extracted with a hot solution of sodium bisulphite, and the residue recrystallised from dilute alcohol containing hydrochloric acid, phenanthrone being obtained in colourless plates with metallic lustre, m. p. 151° (Found: C = 86.8; H = 5.6. Calc., C = 86.6; H = 5.1 per cent.). Its identity was established by direct comparison with phenanthrone prepared by Japp and Findley's method (T., 1897, 71, 1115).

Condensed with phenanthraquinone (1 mol.) in benzene solution, the above compound (1 mol.) yielded dark red prisms, m. p. 158° (Japp and Findley give m. p. $156-157^{\circ}$), which on reduction with hydriodic acid and red phosphorus at 150° for six hours gave tetraphenylenefuran, m. p. 310° (Japp and Findley give m. p. 306°) (Found: C = 90.8; H = 4.3. Calc., C = 91.3; H = 4.3 per cent.).

Five grams of phenanthraquinone and 4 grams of hydrazine hydrate were heated with 30 c.c. of absolute alcohol at 200° for six hours, the product was poured into hydrochloric acid, and the white precipitate crystallised from alcohol, when phenanthrone, m. p. 151° , was obtained in almost quantitative yield. No other product could be isolated.—THE CHEMICAL LABORATORY, DACC UNIVERSITY, EAST BENGAL. [Received, July 9th, 1923.]

OBITUARY NOTICES.

CHARLES BASKERVILLE.

BORN JANUARY 18th, 1870; DIED JANUARY 28th, 1922.

CHARLES BASKERVILLE was a devoted, enthusiastic member of the Society of Chemical Industry. He was tireless in his efforts to promote its ideals in his native land.

It is not easy for one who knew him from early manhood to the close of his life to prepare a proper sketch for the *Journal of the Chemical Society*, because the natural tendency is to dwell at length upon his noble character and upon his aims. The writer can see him—shortly after the attainment of his Bachelor's degree, and hear him expressing his purposes for the future; and then, in his mind, he follows him down to the last of his scientific activities. Throughout them all there was earnest purpose in his procedure and method.

Baskerville loved chemistry ardently. She was truly his mistress. For her he worked day and night, in season and out of season, and it was a great joy to his friends to listen to him from time to time setting forth the solution of problems upon which he had engaged.

Baskerville was loyal. His personality was of such a nature that he attracted men to him. He was a teacher who inspired his pupils. He possessed the power in a remarkable degree of making lucid expositions of his subjects. He was an organiser and administrator of the highest order. For thirty years he occupied a prominently successful position in chemical education.

In addition, Baskerville found time for research on the rare earths and on the chemistry of anæsthetics. In the industrial field, he was active in the refining and hydrogenation of vegetable oils, and established plastic compositions as well as succeeded in reinforcing metals. He was busy, too, with studies on pulp and the paper industry, particularly with that branch which relates to the recovery of used stock.

Baskerville assembled a mass of valuable information on the danger of various manufacturing processes and the best ways to meet and overcome these dangers.

For the State Legislature of New York Baskerville prepared a report on wood alcohol, in which its method of manufacture, the danger incident to its use, and the various commercial applications of it, as well as the discussion of proposed regulations for the control of the manufacture and use of wood alcohol, were exhaustively

studied. He gave attention, also, to hygiene and published lengthy researches on the manufacture and use of various inhalation anæsthetics used in surgery.

One hundred and ninety papers, eight books, and sixteen patents attest the scientific energy of Baskerville in the field of applied chemistry, and in the effort to improve the condition of humanity.

Baskerville was born on June 18th, 1870, in the State of Mississippi. His studies were carried out at the University of that State, at the University of Virginia, Vanderbilt University, and the University of North Carolina. From the latter he received the B.S. degree in 1892, and the Ph.D. degree in 1894. He studied at several German universities. His teaching years were spent as instructor, assistant professor, and professor in the University of North Carolina until 1904, when he became Professor of Chemistry and Director of the Chemical Laboratory of the College of the City of New York. While engaged here he died on January 28th, 1922. A wife, son, and daughter survive him.

Baskerville was one of the most constant attendants on the meetings of the American Chemical Society, labouring earnestly for its best interests. He was also a Fellow of the London Chemical Society, member of the Society of Chemical Industry, of the American Institute of Chemical Engineers, American Electrochemical Society, the Washington and New York Academies of Science, the Franklin Institute, and the American Association for the Advancement of Science.

A review of the many contributions which he made to chemistry will very promptly satisfy the student that Baskerville really extended the borders of human knowledge in his chosen field. His death was a blow, not only to those who knew him intimately, but to every student of chemistry, for he touched upon every department of the science and left a lasting imprint.

EDGAR F. SMITH.

ALEXANDER CRUM BROWN.

BORN MARCH 26TH, 1838; DIED OCTOBER 28TH, 1922.

THE death of Alexander Crum Brown removes the last of those who played a part in the reshaping of organic chemistry in the early sixties. His main scientific work was done while he was yet a young man, and much of it is now forgotten or only vaguely remembered. Had he possessed a spark of worldly ambition his name would occupy a more prominent position in the history of science than to-day it does, for in actual achievement he is worthy to rank with Joseph Black, his great predecessor in the Edinburgh Chair.

ALEXANDER CRUM BROWN

[For *Notes* p. 3422.]

Crum Brown was born in Edinburgh on March 26th, 1838, and came of a long line of distinguished divines and theologians, his father being Dr. John Brown (1784-1858), minister of Broughton Place United Presbyterian Church. On his mother's side, he was descended from Ebenezer Erskine (1680-1754), founder of the Scottish Secession Church. Dr. John Brown was twice married. His son by the first marriage was John Brown, M.D. (1810-1882), well-known as an Edinburgh physician, but who earned a wider fame as the author of "Rab and his Friends," "Horæ Subsecivæ," and other literary essays. Crum Brown, the only son of the second marriage, was named after his maternal grandfather, Alexander Crum, of Thornliebank, a merchant and manufacturer of Glasgow. His mother's brother, Walter Crum, F.R.S. (1796-1867), was a chemist of note, and it is probably due to the influence of this uncle that Crum Brown's thoughts were specially directed to chemistry amongst the various subjects of his university studies.

Crum Brown was a precocious child and always busy with models and inventions. Before he went to school he had made a practical machine for weaving cloth, an early indication of his life-long interest in knots and complicated systems of knitting. His education was received in the Royal High School, Edinburgh, where he spent five years, followed by one year at Mill Hill School. In 1854 he entered the University of Edinburgh as a student, first of Arts, and then of Medicine. He was gold medallist in the classes of Chemistry and Natural Philosophy, and graduated as M.A. in 1858. Continuing his medical studies, he received the degree of M.D. in 1861. During the same time he read for the science degree of London University, and in 1862 he had the distinction of being the first candidate on whom the Doctorate of Science of the University of London was conferred. After his graduation as Doctor of Medicine in Edinburgh he continued the study of chemistry in Germany, first under Bunsen at Heidelberg, and then at Marburg under Kolbe.

In 1863 he was licensed as an Extra-academical Lecturer in Chemistry by the University of Edinburgh. His classes were small—sometimes the total membership was only two—so that he was left ample leisure for research. In 1869 he succeeded Lyon Playfair in the Chair of Chemistry at the University and held office until his retirement in 1908.

Crum Brown's scientific work bears a marked individual stamp. His mind was essentially philosophic and speculative, and he was specially interested in symbolic representation, as is manifest in his thesis for the M.D. degree, presented at the age of twenty-three. This was not a commonplace report of cases, but was entitled "On

the Theory of Chemical Combination," and showed him to be a pioneer in scientific thought. When he took the University course in chemistry under William Gregory there was no laboratory in which practical work could be carried out, and a glance at Gregory's "Hand-book of Organic Chemistry" of the date (1856) shows how small a part theoretical considerations then played in the presentation of the science. Lyon Playfair had succeeded Gregory in 1858, and within a year or two had created a useful teaching laboratory, but that even he was far from being on the scientific level of the young medical student is evidenced by the cold reception given to Crum Brown's thesis in 1861. It was judged as "worthy to compete" for the Dissertation Prizes, but did not receive one, although no fewer than sixteen awards were made. In this thesis he expresses his purpose to sketch the history of the law of equivalence or substitution, and the law of polarity, "to discuss the bearing of recent discoveries on them; and to endeavour to determine what is the form in which they may best be expressed, so as to include all the facts, and be, as nearly as possible, a strict generalisation from them." In the course of the discussion of types and radicals he evolved a system of graphic formulation in all essentials identical with that in use at the present day. These formulæ were the first to represent clearly and satisfactorily both the valency and the linking of atoms in organic compounds (this vol., p. 942). His views of polarity are instructive:—" (1) Bodies (*i.e.*, radicals, simple and compound) may be arranged with general accuracy in a linear series, the members of which differ from each other in polarity (*i.e.*, as being positive or negative) according to their distance from each other in the series. The few exceptions to this seem to indicate that there is more than one cause producing the variations in polarity. (2) Bodies preserve their polar properties in combination, and in compound radicals the substitution of one or more negative for one or more positive atoms renders the radical more negative, and *vice versa*." He concludes by saying "The questions with which we set out [namely, 'What is the nature of the forces which retain the several molecules or atoms of a compound together?' and 'How may their direction and amount be determined?'] are not yet capable of being answered, although a certain amount of progress has been made towards their solution. Chemistry, however, labours, and probably must always labour, under a great disadvantage as compared with most other branches of physics, in so far as the application of mathematical analysis is concerned. The very existence of the atoms, the consideration of which should form the starting-point of such analysis, is hypothetical. Still, it does not seem to me improbable that, by assuming

that these atoms exist, and that certain forces act upon them under certain laws, we may be able to form a mathematical theory of chemistry, applicable to all cases of decomposition and recombination, the truth of whose results shall be independent of the truth of those assumptions by means of which the theory has been formed, just as the truth of the results of the undulatory theory of light is independent of the existence of the luminiferous æther."

In his thesis he displays an insight and a philosophic wideness of vision comparable with that of Archibald Scott Couper, with whose work at that time Crum Brown was unacquainted, although, strangely enough, in the year 1858 they must have been in the University together, Couper having served as Lyon Playfair's assistant for a few months before the onset of his tragic illness.

In 1864 Crum Brown published (*Trans. Roy. Soc. Edin.*, **23**, 707) an important paper "On the Theory of Isomeric Compounds," reprinted in this Journal, 1865, **18**, 230, in which, making free use of his graphic formulæ, he discusses the various types of isomerism, paying special attention to that of fumaric and maleic acids, and in general to compounds that are "absolutely isomeric," (i. e., which possess the same constitutional formula). He criticises the views of Kekulé and of Butlerow, and concludes, "We thus see that the attempts to apply to the explanation of particular cases the principle of a difference between the equivalents of multivalent atoms have failed, not . . . from any absurdity in the principle itself, but rather from a want of well-observed facts to guide us in its application."

In 1866, in continuation of his systematic work he published (*ibid.*, **24**, 331) another paper "On the Classification of Chemical Substances by Means of Generic Radicals." This paper he sent to Frankland, and received from him letters dated May 28th and June 4th, 1866, containing the following extracts which show the reception accorded to graphic formulæ at that period. "Many thanks for the proof of your very interesting paper on the classification of chemical substances. I am much interested in graphic formulæ and consider that yours have several important advantages over Kekulé's. In my lectures here last autumn I used them throughout the entire course and with very great advantage, and I have now in the press a little book of Lecture Notes for Chemical Students in which they are copiously used." "I am just now endeavouring to get Kolbe to express certain of his fundamental formulæ graphically. We should then understand each other better. There is a good deal of opposition to your formulæ here, but I am convinced that they are destined to introduce much more precision into our notions of chemical compounds. The water-type,

after doing good service, is quite worn out." In the *Journal* of this Society Crum Brown's graphic formulæ are used for the first time by others in a paper by Chapman and Thorp (1865, 19, 494), and extensively in one by Frankland and Duppa (1866, 20, 211).

In 1867 Crum Brown published a paper "On an Application of Mathematics in Chemistry" which bears a superficial resemblance to Sir Benjamin Brodie's "Calculus of Chemical Operations," but differs from it in method, object, and result. He uses a functional notation to express certain general and serial relations in those cases where the common atomic notation is inconvenient or obscure. In a criticism of Brodie's system (*Phil. Mag.*, 1867, [iv], 34, 129) he upholds the use of atomic and graphic formulæ and says: "While there can be no doubt that *physical* research points to a molecular constitution of matter, it is perfectly indifferent to a *chemist* whether his symbols represent atoms or units; and graphic formulæ would be as useful as they are now, were it conclusively proved that matter is continuous." It is interesting at the present time to note that in considering the (formal) polymerisation of acetylene he arrives by one method of representation at Dewar's formula for benzene and by an alternative method at Kekulé's.

Although Crum Brown apparently never contemplated the practice of medicine, his training as a medical student gave him an interest in physiology and pharmacology which led him to collaborate during 1867-8 with T. R. Fraser, a distinguished medical graduate a few years younger than himself, in a pioneering investigation of fundamental importance on the connection between chemical constitution and physiological action (*Trans. Roy. Soc. Edin.*, 25, 151, 693). Their method "consists in performing upon a substance a chemical operation which shall introduce a known change into its constitution, and then examining and comparing the physiological action of the substance before and after the change." The change considered was the addition of ethyl iodide to various alkaloids and comparison of the iodides (and the corresponding sulphates) thus obtained with the hydrochlorides of the original alkaloids. Striking regularities were observed, amongst others "that when a nitrile [tertiary] base possesses a strychnia-like action, the salts of the corresponding ammonium [quaternary] bases have an action identical with curare."

Crum Brown's name was now well-known, and in his application for the Edinburgh Chair in 1869 he received the support of nearly all the prominent chemists of this country. Amongst the names of Continental chemists who bore testimony to his ability may be noted those of Baeyer, Beilstein, Bunsen, Butlerow, Cahours, Erlenmeyer, Hofmann, Kolbe, Velhard, and Wöhler.

For some time after his University appointment he published little, but in 1873 he began a series of investigations of the organic sulphur compounds (Crum Brown and Letts, *Trans. Roy. Soc. Edin.*, 28, 571), particularly derivatives of trimethylsulphine, which occupied him for several years, after which there was an intermission in his scientific output. In 1890 he entered a new period of chemical activity. A theoretical paper (*Proc. Roy. Soc. Edin.*, 17, 181) on the relation of optical activity to the character of the radicals united to the asymmetric carbon atom was published simultaneously with Guye's memoir on the same subject. Crum Brown's treatment is more general than Guye's, postulating a function, κ , for each radical, and giving examples of the methods to be employed for its determination. "Of course we cannot as yet even approximate to a formula for the amount of rotation in terms of the four κ 's and temperature, but as the rotation becomes zero when any two κ 's become equal we may presume that it contains the product of the differences of the κ 's. The first thing to be done with this speculation is to find whether κ is really a function of the composition and constitution of the radical and of the temperature of the substance, or varies with the character of the other three radicals." Here once more we have the characteristic breadth of view and clearness of statement. About the same time began the series of researches on the synthesis of dibasic acids by the electrolysis of ester-salts (Crum Brown and Walker, *Trans. Roy. Soc. Edin.*, 36, 211; 37, 361). In 1892 he published, in conjunction with John Gibson (*T.*, 61, 367), the well-known rule for determining the position in the benzene nucleus taken up by an entering radical with respect to one already present.

The then new physico-chemical theories of osmotic pressure and of electrolytic dissociation roused his interest, and whilst he retained an open mind on the subject, he gradually became convinced of their essential validity. He did much to place them clearly before his students, and published experiments illustrating the utility of both theories (*Proc. Roy. Soc. Edin.*, 1896, 21, 57; 1899, 22, 439).

No mention has been made of minor chemical papers dealing with practical matters, nor of the numerous and interesting addresses which he from time to time delivered. Amongst them a very clear account of the processes involved in the rusting of iron may be noted (*Jour. Iron and Steel Inst.*, 1888, p. 129). His view of the position of Chemistry in the domain of the mathematical-physical sciences is stated in his Presidential Address to the Chemical Section of the British Association in 1874. "One thing we can distinctly see—we are struggling towards a theory of Chemistry. Such a theory we do not possess. What we are sometimes pleased to dignify

with that name is a collection of generalisations of various degrees of imperfection. We cannot attain to a real theory of Chemistry until we are able to connect the science by some hypothesis with the general theory of Dynamics. . . . Chemistry will then become a branch of Applied Mathematics, but it will not cease to be an experimental science. Mathematics may enable us retrospectively to justify results obtained by experiment, may point out useful lines of research, and even sometimes predict entirely novel discoveries, but will not revolutionise our laboratories. Mathematical will not replace Chemical Analysis." Following the same strain, in his Presidential Address to this Society in 1892, he exhorts the young chemist to study mathematics. "The most perfect dynamical explanation of chemical constitution and chemical change will not enable us to dispense with the old processes of analysis and preparation. The chemist will still be the man trained in the chemical laboratory, and all the mechanical parts of the work will be done by him. But unless he learns the language of the empire [mathematics], he will become a provincial, and the higher branches of chemical work, that which require reason as well as skill, will gradually pass out of his hands"—surely a prophetic utterance.

Crum Brown had forty years ago very modern views as to crystal structure (Art. "Molecule"—*Encyclopædia Britannica*, 9th edn. 1883). "It is perhaps scarcely correct to speak of a molecular structure of [crystalline] solids at all. Solids are no doubt composed of atoms, and those atoms are evidently arranged in what may be called a tactical order. When the solid is fused or dissolved or volatilised, it breaks into molecules, each repetition of the pattern being ready to become an independent thing under favourable circumstances. It may be urged that the cleavage of crystals indicates that they possess a molecular structure, but a tactical or pattern-like arrangement of atoms may easily be supposed to present planes of easier separation without the assumption of really independent molecules." Many years before the work of Laue or Bragg, Crum Brown in conversation with the writer mentioned that he had constructed a model of the structure of sodium chloride, each chlorine atom having six equidistant sodium neighbours, and each sodium atom six equidistant chlorine neighbours, the type of structure being that now attributed to the crystalline salt.

Crum Brown never lost his interest in physiology and at various times he made valuable contributions to that science. One of these was a study of the sense of rotation and the function of the semicircular canals of the internal ear (*Proc. Roy. Soc. Edin.*, 1873-4, 8, 255, 370). His work was contemporaneous with that of Mach

and Breuer, but his explanation went beyond theirs, suggesting the function of the ampullæ and showing how complete perception of rotation could be secured by the actual arrangement of the canals in the two ears. The relation between the movements of the eyes and the movements of the head also engaged his attention, and on this subject he published several papers. The analysis of vowel sounds too at one time interested him, and he invented a "talking bottle" which when blown emitted vowel sounds varying with the stopping of the holes with which it was provided. The only medical case which he ever described was one of dyspeptic optical vertigo—his own. He detailed the symptoms with minuteness and gusto, made careful observations of his sensations, carried out experiments while in bed and during convalescence, and drew appropriate conclusions—both physiological and psychological.

Several published papers show his serious attention to certain branches of mathematics, for example, one on interlacing surfaces (*ibid.*, 1885, 13, 382), and another (*Trans. Roy. Soc. Edin.*, 1894, 37, 711) on the partition of a parallelepiped into tetrahedra, the corners of which coincide with the corners of the parallelepiped. A favourite hobby was the practical construction of tridimensional models, both crystallographic and mathematical, a glue-pot on the hob and a plentiful stock of cardboard being recognised features of his retiring-room in the University. In literature his reading was extensive, and his knowledge of languages, ancient and modern, was altogether exceptional. His keenness for symbols came out in his study of alphabets and generally of systems of writing.

A man of Crum Brown's great and varied gifts could scarcely prove other than a stimulating teacher, although to the average elementary student his lectures were rather a trial. A former pupil of his writes: "Briskly entering the class-room, he began at once in rapid phrasing to describe the properties of a chemical substance or the intricacies of a chemical process. Chemical formulæ grew like magic on the blackboard. The casual and limp-minded listener found Crum Brown's quick vivid style much too strenuous; but the student who really wished to learn, and had ear and eye in well-trained attention, could not fail to experience keen intellectual delight from the masterly manner in which the whole subject was presented." His lectures on organic chemistry to advanced students were revelations of the working of scientific method. He selected a few topics and dealt with these in full detail, never letting the student lose sight of the end to which the researches he described were directed, or of the logical thread running through them. He delighted in analogies and parables,

and exercised the greatest ingenuity in seeking from familiar life parallels to the scientific lesson which he wished to inculcate. A characteristic example may be found in his Presidential Address (T., 1892; 61, 481), where he likens the behaviour of salt molecules in solution to the doings of a cattle-holding community.

Crum Brown's turn for business was almost as notable as his talent for speculative thought. Before a Faculty of Science was established in the University he long acted as convener of the Science Committee of the Senatus, and directed the course of students desirous to receive a scientific training. For many years, too, he was a member of the University Court, taking a prominent part in the business administration of the University. Outside the University, his Church and the Royal Society of Edinburgh claimed his chief practical interests. In Synod and Assembly he was eagerly listened to for the pith and wisdom of his utterances. His service on the Council of the Royal Society of Edinburgh extended to forty-four years in all, during twenty-six of which he acted as one of the secretaries, and for six as a vice-president. The Society awarded him its Keith Prize in 1875. His loyalty to the Society, in the *Transactions* and *Proceedings* of which he published nearly all his researches, had no doubt much to do with the scant recognition of his work, their circulation amongst chemists being very limited. He was elected a Fellow of the Royal Society in 1879, and had honorary degrees conferred on him by all four Scottish Universities. He occupied the Presidential Chair of the Chemistry section of the British Association in 1874 and of the Chemical Society in 1891-3.

Crum Brown presented the refreshing and fascinating contrast of a simple character combined with a brilliant and subtle intellect. He possessed a keen wit, tempered by the most delightful pawky humour. Being besides a born *raconteur*, he shone in social gatherings, especially at his own hospitable table. He was generous and kindly and his great learning was accompanied by a fine modesty. Although naturally impatient, and although he had counted Clerk Maxwell, Kelvin, and Tait amongst his intimates, he was ready always to listen with sympathy and understanding to the ideas of those who were vastly his intellectual inferiors.

A pair of dark, deep-set, sparkling eyes formed the most striking feature of his appearance, and were the fit index of his vivacious temperament. Although physically not very robust, he spent much of his holiday time in tramping in the Highlands and on the Continent, and was rarely ill. He married early in his professorial life Jane Porter, a daughter of the Rev. James Porter, Drumlie, Down, whose death two years after his retirement from

University duties overshadowed the last decade of his life. Failing bodily health confined him to the house, and for some seven years he had most unwillingly to regard himself as an invalid. His mind lost little of its activity. He read much, and amused himself with original methods of knitting. He enjoyed conversing with his old friends, and even when increasing weakness made this somewhat of an effort for him, he would still with an inextinguishable twinkle of the eye retail some quaint story or interesting reminiscence. He died peacefully on October 28th, 1922, leaving to all who knew him an enduring legacy of very pleasant memories.

J. W.

CHARLES MANN LUXMOORE.

BORN 1857; DIED APRIL 6TH, 1922.

CHARLES MANN LUXMOORE died on April 6th, 1922, aged sixty-five. He was educated at the Commercial School at Bristol, and studied science under Mr. Thomas Coomber and Dr. J. M. H. Munro. At the latter's suggestion, he entered, in 1877, for an exhibition at the Royal College of Science, Dublin, which he was awarded, and studied there under Professors Galloway and Barrett.

Having decided to take up pharmacy, he passed, in 1884, the Major Examination of the Pharmaceutical Society, gaining the silver medal in chemistry, botany, and materia medica.

Luxmoore was for some time engaged in the business of pharmacy, but occupied his leisure in the study of the science of chemistry and in preparation for a degree in science at the University of London. Having gained the pass B.Sc., he proceeded to the Honours degree, and worked in the research laboratory of the Pharmaceutical Society during the years 1891–1894. He gained the Honours (First Class) degree in 1893.

He devoted himself in research principally to a study of the isomerism of the benzaldoximes. In the course of this work he had the misfortune to lose one of his eyes owing to the violent explosion of a glass tube in which he was preparing hydroxylamine.

A preliminary paper, published conjointly with Professor Wyndham Dunstan (P., 1893, 9, 253) contained some interesting observations on α -benzaldoxime and certain of its derivatives and showed that both the oxime itself and its acetyl derivative were obtainable in a crystalline form.

The work was continued by Luxmoore and, in 1895, a full account of his investigations was prepared, and this was accepted as a thesis for the degree of D.Sc. (Lond.). The paper was subsequently published (in part) in the *Journal of the Chemical Society* (T., 1896,

69, 177). One of the most important results of the research was the isolation of a nitrogen ether of benzantialdoxime, which rapidly underwent transformation into the isomeric nitrogen ether of benzsynaldoxime. Luxmoore showed that four distinct series of ethers exist, two of which have the oximino- and two the *iso*-oximino-structure, whilst of each pair one is an *anti*- and the other a *syn*-derivative, and on the basis of this fact he discussed the configuration of the oximes.

Two further papers on the results of work carried out in the research laboratory of the Pharmaceutical Society were published by Luxmoore. One of these recorded the production of α -ethylene-dihydroxylamine dihydrobromide (T., 1895, 67, 1018), whilst in the other, on the alleged isomerism of potassium nitrososulphate (*loc. cit.*, 1019), it was shown that this salt has always the same properties, under whatever conditions it is formed.

Luxmoore was an earnest and persistent worker in chemistry, his particular bent being the detailed investigation of new compounds and the recording of facts. When later he took up agricultural chemistry, the same spirit pervaded his work, always conducted with great perseverance and a minute attention to detail.

On leaving the Pharmaceutical Society Luxmoore became lecturer in chemistry to the Hertford County Council, and subsequently worked at the Rothamsted Experimental Station.

From 1896 to 1906 Luxmoore was lecturer in chemistry and agricultural chemistry at University College, Reading. During this period the College, by arrangement with the Dorset County Council, undertook an examination of the soils of Dorset. Luxmoore was in charge of the extensive analytical work involved. The results of these analyses, and discussion of their practical significance were published in five Annual Reports, of which Luxmoore and the Director of the College Agricultural Department were joint authors.

These reports of necessity were confined to matters of interest in a soil survey; Luxmoore had, however, carried his investigations considerably beyond this stage. He made numerous examinations of the physical properties of the soils, in some cases devising experimental methods for the purpose, and he freely used statistical methods in arriving at the conclusions on the voluminous data he collected.

An account of this work was published in 1907 as a monograph, under the title "The Soils of Dorset. A Report on their Mechanical and Chemical Composition and on their Physical Properties." Two years before, one aspect of these physical studies, "The

Hygroscopic Capacity of Soils," appeared in Vol. I of the *Journal of Agricultural Science*.

The essential feature of Luxmoore's work was first, an attempt to trace the bearings of the geological types of the soils on their physical and chemical properties, and, secondly, to examine the relations of these properties to one another.

Owing to the varied nature of the Dorset strata, the soils represented at least seventeen geological groups. Nearly two hundred soils and sub-soils were sampled and examined, a number which, although adequate for most of the second phase of the inquiry, was not sufficient for the first—the characterisation of the geological groups by the properties of their component soils. Luxmoore therefore confined himself to a number of general relationships, and devoted his main attention to the second half of his problem, where the data were more satisfactory; some thirty distinct quantities were determined on each of the hundred soils, and most of the sub-soils. These measurements were made up of the customary chemical determinations and the mechanical analysis, none of which needs be described here, together with important physical properties. The porosity was calculated from the true and apparent specific gravity after the samples had been brought into a state of tilth by successively moistening with lime-water, freezing, thawing, and drying out. Further, a commendable attempt was made to measure the retentive power for water of the different soils. The porous blocks saturated with water were allowed to dry slowly. When the moisture content was reduced to one-tenth of the saturation value, the blocks were left for a further seven days, and the water still remaining was expressed as a percentage of the one-tenth saturation value. This percentage was called the "capillary-retentivity" of the soil. Many determinations were also made of the hygroscopic capacity of the soils in equilibrium with atmospheres of differing humidity.

By an extensive use of the statistical method of correlation coefficients, Luxmoore brought to light many interesting relations between the different soil properties. A number of these were new at the time, and to others, which were known, a more quantitative basis was given. There is not space to discuss all these relations, and attention is here confined to the more prominent, and to those which show an anticipation of developments in soil science since Luxmoore's time.

High correlation existed between the quantity of carbonate of lime and lime combined with other acids. The explanation suggested was that the soil solution would be saturated by the bicarbonate, which would react with silicates of potash and other

bases, bringing them into solution, and the equivalent amount of calcium would then become an integral part of the moderately soluble silicates. The relation was examined between the hygroscopic coefficient and various minerals present, soluble in hot concentrated hydrochloric acid; the effect of both iron oxide and alumina was pronounced, higher, in fact, than that due to the mechanical dimensions of the soil particles. This may be partly due to the fact that the correlation coefficient between moisture and particle sizes was calculated by taking the proportion of particles below a certain arbitrary dimension as a measure of the fineness of the soil, an admittedly incomplete specification. The connexion between hygroscopicity and soluble minerals may also be indirect and depend on some common cause such as the physical fineness, which would lead to both increased hygroscopicity and solubility. As far as the results went, it appeared that the attraction of particles for water was not proportional to their surface area, but was more nearly represented by the two-thirds power of the diameter. Luxmoore suggested that if the finer particles were mostly derived from the larger ones by fracture and attrition, they would more closely approach a spherical shape, and thus present less surface for moisture condensation than if they were reduced images of the larger particles. The degree to which increasing amounts of organic matter and decreased diameter of the soil particles influenced the hygroscopic coefficient was also examined, and the conclusion drawn that the effect of the two factors was more than additive: besides exerting its own surface attraction, the organic matter was more effective than the coarser mineral particles in keeping the finer particles apart and free to exercise their own hygroscopic capacity. On the other hand, examination of the figures for capillary retentivity showed that the organic matter had no effect in hindering the evaporation of water by capillary action, when this water was in excess of the hygroscopic coefficient. It appears that any effect of the organic matter in this direction was counterbalanced by the increased porosity it communicated to the soil under the experimental conditions. The low correlation coefficients obtained for the capillary retentivity indicated that this property of the soil was not traced so closely to its causes as were, for instance, the hygroscopicity and the porosity. Luxmoore threw out the suggestion that the evaporation of water was dependent on minute structural characteristics of the soil mass not adequately expressed by the comparatively simple data used in his calculations.

In assessing the value of these contributions to agricultural science, it is necessary to remember the position at the time. The

era of Lawes and Gilbert had closed; there were about twenty-five Agricultural Colleges in existence, few of them more than ten years old. A good deal of work in agricultural science was being done, but there was no common journal for its publication until 1905, when the *Journal of Agricultural Science* was started. Much attention was being given to the physical properties of soil in the United States, especially at the Bureau of Soils, but there was no parallel activity in this country. Had Luxmoore continued his work, there is no doubt that the full value of it would have been realised. Unfortunately, he took no part in agricultural science after 1906, and his one paper in the *Journal of Agricultural Science* on the hygroscopic capacity of soils would appear obscure in parts to those who had not his full monograph, the circulation of which was naturally restricted. A further—and self-imposed—difficulty was that Luxmoore realised, before many of his contemporaries, that the unavoidable empiricism of much of the technique applied to a complex material like soil was prone to lead to misleading conclusions unless the results were critically treated by statistical methods. With both subject and treatment unfamiliar, it is not surprising that Luxmoore's contributions suffered the fate of many pioneering investigations.

W. R. DUNSTAN.

B. A. KEEN.

EDWARD WILLIAMS MORLEY.

BORN JANUARY 29TH, 1838; DIED FEBRUARY 24TH, 1923.

EDWARD WILLIAMS MORLEY, an honorary foreign member of the Chemical Society, was born in Newark, New Jersey, January 29th, 1838, and died at Hartford, Connecticut, February 24th, 1923. His father, the Reverend Sardis Brewster Morley, who married Anna Clarissa Treat, was a Congregational minister. Both parents were of early colonial ancestry, and of purely British origin on both sides. It was good stock and productive of good offspring.

During his childhood, Edward suffered much from ill-health. For this reason his early education was undertaken by his father, and he was taught at home until the age of nineteen. He learned to read before he was three years old, began Latin at six, and Greek at eleven. I gather this information, and much that follows, from some autobiographical memoranda which now lie before me. These memoranda give clear information as to the influences which led him to a scientific career, and especially how he happened to become a chemist. In his college days the old classical curriculum

gave little or no training in experimental science, and not much in higher mathematics.

When Edward was quite a young lad he found among his father's many books one entitled "Conversations on Chemistry," which fascinated him more than the "Arabian Nights," which stood near it on the same shelf. When twelve years old he spent all his pocket money on chemical experiments, which he carried on until he entered college. When he was about fourteen years old he obtained a copy of a text-book on chemistry by Benjamin Silliman, then recently published, and, says Morley, "this was so much studied that when the subject was taken up in the junior year of my college course there was not much left to be learned." That means, of course, from such works as were accessible to him.

At the age of nineteen Morley entered Williams College at Williamstown, Massachusetts, his father's *alma mater*. He was able to skip the Freshman year, and to enter with advanced standing as a sophomore. He graduated in 1860 as A.B., and in 1863 he received his Master's degree.

Under Professor Albert Hopkins, astronomy became a fascinating study. It was, perhaps, not so interesting as chemistry, but it provided an opportunity for the study of methods of precision which was not possible in any other subject at that time and place. Morley, therefore, remained at Williams College for further study, and in 1860-61 he mounted a transit instrument, constructed a chronograph, and made the first accurate determination of the latitude of the college observatory. This determination was the subject of his first published paper, which was read before the American Association for the Advancement of Science in 1866. He also read much in the "*Mécanique Céleste*" of Laplace, and in another work on astronomy which was read in college he was able to discover and correct certain errors. He pointed these errors out to the editor of the volume, at whose request he wrote a paper on the subject, which, however, was not intended for publication. This early work is a forecast of his later career, and shows us his intense devotion to accuracy.

It has already been said that Morley's father was a clergyman, and so too was his mother's only brother. Quite naturally, they decided that Edward should follow in their footsteps, and so in 1861 he entered Andover Theological Seminary, where he completed the course in 1864. It was here, probably, that he acquired a good working knowledge of Hebrew.

From 1866 to 1868 Morley was a teacher in a private school, and later, in 1868, he was called to preach in a small country parish in Ohio. At about the same time, however, he was appointed

professor of chemistry in Western Reserve College, then situated at Hudson, Ohio, which was afterwards moved to Cleveland and renamed Western Reserve University, where he remained until his retirement in 1906. This appointment was the turning point in his career. In 1873 he also became professor of chemistry in Cleveland Medical College, but he resigned this chair in 1888 in order to have more time for research. Just before moving to Hudson he married Miss Isabella A. Birdsall.

During his residence in Cleveland Morley brought together one of the best private collections of chemical periodicals to be found in America. He even included the Russian journals, and learned enough of the Russian language to make use of them. After his retirement from teaching, the University purchased his library, and it is now in the new chemical laboratory, for which he drew the plans, and is now known as the Morley Chemical Laboratory. In 1906 he moved to West Hartford, Connecticut, near the home of his boyhood, where he built a small house with a garage and also a laboratory in which he made, with his usual thoroughness, many difficult analyses of rocks and minerals. Of this work I shall have more to say later. Morley could not be idle. Indeed, for many years he was in the habit of working as much as fourteen hours a day.

In Western Reserve College Morley was required to teach, not only chemistry, but also geology and botany, which left him little time for research. Before his advent instruction in the sciences had been by lectures and recitations, for in the smaller American colleges laboratory practice for students was almost unknown. Morley, however, at once fitted up a small room as a laboratory, in which his pupils obtained some real insight into the methods and significance of chemistry.

It was in the college at Hudson that Morley's life-work as a chemist really began. In order to eke out his income, for his salary as a teacher was small, he did some analytical work apart from his regular duties. Nevertheless, he found time during the first ten years at Hudson to publish five minor researches, three of them relating to the accuracy of measurements with the microscope. These researches, except as they show his ambition to make what was thought to be precision more precise, need no further consideration here.

In 1878 Morley began the series of investigations which revealed him to the world as an experimentalist of the first rank. In 1878 his attention was directed to reported variations in the proportion of oxygen in the atmosphere. That the variations were real was not doubted; but what do they mean? That is the question which

Morley sought to answer, at least in part, and his task was one of extreme delicacy. The problem involved several collateral investigations, such as the construction of the most accurate apparatus, and the testing and improvement of analytical methods, and the results obtained appeared in ten separate papers, published between the years 1879 and 1881, three years of labour.

On one side, Morley's main problem was meteorological. Professor Loomis had put forth the hypothesis that so-called "cold waves," those severe and sudden falls in the temperature of the air, were due, not to currents moving from the north southward, but to the descent of air from high elevations, and at times of high barometric pressure. The upper layers of the atmosphere are poorer in the relatively heavy oxygen than the lower layers at the surface of the earth. Hence, if the Loomis hypothesis is correct, the air collected during a cold wave should show a deficiency of oxygen.

Morley had already made many analyses of air from different parts of the globe, and in 1880, during 110 consecutive days, he made analyses of the air at Hudson. Each determination of oxygen was made on the day that the sample was taken. To quote Morley's own words: "The theory that the deficiencies of oxygen in the atmosphere are caused by the descent of air from an elevation fairly well agrees with the facts." Morley's cautious statement shows the scrupulous honesty of the man. A more positive assertion would have been justifiable.

An attempt to trace the workings of another man's mind would, of course, be rather presumptuous. That task may be left to novellists, who can create imaginary characters. It seems highly probable, however, that Morley's research on the composition of air had much in it to suggest his next and most famous investigation, on the composition of water, that is, on the relative atomic weights of oxygen and hydrogen. The transition from one research to the other was quite natural. An intermediate step was the determination of the amount of moisture retained by gases after drying by means of sulphuric acid or over phosphorus pentoxide, and that was an essential preliminary to his work on the composition of water by volume, a study of the proportions in which two gases combine. The two researches overlap.

Morley's work on the atomic weight of oxygen, that of hydrogen being taken as unity, covered a period of eleven years. Much time was spent in the detection of constant errors, in working out the details of his methods, in the careful calibration of his instruments, and in making "assurance doubly sure" as to the purity of his materials. No precaution was overlooked, for the highest possible degree of accuracy was his aim.

Morley's determinations of the atomic weight of oxygen were made by two distinct methods. First, he effected the direct synthesis of water from weighed quantities of its component elements, and, secondly, by determining the densities of the two gases. The results obtained checked each other within all reasonable range of experimental uncertainty, and later determinations by other chemists have made only trivial changes in Morley's figures. The outstanding uncertainty is probably not greater than 1 part in 10,000 parts.

This research of Morley's on the composition of water was about as much physical as chemical; so much so that the physicists are inclined to regard him as one of themselves. Indeed, from this time on until he retired from teaching, his investigations, carried on in co-operation with others, were almost, if not entirely, in the field of physics. With H. T. Eddy, and afterwards with D. T. Miller, he studied the velocity of light in a magnetic field, and also the expansion of certain gases. With W. A. Rogers he measured the expansion of metals, and with C. F. Brush he investigated the conduction of heat by water vapour, and described a new gauge for the measurement of small pressures. In all this work, which I need not discuss further, the constant striving was for accuracy. His one outstanding investigation in the field of physics was carried on in co-operation with A. A. Michelson, and was an attempt to determine the relative motion of the earth and the luminiferous ether. He also worked with Michelson on the development of the interferometer.

In the later years of his life, in his private laboratory at West Hartford, he made about seventy analyses of igneous rocks, that were collected by J. P. Iddings in the Malay Archipelago. It is scarcely necessary to say that these difficult and complicated analyses were made with the highest degree of completeness, and that none better are to be found in the whole literature of petrology. Nineteen of these analyses, of rocks from Java and Celebes, were published in a joint paper by Iddings and Morley in the *Journal of Geology* for April and May, 1915. This was Morley's last contribution to chemistry. Morley was not a voluminous writer; his published bibliography contains only fifty-five titles. But a single great paper may outweigh many small ones.

Professor Morley was the recipient of many honours, among them three medals, namely, the Davy Medal of the Royal Society, the Elliot Cresson Medal from the Franklin Institute of Philadelphia, and the Willard Gibbs Medal of the Chicago section of the American Chemical Society. He also had honorary degrees from five colleges or universities. He was an honorary member of

the Chemical Society and of the Royal Institution. He was also a member of several other learned societies.

Morley was a member of the National Academy of Sciences, and he served as President of the American Chemical Society and of the American Association for the Advancement of Science. In 1912, he was Honorary President of the Eighth International Congress of Applied Chemistry.

Morley was an extremely versatile man and had many interests apart from his devotion to science. He was a well-read man in general literature, and a good amateur musician. During his residence at Hudson he played the organ in the college chapel. He kept his interest in music up to the end of his life. One of his last acts was to give a fund of 5,000 dollars to the Congregational church in Hartford, in memory of his wife. This money was for the purchase of an organ and in aid of the musical part of the church service. He was a religious man, but by no means bigoted or fanatical.

During the closing years of his life Morley found much pleasure in his flower garden and in photography. In summer he enjoyed long motor rides with his wife, himself the driver. Much beautiful scenery was within easy reach of his home, in the hill country of western Connecticut and Massachusetts.

Morley was thoroughly human and very modest. He had no affectations, and was not addicted to blowing his own trumpet. He was a charming friend, as the present writer can affirm after more than forty years of personal acquaintance. My conferences with him were always profitable to me.

Morley outlived his wife by only a few months, and died, following a surgical operation, in the Hartford Hospital, at the age of eighty-five years.

FRANK WIGGLESWORTH CLARKE.

WILLIAM THOMSON.

BORN 1851; DIED OCTOBER 4TH, 1923.

WILLIAM THOMSON, born in Glasgow in 1851, came to Manchester as a young man and entered the laboratory of Dr. Grace Calvert, with whom he afterwards entered into partnership. Dr. Calvert, besides being a chemical manufacturer, had an extensive and varied practice as a consulting and analytical chemist; Thomson thus came into close touch with many of the industries of the district, and the early experience he gained with Calvert did much to build up the practice which he maintained for fifty years.

But Thomson was not only widely known as an analyst; he had remarkable ingenuity in devising apparatus, and he delighted in experiments outside his professional work.

As early as 1873 Thomson became a member of the Manchester Literary and Philosophical Society and he served for many years on its Council, being President in 1917—1918.

It is characteristic of the man that in the first paper he read before the Society he described a method for filling a chamber with pure air by filtering it through cotton wool, and showed that in such a spore-less atmosphere fungus did not grow on paste-covered surfaces. He recommended such a room for surgical operations. In later life he gave much attention to the pollution of the atmosphere in Manchester, and devised simple means by which the amount of smoke in the air could be tested from hour to hour.

After the "arsenic scare" of 1902, when many people were poisoned through the use of arsenical acid in making glucose, Thomson devised several pieces of apparatus for carrying out Marsh's test on small quantities of arsenic in presence of organic matter. He showed that the electrolytic method could be made exceedingly delicate, and, using a cathode of pure zinc or pure tin, he obtained results comparable in accuracy with those given by the more expensive apparatus recommended by the Committee appointed by the Inland Revenue Commissioners. Thomson showed that the dust in the Manchester air contained detectable quantities of arsenic, and a considerably larger quantity in the neighbourhood of glass works and copper smelting works.

Thomson made many experiments on the rotting of india-rubber, and the injurious action of certain metals and salts upon it. Copper, as makers of insulated wire had discovered, is poisonous beyond all metals, and so are its salts; on the other hand, although nitric and sulphuric acids are fatal, many acids, including chromic acid (and the chromates), are harmless, and so is hydrogen peroxide—in marked contrast to ozone.

Thomson was a fellow of the Edinburgh Royal Society, of the Institute of Chemistry, and of the Chemical Society, and he took an active part in the Manchester Section of the Society of Chemical Industry and of the Society of Dyers and Colourists.

He died suddenly in his laboratory on October 4th and was buried on October 7th in the Manchester Southern Cemetery. He was unmarried.

- Ward, Charles Frederick,** bromination of compounds containing the carbonyl group; (a) pyruvic acid; (b) acetophenone, 2207.
- Wardlaw, William, and Norman Darby Sylvester,** the oxidising properties of sulphur dioxide. Part IV. Molybdenum sulphates, 969.
sulphur dioxide as an oxidising agent, 3417.
- Wark, Ian William,** metallic hydroxy-acid complexes. Part I. Cupri-lactates, 1815.
metallic hydroxy-acid complexes. Part II. Cuprimalates; their formation, properties, and composition, 1826.
- Watson, Fred Sheasby.** See *James Brierley Firth*.
- Watson, Herbert Ben.** See *Kennedy Joseph Previté Orton*.
- Weeks, Edward Joseph.** See *Henry Julius Salomon Sand*.
- Werner, Emil Alphonse,** the constitution of carbamides. Part XV. A delicate and trustworthy test for the recognition of cyanic acid, 2577.
- Weston, Frank Edwin,** obituary notice of, 958.
- Wheeler, Richard Vernon.** See *William Payman*.
- Whiteley, (Miss) Martha Annie.** See *(Miss) Edith Hilda Usherwood*.
- Whitworth, Abraham Bruce.** See *Isidor Morris Heilbron*.
- Wilson, Forsyth James, and Robert Burns,** reactions of thiosemicarbazones. Part II. Action of esters of α -halogenated acids, 799.
- Wilson, Forsyth James, and William McNinch Hyslop,** application of the Grignard reaction to some acetylenic compounds. Part I. Preparation of diacetylenic glycols, 2612.
- Wilson, Forsyth James, and Eric Charles Pickering,** derivatives of semioxam-azides. Part I. Ketonic semioxam-azones, 394.
- Wood, Arthur Samuel.** See *Jocelyn Field Thorpe*.
- Wood, Charles Edmund, John Edward Such, and Frank Scarf,** rotatory dispersion of the esters of lactic acid. Part I. Normal esters, 600.
- Wood, John Kerfoot.** See *George Ernest Collins, and Charles Lea*.
- Worrell, Stanley Wilson.** See *Henry Julius Salomon Sand*.
- Worsley, Richard Robert le Geyt, and Herbert Brereton Baker,** the preparation and properties of selenium trioxide and chloroselenic acid, 2870.
- Wright, Robert,** selective solvent action by the constituents of aqueous alcohol. Part II. The effect of some alcohol-soluble semi-solutes, 2493.
- Wylam, Birkett.** See *Walter Norman Haworth*.

INDEX OF SUBJECTS.

TRANSACTIONS. 1923.

Sing's organic compounds of known empirical formula will be found in the Formula Index, p. 3472.

A.

Acetanilides, substituted, freezing-point curves of binary mixtures of (OWEN), 3392.
Acetic acid, cellulose ester, viscosity of solutions of (MARDLEN), 1951.
Acetylenic compounds, application of the Grignard reaction to (WILSON and HYSLOR), 2612.
Acids, aliphatic, distribution of, between water and benzene (BROWN and BERRY), 2430.
 bromination of (SHAW), 2233.
 aromatic open-chain, relative stability of, containing odd and even numbers of carbon atoms (CHALLENGER and THORPE), 2450.
 dicarboxylic, preparation and rotation of di-*l*-menthyl esters of (HALL), 105.
 fatty, structure of, by means of X-rays (MILLER), 2043.
 α -halogenated, esters, action of acetone-thiosemicarbazone on (WILSON and BURNS), 800.
 organic, salts, acid-alkali solution equilibrium in (PRIDEAUX), 1624.
 estimation of, with the quinhydrone electrode (HARRIS), 3501.
Additive reactions and tautomerism (USHERWOOD), 1717.
Address, presidential (WALKER), 939.
Affinity, residual, and co-ordination (MORGAN and REEVES), 414; (MORGAN and SMITH), 1096.
Agar-agar, swelling of (FAIRBROTHER and MARTIN), 1612.
Alabaster, synthesis of (COPESAROW), 796.
Alcohols, mutual solubility of glycerol and (McEWEN), 2284.
Aldehydes, absorption spectra of vapours and solutions of (PURYIN), 2515.
 mutual solubility of glycerol and (McEWEN), 2284.
 condensation of cyanoacetamide with (CUNTING, DAY, and KIMMINS), 3131.
Aldol reaction (USHERWOOD), 1717.

Alkali hydrogen sulphates (DUNNICLIFF), 731.
 polysulphides (THOMAS and RIDING), 1726.
Alkalis, estimation of, in rocks (WALKER), 2336.
Alkyl hypochlorites (CHATTAWAY and BACKEBERG), 2999.
 $\alpha\beta$ -Alkylacylcarbamides, preparation and chlorination of (ROBERTS), 2779.
Allelotropy (LOWRY), 823.
Amidines, tautomerism of (BUNTLES and PYMAN), 361; (PYMAN), 367, 3359.
 condensation of, with ethoxymethylene derivatives of β ketonic esters and of β -diketones (MITTER and HARDMAN), 2179.
 open-chain, alkylation of (PYMAN), 367.
Amines, photosynthesis of (SNOW and STONE), 1509.
 aromatic, chlorosulphonyl derivatives of (JOHNSON and SMILES), 2384.
 hydroferrocyanides of (CUMMING), 2461.
 primary, action of 2-dithiobenzoyl with (McCLELLAND and LONGWELL), 3310.
 tertiary, synthesis of (G. M. and R. ROBINSON), 532.
Amino acids, estimation of, with the quinhydrone electrode (HARRIS), 3294.
Amino alcohols, tertiary, elimination of the amino-group from (McKENZIE and RICHARDSON), 79.
Aminosulphonic acids, aromatic, condensation of, with isocyanic acid, phenylcarbimide, and cyanamide (SCOTT and COHEN), 3177.
Ammines, complex metallic (DUFF), 560.
Ammonia, action of sodium hypochlorite on (JOYNER), 1114.
Ammonium salts, quaternary, formation of (BARNETT, COOK, and DRAICOLL), 503.
 velocity of formation of (DEXTER, McCOMBIE, and SCARBOROUGH), 1229.

- Ammonium salts**, quaternary, perhalides of (CHATTAWAY and HOYLE), 654.
- Ammonium chloride**, equilibrium in the system, ferric chloride, water, and (CLENDINNEN), 1335.
- equilibrium of manganous chloride dihydrate and (CLENDINNEN and RIVETT), 1344.
- equilibria in the systems, water, manganese, iron, cobalt, nickel, or copper chlorides and (RIVETT and CLENDINNEN), 1634.
- nitrate, properties of (PERMAN and SAUNDERS), 841; (PERMAN and HOWELLS), 2128.
- sulphates, action of ethyl alcohol on (DUNNICLIFF), 476.
- hydrogen sulphate (DUNNICLIFF), 731.
- sulphides (THOMAS and RIDING), 1181.
- polysulphides (THOMAS and RIDING), 1726.
- tetranitrodiamminocobaltate (THOMAS), 617.
- Amylopectin**, nature of (LING and NANJI), 2666.
- Amylose**, polymerised, nature of (LING and NANJI), 2666.
- Anehdroxyhimbic acid sulphuric ester**, $C_{10}H_{14}O_4N_4S$.
- Annual General Meeting**, 922.
- Anthracene compounds**, *mesothio-* (HEILBRON and HEATON), 173.
- Anthracene series**, studies in (BARNETT and MATTHEWS), 330, 2549; (BARNETT, COOK, and MATTHEWS), 1994; (BARNETT and COOK), 2631.
- Anthranol alkyl ethers**, preparation of (BARNETT, COOK, and MATTHEWS), 2002.
- Anthranol blue**, constitution of (MASON), 1548.
- Anthraquinones**, hydroxy-, reduction of (HALL and PERKIN), 2029; (BREARE and PERKIN), 2603.
- Anthrene**, $C_{14}H_{10}O$.
- Antimony trichloride**, absorption of light by (MACBETH and MAXWELL), 370.
- trihydride, electrolytic formation of (SAND, WEEKS, and WORRELL), 456.
- Antimonious hydroxides** (LEA and WOOD), 269.
- Antimony organic compounds** (GONDARD), 2315.
- Aquopectaminocobaltic salts**. See under Cobalt.
- Arbutin**, $C_{12}H_{14}O_7$.
- Aromatic compounds**, polynuclear, molecular configurations of (CHRISTIE and KENNER), 779; (BURTON and KENNER), 1043; (CHRISTIE, JAMES, and KENNER), 1948.
- Aromatic compounds**, reactivity of halogens in (RHEINLANDER), 3099.
- Arsenic alloys with tin** (MANSURI), 214.
- Arsenic trichloride**, absorption of light by (MACBETH and MAXWELL), 370.
- Aryldiazonium salts**, condensation of alkylated malonic acids with (WALKER), 2775.
- Arylsulphonhalogeno-amides**, salts, use of, in the estimation and iodination of phenols (ROBERTS), 2707.
- Asymmetric compounds**, resolution of (COHEN), 2716.
- Atmospheric air**, explosion of mixtures of carbon monoxide and, at high pressures (BONE, NEWITT, and TOWNSEND), 2008.
- combustion of mixtures of carbon monoxide, hydrogen, and (PAYMAN and WHEELER), 1251.
- propagation of flame in mixtures of paraffins with (MASON), 210; (PAYMAN and WHEELER), 426.
- Atoms**, Bohr's theory of (SIDGWICK), 725.
- Anramine**, $C_{17}H_{21}N_3$.

B.

- Bacteria**, pigments from (McCOMBIE and SCARBOROUGH), 3279.
- Baeyer Memorial Lecture** (PERKIN), 1520.
- Balance sheets** of the Chemical Society and of the Research Fund. See Annual General Meeting, 922.
- Barium hydrogen sulphate** (DUNNICLIFF), 734.
- Bases**, estimation of, with the quinhydrone electrode (HARRIS), 3302.
- ψ -**Bases** (G. M. and R. ROBINSON), 532.
- Benzaldehydehydrazones**, nitro-, relation of colour and constitution in (CHATTAWAY and CLEMO), 3041.
- Benzobisthiazoles** (EDGE), 153, 1011, 2330.
- Benzene nucleus**, structure of (CHALLENOR and INGOLD), 2066; (INGOLD), 2081.
- influence of nitro-groups on the reactivity of substituents in the (IBBOTSON and KENNER), 1260.
- derivatives, substituted, Tesla-luminescence spectra of (McVICKER, MARSH, and STEWART), 2147.
- vicinal trisubstituted, substitution in (DAVIES), 1575; (DAVIES and RUBENSTEIN), 2839.
- Benzothiazole series** (MILLS, CLARK, and AESCHLIMANN), 2353, 2362.

- Bismarck brown**, $C_{15}H_{15}N_3$.
- Bismuth alloys** with tin and zinc (MUZAFFAR), 2341.
- Bismuth trichloride**, absorption of light by (MACBETH and MAXWELL), 370.
- Boiling point**, determination of elevation of (JARŁCZYŃSKI and KON), 2953.
- Bromination of aliphatic acids** (SHAW), 2333.
- of carbonyl compounds (WARD), 2207.
- Bromine**, interaction of, with acetic anhydride (ORTON, WATSON, and BAYLISS), 3081.
- reaction of ethylene with (NORRISH), 3006.
- action of, on phenylhydrazones (HUMPHRIES, BLOOM, and EVANS), 1766.
- n-Butyl series**, studies in the (MORGAN and HICKINBOTTOM), 97.
- C.**
- Cadmium**, vapour pressure of, and its alloys with zinc (EGERTON and RALEIGH), 3024.
- sulphide, and estimation of the metal (EGERTON and RALEIGH), 3019.
- Cesium hydrogen sulphate** (DUNNICLIFF), 733.
- Calcite**, formation of (COPESBROW), 793.
- Calcium carbonate**, heteromorphism of (COPESBROW), 785.
- hexahydrate (MACKENZIE), 2409.
- chloride, equilibria in the system, magnesium chloride, potassium chloride, water, and (LEE and EGERTON), 706.
- sulphate, heteromorphism of (COPESBROW), 796.
- Calorific value** of carbon compounds (KONOVALOV), 2184.
- Camphor**, $C_{15}H_{16}O$.
- Carbamides**, constitution of (WERNER), 2577.
- substituted, Hofmann reaction applied to (ELLIOTT), 864.
- Carbazole series**, *N*-derivatives in the (STEVENS and TUCKER), 2140.
- Carbocyanines**, formation of (MILLS and BRAUNHOLTZ), 2804.
- relation of methylenediquinaldine derivatives to (HAMEK), 246.
- Carbohydrates**, constitution of (IRVINE), 898.
- preparation of carbon from (FIRTH), 324.
- Carbon**, sorption of iodine by, from chloroform solution (FIRTH and WATSON), 1219.
- from carbohydrates, sorption of iodine by (FIRTH), 323.
- Carbon monoxide**, catalytic action of water vapour on (MEDSFORTH), 1464.
- explosion of mixtures of air and, at high pressures (BONE, NEWITT, and TOWNEND), 2008.
- explosion wave in mixtures of hydrogen and (DIXON and WALLS), 1025.
- combustion of mixtures of hydrogen, air, and (PAYMAN and WHEELER), 1251.
- oxides, action of hydrogen on (MEDSFORTH), 1452.
- Carbonyl compounds**, bromination of (WARD), 2207.
- Carrageen** (*Chondrus crispus*), mucilaginous substance from (HARWOOD), 2254.
- Carvone**, $C_{10}H_{16}O$.
- Castela Nicholsoni**, bitter principle from (BOSMAN), 207.
- Castalamarin**, $C_8H_{14}O_4$.
- Catalytic reactions**, promotion of (MEDSFORTH), 1452.
- Cellulose**, constitution of (IRVINE), 908.
- action of concentrated hydrochloric acid on (HIRST and MORRISON), 3226.
- cotton, molecular structure of (IRVINE and HIRST), 518.
- acetate, viscosity of solutions of (MARDLES), 1951.
- Charcoal**, activated sugar, action of hydrogen peroxide with (FIRTH and WATSON), 1750.
- Chemical constitution** and rotatory power (PICKARD, KENYON, and HUNTER), 1: (KENYON and McNIPT), 14; (PHILLIPS), 22, 44; (HALL), 32, 105; (PICKARD and HUNTER), 431; (HUNTER), 1671.
- reactivity and conjugation (HEILBRON, BARNES, and MORTON), 2559.
- Chemistry**, physical, applications of, in metallurgy (DZSCH), 280.
- Chlorine**, photochemical interaction of hydrogen and (CHAPMAN), 3062.
- monoxide**, photochemical decomposition of (BOWEN), 2328.
- thermal decomposition of (HINSHELWOOD and PRICHARD), 2730.
- monoxide and peroxide**, photochemical decomposition of solutions of (BOWEN), 1201.
- Hydrochloric acid**, influence of, on the enolising action of Grignard reagents (BHAGWAT), 1803.
- Hypochlorous acid**, action of, on boraylene (HENDERSON and MAIR), 1156.

- Chloroselenic acid, preparation and properties of (WORSLEY and BAKER), 2870.
- Chondrus crispus*. See Carrageen.
- Chromium trioxide, solubility of, in nitric acid (MUMFORD and GILBERT), 471.
- Chromoisomerism of stilbene compounds (CULLINANE), 2053.
- Chrysoidine-*Y*, $C_{15}H_{15}N_4$.
- Coal, absorption of water by (MOORE and SINNATT), 275.
- Cobalt, higher oxide of (HOWELL), 65.
- chloride, equilibrium of ammonium chloride, water, and (RIVETT and CLENDINNEN), 1634.
- Aquopentamminecobaltic salts (DUFF), 567, 570.
- Cobalt organic compounds (DUFF), 560.
- Cocoon oil, separation of octoic and decaoic acids from (WALKER), 2837.
- Colloids, transition of, to crystalloids (BIRCHMASHAW), 91.
- Colour, calculation of, of monocyclic compounds (MOIR), 2792.
- Colouring matters of the aurin type (BAINES and DRIVER), 1214.
- from diphenic anhydride (DUTT), 225.
- from heterocyclic bases (SMITH), 2288.
- Combustion of gaseous mixtures (PAYMAN and WHEELER), 1251.
- spiro*Compounds, formation and stability of (BAKER and INGOLD), 122; (INGOLD, LANFAR, and THORPE), 3140.
- Conine, C_8H_9N .
- Co-ordination and residual affinity (MORGAN and REEVES), 444; (MORGAN and SMITH), 1098.
- Co-ordination compounds and the Bohr atom (SUGWICK), 725.
- Copper chlorides, equilibrium of ammonium chloride, water, and (RIVETT and CLENDINNEN), 1634.
- sulphate pentahydrate, dissociation pressures of (PARTINGTON and HUNTINGFORD), 167.
- Cupric chloride, action of sodium hyposulphite on solutions of (FIRTH and HIGSON), 1515.
- salts, action of thiosulphates on (BASSETT and DURRANT), 1279.
- Cuprous nitrate and other cuprous salts, preparation and stability of, in presence of nitriles (MORGAN), 2901.
- Coumarina, amino-, diazo-transformations of (DEV and DALAL), 3384.
- bromonitro-, and their reactions with alkalis (DEV and ROW), 3375.
- Critical solution temperatures as criteria of purity (JONES), 1374, 1384.
- Crystal structure, relation between constitution and, of organic compounds (KNAGGS), 71.
- Crystals, mixed, equilibria of formation of (RIVETT and CLENDINNEN), 1634.
- Cupric salts. See under Copper.
- Caprimalic acid, $C_8H_9O_3Co$.
- iso*Cyanines, thio-, constitution of (MILLS and BRAUNHOLTZ), 2804.
- Cyanine colouring matters (MILLS and BRAUNHOLTZ), 2804.
- Cyanogen:—
- Cyanides, complex, dissociation of (BURROWS), 2026.
- Cyclic compounds, calculation of the colour of (MOIR), 2792.
- of the Ladenburg formula, synthesis of (FARMER), 3332.
- Cysteine, $C_3H_7O_2NS$.

D.

- Deoxy-yohimbine (BARGER and FIELD), 1042.
- Dialkyl sulphides, *ac'*-dichloro- (MANN and POPE), 1172.
- Dianthranyl, $C_{22}H_{18}$.
- Dianthrone, $C_{22}H_{18}O_2$.
- Dihydropentindole, $C_{11}H_{11}N$.
- β -Diketones, ethoxymethylene derivatives, condensation of amidines with (MITTER and BARDHAN), 2179.
- Dimethinediazidines, stability of (INGOLD and PIGGOTT), 2745.
- Disaccharides, constitution of (HAWORTH and LINNELL), 294; (HAWORTH and MITCHELL), 301; (HAWORTH and WYLAN), 3120.
- Dissociation pressure of hydrated salts (PARTINGTON and HUNTINGFORD), 160.
- Distyryl ketones, benzopyrylium salts of (BUCK and HEILBRON), 1395.
- 2-Dithiobenzoyl, $C_7H_4OS_2$.
- Dolomite, formation of (MITCHELL), 1887.
- composition of (MITCHELL), 1055.
- Drying, changes of properties of substances on (BAKER), 1223.

E.

- Electrodes, lead, overvoltage of (GLASSTONE), 2926.
- quinhydrone (VEIBEL), 2203.
- use of, in estimation of amino-acids (HARRIS), 3294.
- Electrolysis, intermittent current (GLASSTONE), 1745, 2926.
- Electrolyte, colloidal, from carrageen (HARWOOD), 2254.

- Electrolytes**, action of silica on (JOSEPH and HANCOCK), 2022.
- Electrotropy** (LOWRY), 828.
- Electrovalency**, studies in (LOWRY), 822; (NORRISH), 3006.
- Element**, new, oxide of (SCOTT), 311, 881.
- Erdmann's salt**, structure of (THOMAS), 617.
- Eserine**, $C_{15}H_{21}O_5N_3$.
- Esters**, Röntgen ray investigation of (SHEARER), 3152.
influence of the base on velocity of saponification of (CASHMORE, McCOMBS, and SCARBOROUGH), 197.
- Ethoxy-derivatives**, analysis of (DAVIES and RUBENSTEIN), 2848.
- Eugenol**, $C_{10}H_{12}O$.
- Explosions**, propagation of, in mixed gases (DIXON and WALLS), 1025.
gaseous, pre-pressure interval in (MORGAN), 1304.
- F.**
- Fenchone**, $C_{10}H_{16}O$.
- Ferric and Ferrous salts**. See under Iron.
- Filter-pump**, improved (HICKMAN), 3414.
- Flame**, propagation of, in mixed gases (MASON), 210; (PAYMAN), 412; (PAYMAN and WHEELER), 1251; (ELLIS), 1435.
- Formulas and symbols** (WALKER), 939.
- Fuel**, absorption of water by (MOORE and SINNATT), 275.
- G.**
- Gases**, explosion of, pre-pressure interval in (MORGAN), 1304.
mixed, rate of detonation in (PAYMAN and WALLS), 420.
effect of pressure on ignition of (PAYMAN and WHEELER), 426.
propagation of explosion in (DIXON and WALLS), 1025.
propagation of flame in (MASON), 210; (PAYMAN), 412; (PAYMAN and WHEELER), 1251; (ELLIS), 1435.
rare (MOUREU), 1905.
- Gas analysis apparatus**, absorption pipette (SAUNDERS), 2826.
- Gas mantles**, incandescent, catalysts in the making of (MEDFORTH), 1467.
- Gas reactions**, heterogeneous (HINSHELWOOD and TOPLEY), 1014; (HINSHELWOOD and PRICHARD), 2725, 2730.
homogeneous (HINSHELWOOD and PRICHARD), 2730.
- Gelatin**, isoelectric point of (PRICE), 410.
- Gentiobiose**, $C_{12}H_{22}O_{11}$.
- Glucosides** (MACBETH and MACKAY), 717.
constitution of (IRVING), 902.
optical rotation of (MALBY), 1401.
- Glucosides**. See also Arbutin.
- Glutaconic acids**, chemistry of (THORPE and WOOD), 62; (GOSS, INGOLD, and THORPE), 327, 8342.
- Glutathione**, $C_6H_{12}O_6N_2S$.
- Glycogen**, constitution of (IRVING), 912.
- Glycols**, diacetylenic (WILSON and HYSLOP), 2612.
- Gold**, catalytic action of (HINSHELWOOD and TOPLEY), 1020.
sols, protective action of potassium oleate on, in alcohol-water mixtures (RIDEAL and BIRCUMSHAW), 1565.
- Grignard reaction**, application of, to acetylenic compounds (WILSON and HYSLOP), 2612.
- Grignard reagents**, influence of hydrochloric acid on the enolising action of (BHAGWAT), 1803.
- H.**
- Hafnium** in zirconium ores (HEVEY and JANTZEN), 3218.
- Halogens**, reactivity of, in aromatic compounds (RHEINLANDER), 3099.
action of, on phenylhydrazones (HUMPHRIES, BLOOM, and EVANS), 1766.
- Halogen atoms**, lability of, in organic compounds (MACBETH), 1122; (HENDERSON, HIRST, and MACBETH), 1130.
- Heat of activation** of heterogeneous gas reactions (HINSHELWOOD and TOPLEY), 1014.
- m*-**Hemipinannilic acid**, $C_{14}H_{18}O_4N$.
- Heparene**, $C_{10}H_{12}$.
- Heptacyclene**, dithio-, $C_{10}H_{12}S_2$.
- Hexatriene**, $C_{10}H_{12}O_4$.
- Hofmann reaction**, application of, to substituted carbamides (ELLIOTT), 804.
- cis*-**Homocacronic acid**, $C_8H_{14}O_4$.
- Hydration** of salts, determination of, by a radioactive method (TERRY and JOLLY), 1979.
- Hydrasine**, preparation of (JOYNER), 1114.
- Hydrocalcite** (COPESAROW), 785.
- Hydrocarbons**, benzenoid, fluorescence spectra of the vapours of (MAISH), 3315.
paraffin, propagation of flame in mixtures of air and (MASON), 210.
- Hydrochloric acid**. See under Chlorine.

Hydroferriocyanides of organic bases (CUMMING), 2457.

Hydroferrocyanides of organic bases (CUMMING), 2457.

Hydrogen, activation of, at low temperature (MITCHELL and MARSHALL), 2448.

co-ordination of (LOWRY and BURGESS), 2111.

tautomeric, theory of, in relation to the theory of induced alternate polarities (ALLSOP and KENNER), 2296.

pure, electrolytic generator for (ELVEDEN and SINKINSON), 2715.

action of, on carbon oxides (MEDSFORTH), 1452.

combustion of mixtures of carbon monoxide, air, and (PAYMAN and WHEELER), 1251.

explosion wave in mixtures of carbon monoxide and (DIXON and WALLS), 1025.

photochemical interaction of chlorine and (CHAPMAN), 3062.

interaction of sulphur and (NORRISH and RIDEAL), 696, 1689, 3202.

peroxide, thermal decomposition of (HINSHELWOOD and PRICHARD), 2726.

action of activated sugar charcoal with (FIRTH and WATSON), 1750.

sulphide, action of, on unsaturated compounds (CHALLENGER, SMITH, and PATON), 1046.

Hydromuconic acids (FARMER), 2531, 3324.

Hydroxy-acids, metallic complexes of (WARK), 1815, 1826.

Hypochlorous acid. See under Chlorine.

Hypophosphorous acid. See under Phosphorus.

I.

Ignition of gases by a spark in a closed tube (ELLIS), 1435.

effect of pressure on (PAYMAN and WHEELER), 426.

Imino-aryl ethers (CHAPMAN), 1150.

Interfacial tension (POUND), 578.

Inulin, constitution of (IRVINE), 914.

Iodine, sorption of, by carbon (FIRTH), 323; (FIRTH and WATSON), 1219. reaction between phosphorous acid and (MITCHELL), 2241.

Iodine acid, reduction of *m*-methoxybenzyl bromide by (SHOESMITH), 2828.

Ionic micelle (McBAIN and BOWDEN), 2417.

Iron, corrosion of (FRIEND), 2996.

Iron chlorides, equilibrium of ammonium chloride, water, and (RIVETT and CLENDINNEN), 1634.

Ferric chloride, equilibrium in the system, ammonium chloride, water, and (CLENDINNEN), 1338.

hydroxide, adsorption of radium-*B* and -*C* and thorium-*B* and -*C* by (CRANSTON and HUTTON), 1318.

oxide, equilibrium of phosphoric acid, water, and (CARTER and HARTSHORNE), 2223.

Ferrous phosphate, kinetics of the reaction between sulphur dioxide and (CARTER and BUTLER), 2370, 2380.

Ivory, vegetable, mannan in (PATTERSON), 1139.

K.

Ketones, absorption spectra of vapours and solutions of (PURVIS), 2515.

mutual solubility of glycerol and (McEWEN), 2279.

unsaturated, reactivity of (HEILBRON and WHITWORTH), 238.

β -Ketonic esters, ethoxymethylene derivatives, condensation of amidines with (MITTER and BARRIHAN), 2179.

Kryptocyanine, constitution of (MILLS and BRAUNHOLTZ), 2804.

L.

β -Lactones, formation of (BAINS and THORPE), 2742.

Lauric acid, $C_{12}H_{24}O_2$.

Lead nitrate, solubility of, in water, and in mixtures with sodium and potassium nitrates (GLASSTONE and SAUNDERS), 2134.

Lead electrode. See Electrodes.

Lectures, delivered before the Chemical Society (DESCH), 280; (IRVINE), 898; (PERKIN), 1520; (MOUREU), 1905; (JEANS), 3398.

Light, absorption of, by inorganic salts (MACBETH and MAXWELL), 370.

Limestone, formation of (COPIBAROW), 794.

Liquids, purity of, from critical solution temperatures (JONES), 1374, 1384.

influence of a third substance on the miscibility of two (BAILEY), 2579.

organic, interfacial tension of, and water (POUND), 583.

Lithium hydrogen sulphate (DUNNICLIFF), 732.

hydrosulphide (JONES and THOMAS), 3285.

Longifolene, $C_{15}H_{24}$.

Longifollic acid, $C_{14}H_{22}O_2$.
 Longifollic acid, $C_{14}H_{22}O_2$.
 Longiforic acid, $C_{14}H_{24}O_4$.

M.

- Magnesium**, reaction between *p*-dibromobenzene and (PINK), 3418.
 carbonate trihydrate. See Nesquehonite.
 chloride, equilibria in the system, calcium chloride, potassium chloride, water, and (LEE and EGERTON), 706.
Maine coals, preparation of xylose from (LING and NANJ), 620.
Malonic acids, alkylated, condensation of aryl diazonium salts with (WALKER), 2775.
Manganese, electrolytic, properties of (CAMPBELL), 2323.
 chloride, equilibria of ammonium chloride, water, and (RIVETT and CLENDINNEN), 1934.
 perchloride, anodic formation of (CAMPBELL), 892.
 Manganous chloride dihydrate, equilibrium of ammonium chloride and (CLENDINNEN and RIVETT), 1344.
Mannan from vegetable ivory, and its derivatives (PATTERSON), 1139.
Marble, synthetic and metamorphic (COPIAROW), 785.
Memorial Lecture, van der Waals (JEANS), 3398.
Menthol, $C_{10}H_{18}O$.
Mercaptans, action of sulphur monochloride on (CHAKRAVARTI), 964.
Mercury, apparatus for purification of (DIXON and MCKEE), 895.
Mercury organic compounds (MAYNARD and HOWARD), 960.
Merotropy (LOWRY), 828.
Metallic hydrides, studies on (SAND, WEEKS, and WORRELL), 456.
 salts, complex (THOMAN and FRANK), 2973.
 hydrated, dissociation pressures of (PARTINGTON and HUNTINGFORD), 160.
Metallurgy, applications of physical chemistry to (DEUCH), 280.
Methanetetra-acetic acid, $C_8H_{12}O_8$.
***p*-Methoxysulphonic acids**, action of bromine on (MILDRUM and SHAW), 1982.
Methyl esters, velocity of saponification of (JONES, McCOMBIE, and SCARROUGH), 2688.
Methyl pentoses, optical rotation of (MALTY), 1404.
Molecular phases and absorption spectra (MORTON and BARNES), 2570.
Moleculon, catalytic activation of (NORRISH), 3906.
Molybdenum sulphates, action of sulphur dioxide on (WARDLAW and SYLVESTER), 969.
Monosaccharides, constitution of (HIRST and PURVES), 1352.
Morphine, $C_{17}H_{19}O_3N$.
Morphine group (GULLAND and ROBINSON), 986, 998.
Moss, Irish. See Carrageen.
Motor, laboratory water (HICKMAN), 3415.
Muconic acids (FARMER), 2531, 3324.

N.

- Naphthalene derivatives**, synthesis of (CHALLENGER and INGOLD), 2068.
Naphthapyrones, amino-, diazo-transformations of (DRY and DALAI), 3384.
Narcotine, $C_{28}H_{48}NO_2$.
Nesquehonite, preparation of, and its solubility (MITCHELL), 1897.
Nickel chloride, equilibrium of ammonium chloride, water, and (RIVETT and CLENDINNEN), 1634.
 higher oxide of (HOWELL), 669, 1772.
 sulphide, oxidation of (DUNN and RIDEAL), 1242.
Nitration, studies in (ARNALL), 3111.
Nitrogen atoms, doubly-linked, stereochemistry of (MILLS and SCHINDLER), 312.
 compounds, photosynthesis of, from carbon dioxide and ammonia (BALY, HILBRON, and STERN), 185.
 trichloride, photochemical decomposition of solutions of (BOWEN), 1203.
Nitric acid, solubility of chromium trioxide in (MUMFORD and GILBERT), 471.
Nitrosyl chloride, preparation of (PICKARD and HUNTER), 441.

O.

Oils, interfacial tension of, and water (POUND), 583.

Oleic acid, $C_{18}H_{34}O_2$.

m-Optianic acid, $C_{10}H_{18}O_4$.

Optical inversion, Walden's (PHILLIPS), 44.

rotation. See Rotation.

Organic compounds, calorific value of (KONOVALOV), 2184.

relation between crystal structure and constitution of (KNAGGS), 71.

lability of halogenatoms in (MACBETH), 1122; (HENDERSON, HIRST, and MACBETH), 1130.

action of sulphuryl chloride on (DURRANS), 1424.

with long carbon chains, Röntgen ray investigation of (SHEARER), 3152; (MÜLLER and SHEARER), 3156.

Overvoltage, measurement of (SAND and WEEKS), 2896.

influence of intermittent current on (GLASTONE), 1745.

Oxalato-salts, dissociation of (BURROWS and WALKER), 2738.

Oximes, isomerism of (BRADY and McHUGH), 1190; (BRADY and DUNN), 1783; (BRADY and RIDGE), 2163; (BRADY and TRUSZKOWSKI), 2434.

influence of dilution on the dissociation of hydrochlorides of (TANSLEY), 3164.

Oxygen, diffusion of, through silver (SPENCER), 2124.

catalytic action of, on the reaction between hydrogen and sulphur (NORRISH and RIDEAL), 1689, 3202. estimation of small amounts of, colorimetrically (HAND), 2573.

Ozone, photochemical reactivity of (GRIFFITH and SHUTT), 2752; (GRIFFITH and MACWILLIE), 2767.

P.

Palladium, catalytic action of (HINSHELWOOD and TOPLEY), 1020.

Paraffins, ignition of mixtures of air and (MASON), 210; (PAYMAN and WHEELER), 426.

Paraformaldehyde, conversion of, into glycollic acid (HAMMICK and BOEREN), 2881.

Pentathionic acid. See under Sulphur.

Phellandrenes, $C_{10}H_{16}$.

Phenanthraquinone colouring matters (A. C. and G. C. SIRCAR), 1559.

Phenols, increased solubility of, in water, on addition of a third substance (BAILEY), 2379.

Phenols, mutual solubility of glycerol and (McEWEN), 2284.

condensation of diphenylformamidine with (SHOESMITH and HALDANE), 2704.

nitrosation of (HODGSON and MOORE), 2499.

estimation and iodination of, by means of salts of arylsulphonhalogeno-amides (ROBERTS), 2707.

Phenols, o-thiol-, derivatives of (GIBSON and SMILES), 2388.

Phenoldiphenesin, $C_{20}H_{18}O_4$.

Phenolthioxin derivatives (KRISHNA), 2782.

Phenylcarbamides, p-substituted, sulphonation of (SCOTT), 3191.

Phenylhydrazones, action of halogens on (HUMPHRIES, BLOOM, and EVANS), 1766.

Phosphatopentamminecobalt, and its hydrogen phosphate (DUFF), 568, 571.

Phosphorus :—

Phosphoric acid, equilibrium of ferric oxide, water, and (CARTER and HARTSHORNE), 2223.

Phosphorous acid, reaction between iodine and (MITCHELL), 2241.

Hypophosphorous acid, studies on (MITCHELL), 629.

Phosphorus organic compounds (BOYD and CHIGNELL), 813.

Photocatalysis (BALY, HEILBRON, and STERN), 185.

Photochemistry of unstable substances (BOWEN), 1199.

Photosynthesis of amines (SNOW and STONE), 1509.

Phototropy (HEILBRON, HUDSON, and HUISH), 2273.

Physostigmine. See Eserine.

Pigments from bacteria, constitution of (McCOMBIE and SCARBOROUGH), 3279.

Pinacol-pinacolin transformation, mechanism of (INGOLD), 1706.

Pinus longifolia, Indian turpentine from (SIMONSEN and RAU), 549; (SIMONSEN), 2642.

Piperazine, $C_4H_{10}N_2$.

Piperidine, $C_4H_{11}N$.

Piperitone, $C_{10}H_{18}O$.

Platinum, valency of, in mercaptan compounds (RAY), 133.

Polarity, theory of induced alternate, in relation to the tautomeric hydrogen theory (ALLSOP and KENNER), 2296.

Polycyclic compounds, chemistry of, in relation to their homocyclic unsaturated isomerides (INGOLD, SEELEY, and THORPE), 853; (GRIMWOOD, INGOLD, and THORPE), 3303.

Polysaccharides, constitution of (IRVINE and HIRST), 518.

Polysulphides, organic (RIDING and THOMAS), 3271.

Posidonia, chemistry of the fibre of (EARL), 3223.

Potassium salts, density of dilute solutions of (HARTLEY and BARRETT), 398.

chloride, equilibrium of ammonium nitrate and (PERMAN and SAUNDERS), 841.

equilibria in the system, calcium chloride, magnesium chloride, water, and (LEE and EGERTON), 706.

nitrate, equilibrium of lead nitrate, water, and (GLASTONE and SAUNDERS), 2134.

freezing-point curves for mixtures of sodium nitrate and (BRISCOE and MADGIN), 1603; (MADGIN and BRISCOE), 2914.

tetroxide, interaction of, with ice and with dilute sulphuric acid (HAWLEY and SAND), 2391.

sulphate, equilibrium of ammonium nitrate and (PERMAN and HOWELLS), 2128.

pentasulphide, action of, on alkyl halides (RIDING and THOMAS), 3271.

Potassium organic compounds:—
arylsulphoniodoamides (ROBERTS), 849.

Potassium, detection and estimation of, with sodium 3-chloro-5-nitro-*m*-toluenesulphonate (H. and W. DAVIES), 2976.

Promoters in catalysis (MEDEWORTH), 1452.

Propane series, keto-cyclol change in the (LANFRAN and THORPE), 1683.

cycloPropane series, tautomerism in (GOSA, INGOLD, and THORPE), 327, 3342.

Prototropy (LOWRY), 828.

Pseudomerism (LOWRY), 828.

Parine group, mercaptans of (RAY, CHAKRAVARTI, and BOSE), 1937.

Purity, critical solution temperatures as criteria of (JONES), 1374, 1384.

Pyrazine, $C_4H_4O_2N_2$.

Pyrazole series, substitution in the (MORGAN and ACKERMAN), 1308.

Pyridine, C_5H_5N .

Pyrylium salts, synthesis of (PRATT and ROBINSON), 745.

Q

Quetracchine. See Yohimbine.

Quinaldine acid, $C_{10}H_8O_3N$.

Quinhydrone electrode. See Electrodes.

Quinoline, C_8H_7N .

Quinones, absorption spectra of the vapours of (PURVIS), 1841.

Quinoxaline derivatives, reduced, isomerism of (BENNETT and GIBSON), 1570.

(BARGER and FIELD), 1040.

Z.

Zinc alloys with bismuth and tin
(MUZAFFAR), 2341.
with cadmium, vapour pressure of
(EGERTON and RALEIGH), 3024.
Zirconium ores, hafnium content of
(HEVESY and JANTZEN), 3218.

FORMULA INDEX.

The following index of organic compounds of known empirical formula is arranged according to Richter's system (see *Lexikon der Kohlenstoff-Verbindungen*).

The elements are given in the order C, H, O, N, Cl, Br, I, F, S, P, and the remainder alphabetically.

The compounds are arranged—

Firstly, in groups according to the number of carbon atoms (thus C₁ group, C₂ group, etc.).

Secondly, according to the number of other elements besides carbon contained in the molecule (thus 5 IV indicates that the molecule contains five carbon atoms and four other elements).

Thirdly, according to the nature of the elements present in the molecule (given in the above order).

Fourthly, according to the number of atoms of each single element (except carbon) present in the molecule.

Salts are placed with the compounds from which they are derived. The chlorides, bromides, iodides, and cyanides of quaternary ammonium bases, however, are registered as group-substances.

C₁ Group.

CH₄ Methane, catalytic preparation of (MEDSFORTH), 1452; synthesis of the polyacetic acids of (DREIFUSS and INGOLD), 2964.

CO Carbon monoxide, catalytic action of water vapour on (MEDSFORTH), 1464; explosion of mixtures of air and (BOKE, NEWITT, and TOWNEND), 2008; explosion of mixtures of hydrogen and (DIXON and WALLS), 1025; combustion of mixtures of hydrogen, air, and (PAYMAN and WHEELER), 1251.

1 II

CHN Hydrocyanic acid, sodium salt, vapour pressure curve for (INGOLD), 895.

CH₂O Formic acid and its esters, preparation and rotation of (PICKARD, KENYON, and HUNTER), 9; decomposition of (HINSHELWOOD and HARTLEY), 1333; thermal decomposition of the vapour of (HINSHELWOOD and TOPLEY), 1014.

CH₂N₂ Cyanamide, condensation of aromatic aminosulphonic acids with (SCOTT and COHEN), 3177.

CH₃O Methyl alcohol, estimation of acetone in, and its purification (BATES, MULLALLY, and HARTLEY), 401.

CH₃N Methylamine, photosynthesis of (BALY, HEILBRON, and STERN), 186.

CNS Thiocyanogen, action of, on unsaturated compounds (CHALLENGER, SMITH, and PATON), 1046.

1 III

CHON Cyanic acid, detection of (WERNER), 2577.

*iso*Cyanic acid, condensation of aromatic aminosulphonic acids with (SCOTT and COHEN), 3177.

CHO₂N Nitroform, electrical conductivity and reduction of derivatives of (HENDERSON, HIRST, and MACHETH), 1130.

CENS Thiocyanic acid, action of, on unsaturated compounds (CHALLENGER, SMITH, and PATON), 1046.

CO₂NEF Bromopicrin, preparation and reactions of (HUNTER), 543.

C₂ Group.

C₂H₄. Ethylene, reaction of bromine with (NORRISH), 3006.

2 II

C₂H₂O₄. Oxalic acid, aquopentammine cobaltic salt (DUFF), 565; esterification of (DUFF), 2714.

C₂H₄O₂. Acetic acid, binary critical solution temperatures as criteria of the purity of (JONES), 1374.

C₂H₄O₃. Glycollic acid, preparation of, from paraformaldehyde (HAMMICK and BORRER), 2881.

C₂H₄S₂. Ethylene disulphide, oxidation of (RAY), 2176.

C₂H₅O. Ethyl alcohol, solubility of substances in mixtures of water and (WRIGHT), 2493; action of, on ammonium sulphates (DUNNICLIFF), 478.

C₂H₆S₂. Dimethyl pentasulphide (RIDING and THOMAS), 3277.

C₂H₅Hg. Mercury dimethyl, preparation of (MAYNARD and HOWARD), 960.

C₂N₂S₂. Substance, from 2:5-dithiol-1:3:4-thiadiazole and sulphur monochloride (CHAKRAVARTI), 967.

2 III

C₂H₃O₂Cl. Dichloroacetic acid, molecular refraction of, and of its derivatives (VANDERSTICHELE), 1225; isomorphism of the amides and substituted amides of chlorobromoacetic acid and (McKIE), 2213.

C₂H₃O₂Cl. Chloroacetic acid, molecular refraction of, and of its derivatives (VANDERSTICHELE), 1225.

C₂H₅OLi. Lithium ethoxide, action of hydrogen sulphide on (JONES and THOMAS), 3285.

C₂H₅O₂N₂. Semioxamazide, derivatives of (WILSON and PICKERING), 394.

C₂H₅O₂S. Methyl sulphate, action of, on diphenylamine and on methyldiphenylamine (GIBSON and VINING), 831.

C₂H₄O₂S₂. Ethane- $\alpha\beta$ -disulphonic acid, barium salt (RAY), 2176.

C₂O₂N₂K₂. *s*-Dipotassium tetranitroethane (HUNTER), 547.

2 IV

C₂H₃O₂ClBr. Chlorobromoacetic acid, molecular refraction of, and of its derivatives (VANDERSTICHELE), 1225; isomorphism of the amides and substituted amides of dichloroacetic acid and (McKIE), 2213.

C₂H₃O₂ClI. Chloroiodoacetic acid, and its barium salt (CROMPTON and CARTER), 576.

C₂H₄OCl₂S. $\alpha\alpha'$ -Dichlorodimethyl sulphoxide (MANN and POPE), 1174.

C₂H₃O₂N₂Co. Oxalatodinitrodiamminecobaltic acid, barium and strychnine salts (THOMAS), 619.

C₂H₃O₂N₂Co. Oxalatopentamminecobaltic hydroxide, nitrate of (+2H₂O) (DUFF), 566.

2 V

C₂H₁₁O₂N₂SCo. Sulphoacetatopentamminecobaltic hydroxide, nitrate of (DUFF), 566.

C₂H₁₁O₂N₂S₂Co. Methionatodipentamminecobaltic nitrate methionate (DUFF), 566.

C₃ Group.

C₃H₄O₄. Malonic acid, conversion of, into *d*-malic acid (McKENZIE and PLENDER-LEITH), 1090.

C₃H₆O. Acetone, estimation of, in methyl alcohol (BATES, MULLALLY, and HARTLEY), 401.

C₃H₄O₃. Lactic acid, complex copper salts of (WARE), 1815; rotatory dispersion of esters of (WOOD, SUCH, and SCARF), 600.

- C_3H_8O , Glycerol, mutual solubility of alcohols, aldehydes, and phenols with (McEWEN), 2284; mutual solubility of ketones and (McEWEN), 2279.
 C_3H_7N Trimethylamine, addition of *p*-nitrobenzyl chloride to (DEXTER, McCOMBIE, and SCARBOROUGH), 1237.

3 III

- $C_3H_3O_2Br$ Bromopyruvic acid (WARD), 2210.
 $C_3H_3N_2Br$ 2-Bromoglyoxaline, and its salts (KING and MURCH), 626.
 C_3H_5ON Cyanoacetamide (CURTIS, DAY, and KIMMINS), 3131.
 C_3H_7OCl Propyl hypochlorites (CHATTAWAY and BACKBERG), 3001.

3 IV

- C_3H_7ONCl Dichloroacetomethylamide (McKIN), 2214.
 $C_3H_7O_2NS$ Cysteine, oxidation and reduction potentials of (DIXON and QUASTEL), 2943.
 $C_3H_7O_2N_2Co$ Malonatodinitro-*cis*-diamminocobaltic acid, barium salt (THOMAS), 619.
 $C_3H_7O_2N_3Co$ Malonatodipentamminecobaltic hydroxide, nitrate of (+ H_2O) (DUFF), 566.

3 V

- $C_3H_7ONClBr$ Chlorobromoacetomethylamide (McKIN), 2214.

 C_4 Group.

- $C_4H_6O_2$ Acetic anhydride, interaction of bromine with (ORTON, WATSON, and BAYLESS), 3081.
 $C_4H_6O_4$ Malic acid, complex copper salts of (WARK), 1826.
 d -Malic acid, preparation of, from malonic acid (McKENZIE and PLENDERLEITH), 1090.
 r -Malic acid, resolution of (McKENZIE, PLENDERLEITH, and WALKER), 2879.
 $C_4H_6O_2$ Racemic acid, optical activation of (McKENZIE, PLENDERLEITH, and WALKER), 2875.
 C_4H_8S Divinyl sulphide, action of halogen hydrides on (BALES and NICKELSON), 2436.
 $C_4H_8S_2$ Diethylidene trisulphide (MANN and POPE), 1177.
 $C_4H_6N_2$ 4-Amino-3,5-dimethylpyrazole, condensation of, with aromatic aldehydes (MORGAN and ACKERMAN), 1311.
 $C_4H_{10}N_2$ Piperazine, hydroferrocyanide of (CUMMING), 2457.
 $C_4H_{10}S_2$ Substance, from ethyl mercaptan and sulphur monochloride (CHAKRAVARTI), 966.
 $C_4H_{10}S_3$ Diethyl pentasulphide (RIDING and THOMAS), 3275.
 $C_4H_{10}S_2$ Substance, from dithioethylene glycol and sulphur monochloride (CHAKRAVARTI), 966.

4 III

- $C_4H_4N_4Pt$ Hydroplatinocyanic acid, equilibrium of mixtures of lithium and potassium salts of, and their hydrates (TERREY and JOLLY), 2217.
 $C_4H_6O_2Cu$ Cupramalic acid, salts of (WARK), 1832.
 $C_4H_6O_4Cl_2$ r - $\gamma\gamma$ -Trichloro- β -hydroxybutyric acid, resolution of (McKENZIE and PLENDERLEITH), 1092.
 $C_4H_3N_2Br$ 2-Bromo-4-methylglyoxaline, and its picrate (PYMAN and TIMMIS), 498.
 $C_4H_5N_3I$ 4-Iodo-3-(or 5-)methylpyrazole, and its salts (MORGAN and ACKERMAN), 1315.
 $C_4H_7O_2Br$ Ethyl bromoacetate, addition of, to pyridine (DEXTER, McCOMBIE, and SCARBOROUGH), 1236.

FORMULA INDEX.

4 II-4 V

- C_2H_5ClS α -Chloroethyl vinyl sulphide (BALES and NICKELSON), 2488.
 C_2H_5BrS α -Bromoethyl vinyl sulphide (BALES and NICKELSON), 2488.
 $C_2H_5O_2S$ 1:4-Thioxan sulphoxide (CASHMORE), 1741.
 $C_2H_5Cl_2S$ $\beta\beta'$ -Dichlorodiethyl sulphide, hydrolysis of (BALES and NICKELSON), 2486; interaction of, with glycine ester and with potassium phthalimide (CASHMORE and McCOMBIE), 2884.
 $C_2H_5Br_2S$ $\alpha\alpha'$ -Dibromodiethyl sulphide (BALES and NICKELSON), 2488.
 C_2H_5OCl Butyl hypochlorites (CHATTAWAY and BACKERBERG), 3001.
 $C_2H_5O_2N$ Ethyl glycine, interaction of, with $\beta\beta'$ -dichlorodiethyl sulphide, sulphone, and sulphoxide (CASHMORE and McCOMBIE), 2884.
 $C_2H_4O_2S$ $\beta\beta'$ -Dihydroxydiethyl sulphoxide (CASHMORE), 1742.
 $C_2H_5O_2S$ Diethylsulphonedisulphonic acid, barium salt (RAY), 2176.
 C_2H_7OTl Thalliumdiethyl hydroxide, salts of (GODDARD), 1166.
 $C_4H_{12}NBr_3$ Tetramethylammonium tribromide (CHATTAWAY and HOYLE), 656.
 $C_4H_{12}O_2N$ Maleatopentamminecobaltic hydroxide, nitrate of (DUFF), 567.

4 IV

- $C_4H_5O_2N_2Br$ 5-Bromoglyoxaline-4-carboxylic acid, and its nitrate (KING and MURCH), 628.
 $C_4H_5O_2N_2I$ 4-Iodopyrazolecarboxylic acid, and its silver salt (MORGAN and ACKERMAN), 1315.
 $C_4H_5ONCl_2$ Dichloroacetoethylamide (McKIE), 2215.
 $C_4H_5ON_2S$ 2:4-Diketo-5-methyltetrahydrothiazole-2-hydrazone, hydrochloride of (WILSON and BURNS), 801.
 C_4H_5ONCl Butyrylchloroamides (ROBERTS), 2781.
 $C_4H_5OCl_2S$ $\beta\beta'$ -Dichlorodiethyl sulphoxide, hydrolysis of (CASHMORE), 1738; interaction of, with glycine ester and with potassium phthalimide (CASHMORE and McCOMBIE), 2884.
 $C_4H_5O_2Cl_2S$ $\beta\beta'$ -Dichlorodiethylsulphone, hydrolysis of (CASHMORE), 1738; interaction of, with glycine ester and with potassium phthalimide (CASHMORE and McCOMBIE), 2884.
 C_4H_5ClBrS α -Chloro- α' -bromodiethyl sulphide (BALES and NICKELSON), 2488.
 $C_4H_5ClS_2Pt$ Substance, from diethyl disulphide and platinum chloride (RAY), 139.
 $C_4H_{12}NCl_4$ Tetramethylammonium tetraiodochloride (CHATTAWAY and HOYLE), 658.
 $C_4H_{12}NCl_2Br$ Tetramethylammonium dichlorobromide (CHATTAWAY and HOYLE), 655.
 $C_4H_{12}NBrI_2$ Tetramethylammonium di-iodobromide (CHATTAWAY and HOYLE), 656.
 $C_4H_{12}NBrI_3$ Tetramethylammonium tri-iodobromide (CHATTAWAY and HOYLE), 658.
 $C_4H_{12}NBrI_4$ Tetramethylammonium tetra-iodobromide (CHATTAWAY and HOYLE), 658.
 $C_4H_5O_2N_2Co$ Mesotartratopentamminecobaltic hydroxide, nitrate of (+3H₂O) (DUFF), 569.
 $C_4H_5O_2N_2Co$ Maleatodipentamminecobaltic hydroxide, nitrate of (DUFF), 567.
 $C_4H_5O_2N_2Co$ Malatodipentamminecobaltic hydroxide, nitrate of (DUFF), 567.

4 V

- $C_4H_5ONClBr$ Chlorobromoacetoethylamide (McKIE), 2215.

3475

5 Z

CXXIII.

$C_4H_{12}NCIBrI$ Tetramethylammonium chlorobromiodide (CHATTAWAY and HOYLE), 655.

C₅ Group.

C_5H_8 Hydrocarbon, from dibromodimethylcyclopropane, oxidation of (INGOLD), 1711.

5 II

C_5H_5N Pyridine, photosynthesis of (BALY, HEILBRON, and STERN), 188; addition of ethyl bromoacetate to (DEXTER, McCOMBIE, and SCARBOROUGH), 1236; ferrocyanides of, and its separation from isoquinoline (CUMMING), 2461.

$C_5H_{10}O_5$ Xylose, structure of (HIGER and PURVES), 1352; preparation of, from maize cobs (LING and NANJI), 620.

$C_5H_{11}N$ Piperidine, photosynthesis of (BALY, HEILBRON, and STERN), 188; hydroferrocyanide of (CUMMING), 2457.

$C_5H_{11}N$ Methyl-diethylamine, preparation of, and its chloroplatinate (G. M. and R. ROBINSON), 539.

5 III

$C_5H_8OS_2$ 2-Dithiobenzoyl, action of primary amines with (McCLELLAND and LONGWELL), 3311.

$C_5H_7N_2Cl$ 4-Chloro-3:5-dimethylpyrazole (MORGAN and ACKERMAN), 1317.

$C_5H_7N_2Br$ 4-Bromo-3:5-dimethylpyrazole, and its chloraurate (MORGAN and ACKERMAN), 1316.

$C_5H_7N_2I$ 4-Iodo-3:5-dimethylpyrazole, and its salts (MORGAN and ACKERMAN), 1313.

$C_5H_8O_4N_2$ Pentaerythritol nitrate, crystal structure of (KNAGGS), 77.

$C_5H_8O_4N_2$ Acetone-semioxamazone, and its sodium salt (WILSON and PICKERING), 395.

C_5H_9OCI *tert.*-Amyl hypochlorite (CHATTAWAY and BACKERBERG), 3002.

5 IV

$C_5H_8ON_2S_2$ 2:6-Dithiol-8-hydroxypurine, and its sodium salt (RAY, CHAKRAVARTI, and BOSE), 1959.

$C_5H_8ON_2Br$ 2-Bromo-4-methylglyoxaline 5-carboxylic acid (PYMAN and TIMMIS), 498.

$C_5H_8ON_2I$ 4-Iodo-3 (or 5)-methylpyrazolecarboxylic acid, and its silver salt (MORGAN and ACKERMAN), 1316.

$C_5H_8ON_2Br$ Bromonitrodimethylglyoxalines (PYMAN and TIMMIS), 502.

$C_5H_8ON_2S$ 5-Nitro-1:4-dimethylglyoxaline-2-sulphonic acid (PYMAN and TIMMIS), 502.

$C_5H_7N_2ICl_2$ 4-Iodo-3:5-dimethylpyrazole dichloride (MORGAN and ACKERMAN), 1314.

$C_5H_7N_2IBr$ 4-Iodo-3:5-dimethylpyrazole dibromide (MORGAN and ACKERMAN), 1314.

$C_5H_8ON_2S$ 3:5-Dimethylpyrazole-4-sulphonic acid (+ $\frac{1}{2}H_2O$) (MORGAN and ACKERMAN), 1313.

$C_5H_7N_3S$ 2-Methyltriazole methiodide (SMITH), 2290.

$C_5H_7N_2ICl$ 4-Iodo-3:5-dimethylpyrazole iodochloride hydrochloride (MORGAN and ACKERMAN), 1314.

$C_5H_8ON_2S_2$ 2:4-Diketo-5-ethyltetrahydrothiazole-2-hydrazide, and its hydrochloride (WILSON and HUENA), 802.

$C_5H_{12}O_4N_2Co_2$ Citraconatodipentamminecobaltic hydroxide, nitrate of (DUFF), 565.

Itaconatodipentamminecobaltic hydroxide, nitrate of (DUFF), 568.

FORMULA INDEX.

5 IV-6 III

$C_6H_{10}O_8N_4CO_2$ Glutaratodipentamminecobaltic hydroxide, nitrate of (DUFF), 568.

5 V

$C_6H_7O_2N_4ClS$ 3:5-Dimethylpyrazole-4-sulphonyl chloride (MORGAN and ACKERMAN), 1313.

C₆ Group.

C_6H_6 Benzene, constitution of (FRASER), 2712; Tesla-luminescence spectrum of (McVICKER, MARSH, and STEWART), 642; (McVICKER and MARSH), 817; fluorescence spectrum of the vapour of (McVICKER and MARSH), 820; and its homologues, fluorescence spectra of the vapours of (MARSH), 3315; distribution of fatty acid between water and (BROWN and BURY), 2430.

6 II

- $C_6H_4Br_2$ *p*-Dibromobenzene, reaction between magnesium and (PINK), 3418.
- $C_6H_4Cl_2$ *p*-Dichlorobenzene, nitration of (PAGE and HEARMAN), 3247.
- $C_6H_5N_3$ Benzisotriazole, chloroplatinate of (MILLS and SCHINDLER), 321.
- C_6H_5O Phenol, velocity of nitration of (ARNALL), 3111.
- $C_6H_4O_4$ 3-Methyl- Δ^3 -cyclopropene-1:2-dicarboxylic acid (GOSS, INGOLD, and THORPE), 348.
- $C_6H_4O_4$ *trans*-3-Methylcyclopropane-1:2-dicarboxylic acid (GOSS, INGOLD, and THORPE), 3353.
- $C_6H_8N_2$ Phenylenediamines, solubility of (SIDGWICK and NEILL), 2813.
- $C_6H_{11}O_5$ Galactose, structure of (PRYDE), 1898.
- Glucose, action of concentrated hydrochloric acid on derivatives of (HIEST and MORRISON), 3226.
- $C_6H_{12}S_3$ Triethylene trisulphide, oxidation of (RAY), 2174.
- Trithioacetaldehydes, isomeric (MANN and POPE), 1178.
- $C_6H_{12}S_4$ Triethylene tetrasulphide, oxidation of (RAY), 2174.
- $C_6H_{14}S_5$ Dipropyl pentasulphide (RIDING and THOMAS), 3278.

6 III

- $C_6H_5O_{11}Al$ Aluminioxalic acid, sodium salt, dissociation of (BURROWS and WALKER), 2741.
- $C_6H_5O_{12}Cr$ Chromoxalic acid, dissociation of salts of (BURROWS and WALKER), 2740.
- $C_6H_5O_{12}Fe$ Ferrioxalic acid, dissociation of salts of (BURROWS and WALKER), 2741.
- $C_6H_5N_4Co$ Hydrocobalticyanic acid, potassium salt, dissociation of (BURROWS), 2029.
- $C_6H_5N_4Cr$ Hydrochromicyanic acid, potassium salt, dissociation of (BURROWS), 2029.
- $C_6H_5N_4Fe$ Hydroferricyanic acid, potassium salt, dissociation of (BURROWS), 2028.
- $C_6H_5O_4N_6$ 6-Nitro-1-hydroxy-1:2:3-benzotriazole (BRADY and DAY), 2266.
- $C_6H_5N_4Fe$ Hydroferrocyanic acid, salts, dissociation of (BURROWS), 20-8; salts of, with organic bases (CUMMING), 2457.
- $C_6H_5O_2N$ Nitrobenzene, freezing point of, and its use in cryoscopy (ROBERTS and BURY), 2037.
- $C_6H_5O_4Br$ 1-Bromo-3-methyl- Δ^3 -cyclopropene-1:2-dicarboxylic acid (GOSS, INGOLD, and THORPE), 3356.
- $C_6H_8N_4Cl_3$ 2:4:6-Trichlorophenylhydrazine, and its hydrochloride (ELLIOTT), 812.
- $C_6H_5N_3S$ Benzisotriazolyl mercaptan (MILLS and SCHINDLER), 321.

- $C_6H_8O_4Br_2$ *trans*-1:2-Dibromomethylcyclopropane-1:2 dicarboxylic acid (GOSS, INGOLD, and THORPE), 3355.
 $C_6H_8N_2Br_2$ 3:4-Dibromophenyldiazine, preparation of (HUMPHRIES, BLOOM, and EVANS), 1769.
 $C_6H_8O_4Cl$ 3-Acetylpropionylchloromethane, copper salt (MORGAN and REEVES), 449.
 $C_6H_8O_4Te$ Tellurium acetylpropionylmethane (MORGAN and REEVES), 450.
 $C_6H_8O_4Cl_2$ *ss'*-Dichloroadipic acid (FARMER), 2540.
 $C_6H_{11}O_2N_2$ Methyl ethyl ketone semioxamazone, and its sodium salt (WILSON and PICKERING), 395.
 $C_6H_{10}O_4S_2$ Triethylenedisulphone disulphide (+ H_2O) (RAY), 2177.
 $C_6H_{10}O_4S_3$ Triethylenetrisulphone (RAY), 2177.
 $C_6H_{14}O_4S_2$ *ss'*-Dimethoxydiethylsulphone (CASHMORE), 1743.
 $C_6H_{14}O_{10}S_4$ Triethylenedisulphonedisulphonic acid, barium salt (RAY), 2176.
 $C_6H_{14}S_4Pt$ Substance, from dithioethylene glycol and platinum chloride (RAY), 133.

6 IV

- $C_6H_8O_2N_2Cl_2$ Dichloronitrophenyldichloroamines (ORTON and BAYLISS), 2792.
 $C_6H_8O_2NCl$ 3-Chlorobenzoquinone-4-oximes, stereoisomeric (HODGSON and MOORE), 2504.
 3-Chloro-4-nitrosophenol (HODGSON and MOORE), 2499.
 $C_6H_8O_2NI$ 4-Iodo-6-nitrophenol (ROBERTS), 2710.
 $C_6H_8O_2N_2Br_2$ *ss'*-Dibromomuconamides, isomeric (FARMER), 2544.
 $C_6H_8O_2N_2Br$ Ethyl 5-bromoglyoxaline-4-carboxylate (KING and MURCH), 623.
 $C_6H_8O_4Cl_2Te$ Tellurium acetylpropionylmethane dichloride (MORGAN and REEVES), 450.
 $C_6H_8O_4Br_2Te$ Tellurium acetylpropionylmethane dibromide (MORGAN and REEVES), 451.
 $C_6H_8O_4I_2Te$ Tellurium acetylpropionylmethane diiodide (MORGAN and REEVES), 451.
 $C_6H_{11}O_4NS$ 1:4-Sulphonazan-4-acetic acid, and its salts (CASHMORE and MCCORMICK), 2888.
 $C_6H_{10}O_4N_2Co$ Citratopentamminecobalt (+ $2H_2O$) (DUVE), 569.
 $C_6H_{10}O_4N_2Co$ Malonatopentamminecobaltic malonate nitrate (+ $2H_2O$) (DUVE), 570.
 $C_6H_{10}O_4N_2Co$ Adipatodipentamminecobaltic hydroxide, nitrate of (DUVE), 569.
 $C_6H_{10}O_4N_2Co$ Citratotripentamminecobaltic hydroxide, dihydrogen citrate of (DUVE), 571.

6 V

- $C_6H_8O_4NClS$ 6-Chloro-3-nitrobenzenesulphonic acid (KRISHNA), 157.
 $C_6H_8O_4NIS$ Benzenesulphoniodoamide, potassium salt (ROBERTS), 351.
 $C_6H_8O_4NBrS$ *o*-Bromoaniline-*p*-sulphonic acid (SCOTT and COHEN), 3185.

C, Group.

- C_7H_6O Benzaldehyde, nitration of (BRADY and HARRIS), 484.
 C_7H_6O Benzoic acid, and its salts, neutralisation of (PRIDEAUX), 1624.
 Hydroxybenzaldehydes, solubility of (SIDGWICK and ALLOTT), 2819.

FORMULA INDEX.

7 II-7 IV

- $C_7H_6O_2$ β -Resorcyraldehyde, synthesis of (SHOESMITH and HALDANE), 2704.
 Salicylic acid, and its salts, neutralisation of (PRIDEAUX), 1628.
 $C_7H_6O_4$ 3- and 4-Methyl- α -pyrone-6-carboxylic acids (HIGGINBOTHAM and LAPWORTH), 1328.
 $C_7H_6O_4$ γ -Oxalyldimethylacrylic acids (HIGGINBOTHAM and LAPWORTH), 1329.
 $C_7H_8O_4$ 3-Methoxy-3-methylcyclopropane-1:2-dicarboxylic acid (GOSS, INGOLD, and THORPE), 3358.
 $C_7H_{10}O_4$ Methanetriacetic acid, synthesis of (DREIFUSS and INGOLD), 2864.
 $C_7H_{10}S_2$ cycloHexylene trithiocarbonate (MILLS and SCHINDLER), 320.
 $C_7H_{10}O_4$ β -Methoxyadipic acid (FARMER), 3331.

7 III

- $C_7H_6OS_2$ 2-Dithiobenzoyl, preparation and reactions of (McKIBBEN and McCLELLAND), 170.
 C_7H_6ON Phenylcarbimide, condensation of aromatic aminosulphonic acids with (SCOTT and COHEN), 3177.
 C_7H_5OCl Benzoyl chloride, chlorination of (HOPE and RILEY), 2470.
 C_7H_5ON *o*-Nitrobenzaldehyde, monotropy of (BRADY and HARRIS), 484.
 $C_7H_5O_2Br$ 3-Bromosalicylic acid, preparation of, and its salts (MELDRUM and SHAH), 1990.
 $C_7H_5O_2N_4$ Nitrohydroxymethyl-1:2:3-benzotriazoles (BRADY and DAY), 2261.
 6-Nitro-1-methoxy-1:2:3-benzotriazole (BRADY and DAY), 2266.
 $C_7H_5O_2S$ Sulphosalicylic acid (+ 2H₂O), constitution of (MELDRUM and SHAH), 1986.
 $C_7H_5O_2N$ Nitrocresols (GIBSON), 1272.
 $C_7H_5O_2N_2$ Dinitrotoluenes, preparation of (PAGE and HEASMAN), 3235.
 $C_7H_5O_2N_2$ Methyl isopropyl ketone semioxamazone (WILSON and PICKERING), 395.
 $C_7H_{11}N_2S_2$ Substance, from thioacetamide and sulphur monochloride (CHAKRAVARTI), 968.
 $C_7H_{11}ON$ Dimethylaminomethyl isobutyl ether (G. M. and R. ROBINSON), 536.

7 IV

- $C_7H_5O_2Cl$ 3-Chloro-2-iodobenzoic acid (CHRISTIE, JAMES, and KENNER), 1949.
 $C_7H_5O_2NCl$ 3-Chloro-5-nitro-2-hydroxybenzaldehyde (DAVIES and RUBENSTEIN), 2850.
 $C_7H_5O_2NCl$ 3-Chloro-5-nitro-2-hydroxybenzoic acid (DAVIES and RUBENSTEIN), 2852.
 $C_7H_5O_2NBr$ 2-Bromo-4-nitrosalicylic acid (DEV and ROW), 3380.
 C_7H_5ONS 2-Thiobenzimide (McKIBBEN and McCLELLAND), 173.
 $C_7H_5O_2BrS$ 3-Bromo-5-sulpho-2-hydroxybenzoic acid, and its salts (MELDRUM and SHAH), 1989.
 C_7H_5ONCl *p*-Nitrobenzyl chloride, addition of, to trimethylamine (DEXTER, McCOMBIE, and SCARBOROUGH), 1237.
 $C_7H_5O_2NI$ 2-Iodo-3-aminobenzoic acid, hydrochloride of (CHRISTIE, JAMES, and KENNER), 1949.
 $C_7H_5O_2Cl_2S_2$ *p*-Cresoldisulphonyl chloride (GIBSON and SMILES), 2390.
 $C_7H_5ON_2S_2$ 2:6-Dithiol-8-hydroxypurine dimethyl ether (RAY, CHAKRAVARTI, and BOSE), 1960.
 2:6-Dithiol-8-oxy-7:9-dimethylpurine, and its potassium salt (RAY, CHAKRAVARTI, and BOSE), 1962.

- $C_7H_6ON_4I$ Acetyl-4-iodo-3:5-dimethylpyrazole (MORGAN and ACKERMAN), 1313.
 $C_7H_6ON_4Br$ 1-Acetyl-3:5-dimethylpyrazole (MORGAN and ACKERMAN), 1313.
 $C_7H_6ON_4Se$ Cyano-3-selenium acetylpropionylmethane, and its copper salt (MORGAN and REEVES), 449.
 $C_7H_6O_2N_4Br$ Ethyl 2-bromo-4-methylglyoxaline-5-carboxylate (PYMAN and TIMMIS), 498.
 $C_7H_6O_2N_4S$ *p*-Aminophenylcarbamidesulphonic acid (SCOTT and COHEN), 3182.
 p-Nitrotoluene- α -sulphonhydrazide (CLUTTERBUCK and COHEN), 2514.
 $C_7H_6O_2N_4S$ Toluene- α -sulphonhydrazide (CLUTTERBUCK and COHEN), 2513.
 $C_7H_{11}ON_4S$ 2:4-Diketo-5-methyltetrahydrothiazole-2-isopropylidenehydrazone (WILSON and BURNS), 801.
 $C_7H_{11}O_4N_4Co$ Salicylatotetramminecobaltic hydroxide, salts of (MORGAN and SMITH), 1100.

7 V

- $C_7H_6ON_4ClS$ 6-Chloro-5-nitro-*m*-toluenesulphonic acid, sodium salt, as a reagent for potassium (H. and W. DAVIES), 2978.
 $C_7H_6ON_4ClS$ 2-Chloro-6-thiol-8-oxy-7:9-dimethylpurine, and its salts (RAY, CHAKRAVARTI, and BOSE), 1960.
 $C_7H_6O_2N_4ClS$ 5-Chlorophenylcarbamide-*o*-sulphonic acid, potassium salt (SCOTT and COHEN), 3184.
 p-Chlorophenylcarbamide-*o*-sulphonic acid, and its salts (SCOTT), 3198.
 $C_7H_6O_2N_4BrS$ *p*-Bromophenylcarbamide-*o*-sulphonic acid, and its salts (SCOTT), 3199.
 p-Bromophenylcarbamide-*m*-sulphonic acid (SCOTT and COHEN), 3184.
 $C_7H_6O_2N_4IS$ Toluenesulphoniodoamides, potassium and sodium salts (ROBERTS), 851.
 $C_7H_6O_2N_4ClS$ *p*-Chlorophenylguanidine-*o*-sulphonic acid, and its potassium salt (SCOTT and COHEN), 3188.
 $C_7H_6O_2N_4BrS$ *p*-Bromophenylguanidine-*o*-sulphonic acid, and its potassium salt (SCOTT and COHEN), 3187.
 $C_7H_6O_2N_4ClS$ *p*-Chlorotoluene- α -sulphonhydrazide (CLUTTERBUCK and COHEN), 2514.

C₈ Group.

- C_8H_6O Phthalonic anhydride (KURODA and PERKIN), 2105.
 C_8H_6O Acetophenone, bromination of (WARD), 2207.
 C_8H_6O Hydroxytolualdehydes, solubility of (SIDGWICK and ALLOTT), 2819.
 C_8H_6O Oxalacetic acid, derivatives of, from tartaric acid (CHATTAWAY and PARKER), 663.
 $C_8H_6N_4$ 2:5-Imino-1-phenyldihydro-1:2:3-triazole, and its picrate (DUTT), 271.
 C_8H_6N Coniine, photosynthesis of (BALY, HILLBORN, and STEWY), 191.
 C_8H_6O Methyl 3-methyl- Δ^4 -cyclopropene-1:2-dicarboxylate, sodium salt (GOS, INGOLD, and THORPE), 3357.
 Methyl muconates, isomeric (FARMER), 2547.
 1:3:3-Trimethylcyclopropan-2-ol-1:2-dicarboxylactone (PANDYA and THORPE), 2264.
 $C_8H_{10}O_4$ *B*-Hydroxybutane- α : β -dicarboxylic- γ -acetic lactone (FARMER), 3337.
 3-Methylcyclopropane-1:2-dicarboxylic-3-acetic acid (FARMER), 3337.
 $C_8H_{10}N_2$ Benzenylmethylimidine, and its salts (PYMAN), 3869.

FORMULA INDEX.

8 II-8 III

- $C_6H_{11}O_6$ *cis*-Homocaronic acid, and its silver salt (SIMONSEN and RAU), 556.
cis- and *trans*-3-Methyl-3-ethylcyclopropane-1:2-dicarboxylic acids (SINGH and THORPE), 121.
 $C_6H_{11}O_6$ 3-Ethoxy-3-methylcyclopropane-1:2-dicarboxylic acid (GOSS, INGOLD, and THORPE), 360.
 α -Keto- $\beta\beta$ -methyl ethylglutaric acid (SINGH and THORPE), 120.
trans-Lactonic acid of $\alpha\alpha'$ -dihydroxy- $\beta\beta$ -methyl ethylglutaric acid (SINGH and THORPE), 118.
 Methyl hydrogen 3-methoxy-3-methylcyclopropane-1:2-dicarboxylate (GOSS, INGOLD, and THORPE), 360.
 $C_6H_{12}O_6$ Butane- $\alpha\beta$ -dicarboxylic- β -acetic acid (FARMER), 3330.
 $C_6H_{12}O_6$ $\alpha\beta\beta$ -Trimethylglutaric acid, preparation and bromination of (PANDYA and THORPE), 2358.
 $C_6H_{12}O_6$ Lactone, from oxidation of tetramethyl γ -fructose (HAWORTH and LINSELL), 299.
 $C_6H_{12}O_6$ $\alpha\alpha'$ -Dihydroxy- $\beta\beta$ -methyl ethylglutaric acid, and its silver salt (SINGH and THORPE), 120.
 $C_6H_{12}O_6$ Xylo-trimethoxyglutaric acid (HIRST and PURVES), 1358.
 $C_6H_{12}O_6$ Octoic acid from coconut oil (WALKER), 2836.
 $C_6H_{17}N$ $\Delta\gamma$ -Butenyldiethylamine, and its salts (G. M. and R. ROBINSON), 540.
 $C_8H_{18}O$ *d*- β -Octanol, preparation and rotation of the dicarboxylic esters of (HALL), 32; preparation and rotation of the aliphatic ethers of (KENTON and McNICOL), 14.

8 III

- $C_8H_8N_2Br_2$ 2:3-Dibromoquinoxaline (USHERWOOD and WHITELEY), 1083.
 $C_8H_8O_2N$ Phthalimide, potassium salt, interaction of, with $\beta\beta'$ -dichlorodiethyl sulphide, sulphone, and sulphoxide (CASHMORE and McCOMBIE), 2584.
 $C_8H_8O_2N_4$ 6-Nitro-1-acetoxy-1:2:3-benzotriazole (BRADY and DAY), 2266.
 $C_8H_7O_2Cl$ 3-Chloro-2-methoxybenzaldehyde (DAVIES and RUBENSTEIN), 2851.
 $C_8H_7O_2Cl$ 3-Chloro-2-methoxybenzoic acid (DAVIES and RUBENSTEIN), 2851.
 $C_8H_7O_2Br$ 5-Bromo-2-methoxybenzoic acid (MELDRUM and SHAH), 1985.
 $C_8H_7NS_2$ Thio-2-methylbenzothiazolone (MILLS, CLARK, and AESCHLMANN), 2367.
 $C_8H_7OBr_2$ 4:6-Dibromo-*m*-tolyl methyl ether (HAWORTH and LAFWORTH), 2995.
 $C_8H_7O_2N_4$ 6-Nitrodimethyl-1:2:3-benzotriazole 1-oxides (BRADY and DAY), 2262.
 Nitromethoxymethyl-1:2:3-benzotriazoles (BRADY and DAY), 2262.
 $C_8H_7O_2Cl_2$ Methyl $\alpha\alpha'$ -dichloromuconates, isomeric (FARMER), 2544.
 $C_8H_7O_2Cl_2$ Methyl $\alpha\alpha'\beta$ -trichlorohydromuconate (FARMER), 2545.
 $C_8H_7O_2S$ Sulphosalicylic acid methyl ether, and its salts (MELDRUM and SHAH), 1991.
 C_8H_7OCl Chloro-*o*-xylenols (HINKEL, COLLINS, and AYLING), 2968.
 C_8H_7OBr 5-Bromo-2-methoxytoluene (+ $1\frac{1}{2}H_2O$) (MELDRUM and SHAH), 1984.
m-Methoxybenzyl bromide, reduction of, by hydriodic acid (SHOESMITH), 2628.
 Methoxybenzyl bromides, isomeric (SHOESMITH), 2698.
 $C_8H_7O_2N$ *m*-Methoxybenzamide (BRADY and DUNN), 1802.
 $C_8H_7O_2N$ 2-Nitro-*m*-tolyl methyl ether (GIBSON), 1273.

- $C_8H_6O_4N_2$ 2,4-Dinitro-6-amino-*m*-xylene (IBBOTSON and KENNER), 1267.
 $C_8H_6O_4N$ 5-Nitro-2,3-dimethoxybenzaldehyde (DAVIES), 1683.
 C_8H_6NS 2-Methylbenzothiazoline (MILLS, CLARK, and AESCHLIMANN), 2361.
 $C_8H_{10}ON_2$ Acetylphenylenediamines, solubility of (SIDGWICK and NEILL), 2818.
 $C_8H_{10}OS$ 4-Methoxy-*m*-tolyl mercaptan (KRISHNA), 2788.
 $C_8H_{10}O_2N_2$ 5-Nitro-2-*m*-xylidine (IBBOTSON and KENNER), 1268.
 $C_8H_{10}O_2N_2$ Nitro-*s*-xylidines (IBBOTSON and KENNER), 1266.
 $C_8H_{10}O_2S$ Methoxytoluenesulphonic acids (HAWORTH and LAPWORTH), 2987.
 $C_8H_{10}O_2S$ Methoxytoluenesulphonic acids, salts of (HAWORTH and LAPWORTH), 2987.
 $C_8H_{10}O_2Br$ $\alpha\alpha'$ -Dibromo- $\beta\beta$ -methyleneethylglutaric acids (SINGH and THORPE), 117.
 $\alpha\gamma$ -Dibromo- $\alpha\beta\beta$ -trimethylglutaric acids (PANDYA and THORPE), 2861.
 $\alpha\gamma$ -Dibromo- $\beta\beta'$ -dibromoadipate (FARMER), 2542.
 $C_8H_{10}O_2N_2$ Mesityl oxide semioxamazone, and its sodium salt (WILSON and PICKERING), 396.
 $C_8H_{10}O_2N_2$ *cyclo*Pentan-1-one-3-acetic acid semicarbazone (FARMER), 3330.
 $C_8H_{10}O_2N_2$ Methyl isobutyl ketone semioxamazone (WILSON and BRADLEY), 396.
 $C_8H_{11}O_2N$ Xylo-trimethoxyglutaramide (HIRST and PURVES), 1359.
 $C_8H_{11}O_2S$ $\alpha\alpha'$ -Diethoxydiethyl sulphide (MANN and POPE), 1177.
 $C_8H_{11}O_2S$ $\beta\beta'$ -Diethoxydiethyl sulphoxide (CASHMORE), 1741.
 $C_8H_{11}S_2Pt$ Substance, from dithioethylene glycol and platinum chloride (RAY), 139.
 $C_8H_{12}NCl_4$ Tetraethylammonium trichloride (CHATTAWAY and HOYLE), 659.

8 IV

- $C_8H_6O_4N_2Br$ 5-Bromo-*o*-carbamidobenzoic acid hydantoin (SCOTT and COHEN), 3187.
 $C_8H_6O_4Cl$ Methyl 3-chloro-2-iodobenzoate (CHRISTIE, JAMES, and KENNER), 1949.
 $C_8H_6O_4NCl$ Phenyl chloriodoacetate (CROMPTON and CARTER), 577.
 $C_8H_6O_4NCl$ 3-Chloro-5-nitro-2-methoxybenzaldehyde (DAVIES and RUBENSTEIN), 2850.
 $C_8H_6O_4NCl$ 3-Chloro-5-nitro-2-methoxybenzoic acid (DAVIES and RUBENSTEIN), 2850.
 $C_8H_6O_4N_2Br$ 5-Bromo-*o*-carbamidobenzoic acid (SCOTT and COHEN), 3187.
 $C_8H_6O_4NCl_2S$ 2-Nitro-3-methoxytoluene-4,6-disulphonyl chloride (HAWORTH and LAPWORTH), 2992.
 C_8H_6ONS ψ -Base from benzothiazole methiodide, silver derivative of (MILLS, CLARK, and AESCHLIMANN), 2357.
 $C_8H_6O_4NCl$ 3,4-Methylenedioxybenzaldoxime hydrochlorides (BRADY and DUNN), 1797.
 $C_8H_6O_4NI$ 4-Iodo-2-nitrophenetole (BRADY and McHUGH), 2050.
 $C_8H_6O_4NS$ 3-Hydroxy-7-methyl-1:2,4-benzosulphonediazine (SCOTT), 3197.
 $C_8H_6O_4Cl_2S$ 3-Methoxytoluene-4,6-disulphonyl chloride (HAWORTH and LAPWORTH), 2992.
 $C_8H_6O_4Cl_2S$ Methoxytoluenesulphonyl chlorides (HAWORTH and LAPWORTH), 2988.

FORMULA INDEX.

8 IV-8 V

- $C_8H_{10}ON_2Br$, Acetylphenylhydrazine (HUMPHRIES, BLOOM, and EVANS), 1772.
- $C_8H_9O_4N_2S$, *p*-Carbamidotoluene-*o*-sulphonic acid, and its potassium salt (SCOTT), 3194.
- $C_8H_9O_4NS$, Methoxytoluenesulphonamides (HAWORTH and LAPWORTH), 2988.
- $C_8H_{11}O_4N_2S$, *p*-Guanidinotoluene-*m*-sulphonic acid (SCOTT and COHEN), 3189.
- $C_8H_{11}O_4N_2S_2$, 3-Methoxytoluene-4:6-disulphonamide (HAWORTH and LAPWORTH), 2992.
- $C_8H_{11}O_4N_2S_2$, 2-Nitro-3-methoxytoluenedisulphonamide (HAWORTH and LAPWORTH), 2993.
- $C_8H_{11}ON_2S$, 2:4-Diketo-5-ethyltetrahydrothiazole-2-*isopropylidene*-hydrazone (WILSON and BURNS), 802.
- $C_8H_{10}O_4Cl_3Te$, Tellurium *O*-ethylacetylpropionylmethane trichloride (MORGAN and REEVES), 451.
- $C_6H_8O_4N_2S$, Glutathione, oxidation and reduction potentials of (DIXON and QUASTEL), 2943.
- $C_6H_{11}O_4NS$, Ethyl 1:4-sulphonazan-4-acetate (CASHMORE and McCOMBIE), 2888.
- $C_6H_{10}O_4N_2S$, *ss'*-Diglycinodiethyl sulphide (CASHMORE and McCOMBIE), 2887.
- $C_6H_8O_4N_2Co$, Phthalatopentamminecobaltic hydroxide, nitrate of (+2H₂O) (DUFF), 569.
- $C_6H_{18}NCl_2Br$, Tetraethylammonium dibromochloride (CHATTAWAY and HOYLE), 660.
- $C_6H_{18}NCl_2Br$, Tetraethylammonium hexabromochloride (CHATTAWAY and HOYLE), 660.
- $C_6H_{18}NClI$, Tetraethylammonium diiodochloride (CHATTAWAY and HOYLE), 659.
- $C_6H_{18}NClI_4$, Tetraethylammonium tetraiodochloride (CHATTAWAY and HOYLE), 660.
- $C_6H_{18}NCl_2Br$, Tetraethylammonium dichlorobromide (CHATTAWAY and HOYLE), 659.
- $C_6H_{18}NCl_4I$, Tetraethylammonium tetrachloriodide (CHATTAWAY and HOYLE), 661.
- $C_6H_{18}NBr_2I$, Tetraethylammonium dibromoiodide (CHATTAWAY and HOYLE), 661.
- $C_6H_{12}Cl_2S_2Pt$, Substance, from diethyl sulphide and platinum chloride (RAY), 140.
- $C_6H_{12}Cl_2S_2Pt$, Substance, from diethyl sulphide and platinum chloride (RAY), 141.
- $C_6H_{10}O_4N_2Co$, Phthalatodipentamminecobaltic hydroxide, nitrate of (DUFF), 568.
- $C_6H_{10}O_4N_2Co$, Malatodipentamminecobaltic malate nitrate (DUFF), 570.
- $C_6H_{10}O_4N_2Co$, Mesotartaratodipentamminecobaltic nitrate meso-tartrate (DUFF), 566.

8 V

- $C_7H_5ON_2ClS$, 3-Chloronitro-7-methyl-1:2:4-benzosulphonediazine (SCOTT), 3197.
- $C_7H_5ONClBr$, Chlorobromoacetanilide (McKIE), 2215.
- C_7H_5ONClI , Chloriodoacetanilide (CROMPTON and CARTER), 577.

- $C_8H_6O_4N_2$ CIS 3-Chloro-7-methyl-1:2:4-benzosulphonediazine, and its salts (SCOTT), 3196.
 $C_8H_6O_4N_2BrS$ *o*-Bromophenylbiuret-*p*-sulphonic acid (SCOTT and COHEN), 3186.
 $C_8H_6ON_4CIS$ 2-Chloro-6-thio-1:8-oxy-7:9-dimethylpurine methyl ether (RAY, CHAKRAVARTI, and BOSE), 1961.

C, Group.

- C_8H_8N *n*- and *iso*-Quinolines, hydroferrocyanides of (CUMMING), 2463.
 $C_8H_6O_2$ 6-Hydroxy-1-hydrindone (INGOLD and PIGGOTT), 1492.
 $C_8H_6O_2$ Hydroxymethoxyaldehydobenzoic acids (PERKIN and STOVLE), 3175.
 $C_8H_8N_2$ Triazomesityleneindazole (MORGAN and DAVIES), 232.
 $C_8H_8N_2$ Tristriazomesitylene (MORGAN and DAVIES), 237.
 $C_8H_{10}O_2$ Hydratropic acid, resolution of (RAPER), 2557.
 $C_8H_{10}O_2$ *o*-Methoxyacetophenone (PRATT and ROBINSON), 748.
 $C_8H_{10}O_2$ 3-Methoxy-*o*-toluic acid (GIBSON), 1274.
 $C_8H_{10}O_2$ Ethyl 4-methyl- α -pyrone-6-carboxylate (HIGGINBOTHAM and LAFWORTH), 1329.
 $C_{10}H_{10}O_4$ *cis-cyclo*Pentanespiro-1-hydroxycyclopropane-1:2-dicarboxylic anhydride (LANFAR and THORPE), 1687.
 $C_{10}H_{10}O_4$ 2:5:5-Trimethyl- Δ^1 -cyclopentene-3:4-dione-1-carboxylic acid (GRIMWOOD, INGOLD, and THORPE), 3308.
 $C_{10}H_{10}O_4$ Anhydride from $\alpha\gamma$ -trimethylaconitic acid (GRIMWOOD, INGOLD, and THORPE), 3309.
 $C_{10}H_{12}N_2$ Methyl derivative of 2:5-imino-1-phenyldihydro-1:2:3-triazole (DUTT), 271.
 $C_{10}H_{12}N_2$ Bistriazomesitylene (MORGAN and DAVIES), 234.
 $C_{10}H_{12}N_2$ Bistriazomesidine (MORGAN and DAVIES), 237.
 $C_{10}H_{11}As$ *As*-Methyldihydroarsindole (TURNER and BERT), 2489.
 $C_{10}H_{11}O$ *d*-Benzylmethylcarbinol, preparation and rotation of the *n*-alkyl ethers of (PHILLIPS), 22; preparation of *l*-benzylmethylcarbinol acetate from (PHILLIPS), 47.
 $C_{10}H_{12}O_4$ 1-Methoxy-3-methyl-3-ethylcyclopropane-1:2-dicarboxylic anhydride (SINGH and THORPE), 120.
 $C_{10}H_{12}O_4$ α -Ketocyclopentane-1:1-diacetic acid, and its silver salt (LANFAR and THORPE), 1688.
 $C_{10}H_{12}O_4$ *cis-cyclo*Pentanespiro-1-hydroxycyclopropane-1:2-dicarboxylic acid, and its silver salt (LANFAR and THORPE), 1686.
 $C_{10}H_{12}O_4$ $\alpha\gamma$ -Trimethylaconitic acid (GRIMWOOD, INGOLD, and THORPE), 3309.
 $C_{10}H_{12}O_4$ Methanetetraacetic acid, crystal structure of (KNAGGS), 78.
 $C_{10}H_{12}N_2$ Dimethylaminobenzonylimidine, salts of (PYMAN), 3371.
 $C_{10}H_{12}N_2$ Methylaminobenzonylmethylimidine, and its salts (PYMAN), 3372.
 $C_{10}H_{12}O$ *cyclo*Hexenylacetone, synthesis of (BIRCH, KON, and NORRIS), 1270.
 $C_{10}H_{12}O_2$ *cyclo*Heptylideneacetic acid, and its silver salt (BAKER and INGOLD), 132.
 $C_{10}H_{12}O_2$ Castelamarin, constitution and properties of (BOSSMAN), 207.
 $C_{10}H_{12}O_2$ Ethyl ethylenemalonate, reduction of (HIGGINBOTHAM and LAFWORTH), 1618.

FORMULA INDEX.

9 II—9 III

$C_8H_{10}O_4$ *cis*- and *trans*-1-Methoxy-3-methyl-3-ethylcyclopropane-1:2-dicarboxylic acids (SINGH and THORPE), 120.

Methyl 3-methoxy-3-methylcyclopropane-1:2-dicarboxylate (Goss, INGOLD, and THORPE), 360.

$C_8H_{10}O_4$ Methyl β -methoxyadipate (FARMER), 3330.

9 III

$C_8H_8O_2N$ 6-Nitro-1:2-diketohydrindene (INGOLD and PIGGOTT), 1488.

$C_8H_8O_2N$ 4-Nitrocoumarilic acid, and its salts (DEY and ROW), 3380.

$C_8H_8O_2N$ 2-Oximino-6-nitro-1-hydrindone (INGOLD and PIGGOTT), 1483.

$C_8H_8O_2N$ 6-Nitro-1-hydrindone (INGOLD and PIGGOTT), 1486.

Substance, from nitration of 1-hydrindone (INGOLD and PIGGOTT), 1493.

$C_8H_8O_2N$ Acid, from oxidation of 6-nitrohydrindene (INGOLD and PIGGOTT), 1498.

$C_8H_8O_2N$ 2-Keto-3-hydroxy-1-methyl-1:2-dihydroquinoxaline (USHERWOOD and WHITELEY), 1082.

1-Methylbenziminazole-2-carboxylic acid (USHERWOOD and WHITELEY), 1086.

3:4-Oxido-2-hydroxy-1-methyl-1:4-dihydroquinoxaline (USHERWOOD and WHITELEY), 1089.

$C_8H_8O_2N$ 6-Nitro-1-hydrindone oxime (INGOLD and PIGGOTT), 1486.

3:4-Oxido-2-keto-3-hydroxy-1-methyl-1:2:3:4-tetrahydroquinoxaline, and its salts (USHERWOOD and WHITELEY), 1082.

Oxime of substance $C_8H_8O_2N$ (INGOLD and PIGGOTT), 1495.

$C_8H_8O_2N$ Nitroacetoxymethyl-1:2:3-benzotriazoles (BRADY and DAY), 2262.

C_8H_8ON 4- and 6-Amino-1-hydrindones (INGOLD and PIGGOTT), 1486.

3-Methoxy-*o*-toluonitrile (GIBSON), 1274.

C_8H_8ON Bistriazonitromesitylene (MORGAN and DAVIES), 235.

C_8H_8ON *p*-Nitro- β -phenylpropaldehyde (INGOLD and PIGGOTT), 1505.

C_8H_8OCl ω -Chloacetovanillone (PRATT and ROBINSON), 753.

C_8H_8OBr 5-Bromo-2:3-dimethoxybenzaldehyde (DAVIES), 1586.

C_8H_8ON Nitrotolyl acetates (GIBSON), 1272.

C_8H_8OBr 5-Bromo-*o*-veratric acid (DAVIES), 1587.

C_8H_8ON 5-Nitro-2-hydroxy-3-ethoxybenzaldehyde (DAVIES), 1587.

C_8H_8ON 5-Nitro-2-hydroxy-3-ethoxybenzoic acid, and its sodium salt (DAVIES), 1589.

C_8H_8NBr 3-Bromo-*p*-dimethylaminobenzonitrile (BRADY and TRUSZKOWSKI), 2439.

C_8H_8ON Bistriazohydroxymesitylene (MORGAN and DAVIES), 235.

$C_8H_8O_2N$ Formylaminoacetanilide or 2-Hydroxy-4-keto-3-phenyltetrahydroglyoxaline (USHERWOOD and WHITELEY), 1086.

6-Nitro-1-hydrindamine (INGOLD and PIGGOTT), 1484.

$C_8H_8O_2N$ Triazonitromesitylene (MORGAN and DAVIES), 231.

$C_8H_8O_2Cl$ 4:4-Dichloro-2:5:5-trimethyl- Δ^1 cyclopenten-3-one-1-carboxylic acid (GRIMWOOD, INGOLD, and THORPE), 3307.

$C_8H_8O_2S$ 4-Hydroxytoluene-3-sulphonacetic acid (GIBSON and SMILES), 2391.

C_8H_8ON 3-Methoxy-*o*-toluamide (GIBSON), 1274.

$C_8H_8O_2N$ Triazonitroaminomesitylene (MORGAN and DAVIES), 235.

$C_8H_8O_2N$ 3:4-Dimethoxybenzaloximes (BRADY and DUNN), 1799.

$C_8H_8O_2N$ Nitromesitylenediazonium hydroxide, salts of (MORGAN and DAVIES), 231.

- $C_8H_{11}O_2N$ 4-Oximino-2:5:5-trimethyl- Δ^1 -cyclopenten-3-one-1-carboxylic acid (GRIMWOOD, INGOLD, and THORPE), 3307.
- $C_6H_{11}O_2N_4$ Mesitylenebisdiazonium hydroxide, salts of (MORGAN and DAVIES), 233.
- $C_6H_{11}O_2N_4$ Nitroaminomesitylenediazonium hydroxide, chlorosaurate hydrochloride of (MORGAN and DAVIES), 234.
- $C_6H_{11}ClAs$ β -Phenylethylmethylchloroarsine (TURNER and BURY), 2491.
- $C_6H_{11}O_2N_4$ Nitrodiaminomesitylene (MORGAN and DAVIES), 234.
- $C_6H_{11}O_2N_4$ Aminomesitylenebisdiazonium hydroxide, chlorosaurate of, and its hydrochloride (MORGAN and DAVIES), 236.
- $C_8H_{11}O_2Br_2$ $\alpha\beta$ -Dibromocycloheptanecarboxylic acid (BAKER and INGOLD), 132.
- $C_8H_{11}O_2Br_2$ $\alpha\alpha'$ -Dibromosuccinic acid (CHALLENGER and THORPE), 2483.
- $C_8H_{11}O_2Cl$ Ethyl α -chloropropylacetate (MACBETH), 1126.
- $C_8H_{11}O_2Br$ Ethyl α -bromopropylacetate (MACBETH), 1127.
- $C_8H_{11}ON$ 4-Hydroxy-1:2:2:6-tetramethylpiperidine, benzilate and tropate of (KIPFING), 3117.
- $C_6H_{11}O_2N$ d - γ -Nonyl nitrite, rotatory and refractive dispersions and absorption spectrum of (PICKARD and HUNTER), 434.
- $C_6H_{11}ON$ Diethylaminomethyl n -butyl ether (G. M. and R. ROBINSON), 536.
- $C_8H_{11}O_2N$ Methyl-diethyl- n -butoxymethylammonium hydroxide, salts of (G. M. and R. ROBINSON), 538.

9 IV

- $C_8H_6O_2NBr$ 3:8-Dibromo-6-nitrocoumarin (DEY and ROW), 3380.
- $C_8H_6O_2NBr$ 6-Bromo-4-nitrocoumarilic acid, and its salts (DEY and ROW), 3382.
- $C_8H_6O_2NBr$ 3:8-Dibromo-6-aminocoumarin (DEY and ROW), 3381.
- $C_8H_6O_2NBr$ 2:2-Dibromonitro-1-hydrindones (INGOLD and PIGGOTT), 1487.
- $C_8H_6O_2NBr$ 3- α -Dibromo-5-nitrocoumarinic acid, and its silver salt (DEY and ROW), 3381.
- $C_8H_6O_2NBr$ α -Bromo-5-nitrocoumarinic acid, and its silver salt (DEY and ROW), 3379.
- $C_8H_6O_2NS$ Acetyl-2-thiobenzimide (McCLELLAND and LONGWELL), 3314.
- $C_8H_6O_2NCl$ p -Nitro- β -phenylpropionyl chloride (INGOLD and PIGGOTT), 1503.
- $C_8H_6O_2NBr$ 5-Bromo-6-nitro-2:3-dimethoxybenzaldehyde (DAVIES), 1586.
- C_8H_6ONCl Dichloroacetobenzylamide (MCKIE), 2215.
- Dichloroacetomethylanilide (MCKIE), 2215.
- C_8H_6ONS 2:4-Diketo-5-phenyltetrahydrothiazole-2-hydrazone, hydrochloride of (WILSON and BURNS), 803.
- $C_8H_{10}ONBr$ 3-Bromo- p -dimethylaminobenzaldehyde (BRADY and TRUSZKOWSKI), 2438.
- $C_8H_{10}ONBr$ 3-Bromo- p -dimethylaminobenzoic acid (BRADY and TRUSZKOWSKI), 2439.
- $C_8H_{10}ONBr$ 3-Bromo- p -dimethylaminobenzaldoximes (BRADY and TRUSZKOWSKI), 2438.
- $C_8H_{12}ONS$ Aceto- p -toluidide-2-sulphinic acid (JOHNSON and SMILES), 2386.
- $C_8H_{11}O_2NS$ Ethyl p -amino- m -sulphobenzoate (SCOTT and COHEN), 3181.
- C_8H_6ONS 2:6-Dithiol-8-oxy-7:9-dimethylpurine dimethyl ether (RAT, CHAKRAVARTI, and BONE), 1962.
- C_8H_9NClBr Phenyltrimethylammonium bromide dichloride (McCONNIE and READ), 149.

FORMULA INDEX.

9 IV-10 II

- $C_6H_{11}NCl_4$ Phenyltrimethylammonium chloride iodotrichloride (McCOMBIE and READE), 151.
 $C_6H_{11}NBrI_2$ Phenyltrimethylammonium bromide di-iodide (McCOMBIE and READE), 150.
 $C_6H_{11}NBr_2I$ Phenyltrimethylammonium bromide iodobromide (McCOMBIE and READE), 149.

9 V

- $C_6H_5ONClBr$ Chlorobromoacetobenzylamide (McKIE), 2215.
 Chlorobromoacetomethylanilide (McKIE), 2215.
 C_6H_5ONBrS *p*-Bromophenylurethane-*o*-sulphonic acid, potassium salt (SCOTT), 3201.
 $C_6H_{11}O_2NCl_2S_2$ $\alpha\alpha'$ -Dichlorodimethylsulphine-*p*-toluenesulphonyl-imine (MANN and POPE), 1174.
 $C_6H_{11}NClBrI$ Phenyltrimethylammonium bromide iodochloride (McCOMBIE and READE), 149.

C_{10} Group.

- $C_{10}H_8$ Naphthalene, constitution of (CHALLENGER and INGOLD), 2066.
 $C_{10}H_{14}$ Phellandrenes (SMITH, HURST, and READ), 1657.
 Sabinene, oxidation of, with hydrogen peroxide (HENDERSON and ROBERTSON), 1849.
 Thujene, preparation of, from sabinol (HENDERSON and ROBERTSON), 1713.
 $C_{10}H_{18}$ Heparene (CHAPMAN), 778.
 Hydrocarbon, from the action of heat on spinacene (CHAPMAN), 775.

10 II

- $C_{10}H_{16}O$ Camphor, and its derivatives, absorption spectra of (PURVIS), 2515.
 $C_{10}H_{16}O_2$ Acid, from $\alpha\alpha'$ -dibromo-*o*-phenylenediacetyl chloride and sodium hydroxide (CHALLENGER and INGOLD), 2076.
 $C_{10}H_{16}O_2$ $\alpha\alpha'$ -Dihydroxy-*o*-phenylenediacetolactone (CHALLENGER and INGOLD), 2075.
 $C_{10}H_{16}O$ Methoxyindene, and its picrate (INGOLD and PIGGOTT), 1506.
 $C_{10}H_{16}O_2$ Methoxy-1-hydrindones (INGOLD and PIGGOTT), 1492.
 $C_{10}H_{16}O_2$ β -Keto- γ -phenylbutyric acid (ATTWOOD, STEVENSON, and THORPE), 1763.
 $C_{10}H_{16}O_2$ 2:4-Dihydroxy- β -benzoylpropionic acid, silver salt (BIGGS and POPE), 2938.
 5-Methoxyhomophthalic acid (INGOLD and PIGGOTT), 1507.
m-Opianic acid, synthesis of (PERKIN and STOVLE), 3171.
 $C_{10}H_{16}O_2$ $\alpha\alpha'$ -Dihydroxy-*o*-phenylenediacetic acid, and its silver salt (CHALLENGER and INGOLD), 2075.
 $C_{10}H_{16}O_2$ *cyclo*Propyl*cyclo*propanetetracarboxylic acid (FARMER), 3340.
 $C_{10}H_{16}Cl_4$ Substance, from methylchavicol and sulphuryl chloride (DURRANS), 1429.
 $C_{10}H_{12}O$ *n*- and *iso*-Eugenols, ultra-violet absorption spectra of (THOMPSON), 1594.
 $C_{10}H_{12}O_2$ α :4-Dimethoxyacetophenone (PRATT and ROBINSON), 750.
 4:5-Dimethoxy-*o*-tolualdehyde (KURODA and PERKIN), 2110.
 5-*cyclo*Hexane*spirocyclo*- Δ^2 -penten-3-ol-1:4-dione (INGOLD, SEELEY, and THORPE), 864.
 2-Methoxy-3-ethoxysalicylaldehyde (DAVIES), 1590.
 5-*cyclo*Pentane*spiro**cyclo*pentan-3-one-1-carboxylic acid (INGOLD, LANFEAR, and THORPE), 3150.

- $C_{10}H_{16}O_4$ *cis-cycloHexanespiro-1-hydroxycyclopropane-1:2-dicarboxylic anhydride* (LANFAR and THORPE), 2869.
 2-Methoxy-3-ethoxybenzoic acid (DAVIES), 1591.
- $C_{10}H_{14}O$ Carvone, absorption spectra of (PURVIS), 2518.
- $C_{10}H_{14}O_2$ 1:3-Dihydroxy-5-cyclohexanespiro Δ^2 -cyclopentane (INGOLD, SEELEY, and THORPE), 870.
 Acid, from oxidation of longifolic acid (SIMONSEN), 2658.
- $C_{10}H_{14}O_2$ *cycloPentanespirocyclopentan-3-one-1-carboxylic acid* (INGOLD, LANFAR, and THORPE), 3150.
- $C_{10}H_{14}O_4$ Ethyl 3-methyl- Δ^2 -cyclopropene-1:2-dicarboxylates (GOSS, INGOLD, and THORPE), 350.
 Ethyl muconates, isomeric (FARMER), 2547.
cycloHexylidenesuccinic acid (INGOLD, SEELEY, and THORPE), 866.
- α -1- α -Hydroxy-3-carboxy- α :1:1-trimethylcyclopropane-2-propionolactone (SIMONSEN and RAU), 557.
- $C_{10}H_{16}O_4$ *cycloHexanespiro-1-hydroxycyclopropane-1:2-dicarboxylic acids*, and their silver salts (LANFAR and THORPE), 2868.
 α -Ketocyclohexane-1:1-diacetic acid (INGOLD, SEELEY, and THORPE), 867; (LANFAR and THORPE), 2869.
cis- and trans-cycloPentanespiro-1-methoxycyclopropane-1:2-dicarboxylic acids, and their silver salts (LANFAR and THORPE), 1687.
- $C_{10}H_{14}O_6$ α -Hydroxy-1-carboxy- β -1-cyclohexanesuccinolactone (INGOLD, SEELEY, and THORPE), 866.
 Acetyl derivative of lactonic acid, $C_9H_{13}O_5$ (SINGH and THORPE), 119.
- $C_{10}H_{14}O_6$ Ethyl acetylaloacetate (GOSS, INGOLD, and THORPE), 355.
- $C_{10}H_{11}N_3$ Dimethylaminobenzylmethylimidine, salts of (PYMAN), 8372.
- $C_{10}H_{16}O$ Sabinol, conversion of, into thujene (HENDERSON and ROBERTSON), 1713.
- $C_{10}H_{16}O$ Fenchone, absorption spectra of solutions and vapours of (PURVIS), 2518.
 Piperitone (READ and SMITH), 2267; reduction of (HUGHESON, SMITH, and READ), 2916.
- $C_{10}H_{16}O_4$ $\beta\beta$ -Di- α -propylmalic acid lactone (BAINS and THORPE), 2745.
- $C_{10}H_{16}O_6$ 1-Ethoxy-3-methyl-3-ethylcyclopropane-1:2-dicarboxylic acid (SINGH and THORPE), 119.
 1- α -Hydroxy-3-carboxy- α :1:1-trimethylcyclopropane-2-propionic acids, and the silver salt (SIMONSEN and RAU), 557.
- $C_{10}H_{16}O_2$ Glycol anhydrides, isomeric, from oxidation of sabinene (HENDERSON and ROBERTSON), 1853.
- $C_{10}H_{16}O_4$ $\alpha\beta$ -Dihydroxy- α -methyl- β -isopropyladipic acids, resolution of (HENRY and PAGET), 1878.
 Tetramethylgalactonolactone (PRYDE), 1808.
- $C_{10}H_{16}O_7$ Dimethyl xylotrimethoxyglutarate (HIRST and PURVES), 1358.
- $C_{10}H_{16}O$ 1-Menthol, preparation and rotation of dicarboxylic esters of (HALL), 105.
- $C_{10}H_{16}O_2$ Decole acid from coconut oil (WALKER), 2837.
- $C_{10}H_{16}O_5$ Tetramethyl γ -fructose, oxidation of, with nitric acid (HAWORTH and LINNELL), 299; oxidation of, with permanganate, and its reduction (HAWORTH and MITCHELL), 305, 309.
- $C_{10}H_{11}N$ 1- α -Amyl piperidine, and its picrate (G. M. and R. ROBINSON), 541.
 1-Menthylamine, hydroferrocyanide of (CUMMING), 2457.
- $C_{10}H_{16}N_2$ 1:4-Dipropylpiperazine, and its picrates (G. M. and R. ROBINSON), 542.

FORMULA INDEX.

10 II—10 III

$C_{10}H_{20}N$ 3-Methyl- α -amyldiethylamine, and its salts (G. M. and R. ROBINSON), 541.

10 III

$C_{12}H_8ON$ 6-Cyanocoumarin (DEY and DALAL), 3387.

$C_{12}H_8O_2Cl$ Coumarin-6-carboxyl chloride (DEY and DALAL), 3388.

$C_{10}H_8O_2N$ Quinaldine acid, preparation of (HAMMICK), 2882.

$C_{10}H_8NCl_3$ ω -Trichloroquinaldine (HAMMICK), 2883.

$C_{12}H_8NBr_2$ ω -Tribromoquinaldine (HAMMICK), 2883.

$C_{12}H_8N_2Br_2$ Dibromo- α -phenylenediacetonitrile (CHALLENGER and INGOLD), 2078.

$C_{12}H_8O_2N$ Nitronaphthalenes, reduction of (CUMMING and STEEL), 2464.

$C_{12}H_8O_2N$ Coumarin-6-carboxylamide (DEY and DALAL), 3389.

$C_{12}H_8O_2Cl_2$ $\gamma\gamma$ -Dichlorobenzoylacetone (MACBETH), 1129.

$C_{12}H_8O_2N_2$ α -Cyano- β -2-hydroxyphenylacrylamide (CURTIS, DAY, and KIMMINS), 3139.

$C_{12}H_8O_2N_2$ 3:5-Dicyano-2:6-dihydroxy-4-isopropylpyridine (CURTIS, DAY, and KIMMINS), 3135.

$C_{12}H_8O_2Cl$ γ -Chlorobenzoylacetone (MACBETH), 1128.

$C_{10}H_8O_2N_2$ Methyl 5-hydroxy-1-phenyl-1:2:3-triazole-4-carboxylate, tautomerism of (DEXTER, McCOMBIE, and SCARBOROUGH), 1234.

$C_{10}H_8O_2N$ 5-Nitro-2-hydroxystyryl methyl ketone (HEILBRON and WHITWORTH), 210.

$C_{10}H_8OCl$ Substance, from anethole and sulphuryl chloride (DUFRANS), 1428.

$C_{10}H_8O_2N_2$ Hydroxydihydroquinoxalineacetic acid (PERKIN and RILEY), 2405.

$C_{10}H_8O_2N_4$ 6-Nitro-1-hydrindone semicarbazone (INGOLD and PIGGOTT), 1487.

Semicarbazone from substance $C_{10}H_8O_2N$ (INGOLD and PIGGOTT), 1495.

$C_{10}H_8O_2Br_2$ Dibromo-derivative of 5-cyclohexanespirocyclo- Δ^2 -penten-3-ol-1:4-dione (INGOLD, SEELEY, and THORPE), 864.

$C_{10}H_8O_2N_2$ Carbethoxynitrobenzylaloximes (BRADY and McHUGH), 1198.

$C_{10}H_8ON_2$ Cinnamaldehydesemicarbazone, phototropy of (HEILBRON, HUDSON, and HUISS), 2273.

$C_{10}H_{11}O_2N$ 6-Methoxy-1-hydrindoxime (INGOLD and PIGGOTT), 1492.

$C_{10}H_{11}O_2N_2$ Acetophenone semioxamazone, potassium salt (WILSON and PICKERING), 397.

$C_{10}H_{11}O_2Cl$ m -Methoxy- β -phenylpropionyl chloride (INGOLD and PIGGOTT), 1503.

$C_{10}H_{11}O_2N$ Carbethoxybenzylaloxime (BRADY and McHUGH), 1199.

$C_{10}H_{11}O_2Br$ Bromo-5-cyclohexanespirocyclo- Δ^2 -penten-3-ol-1:4-dione (INGOLD, SEELEY, and THORPE), 865.

5-Bromo-2-methoxy-3-ethoxybenzaldehyde (DAVIES), 1593.

$C_{10}H_{11}O_2N$ 5-Nitro-2-methoxy-3-ethoxybenzaldehyde (DAVIES), 1588.

5-Nitro-3-methoxy-2-ethoxybenzaldehyde (DAVIES and RUBENSTEIN), 2846.

$C_{10}H_{11}O_2N_2$ Acetyl derivative of 2:4-dinitro-6-amino- m -xylene (IBBOTSON and KENNER), 1267.

$C_{10}H_{11}O_4N$ Nitromethoxyethoxybenzoic acids (DAVIES), 1588, 1592; (DAVIES and RUBENSTEIN), 2847.

$C_{10}H_{11}ON_2$ Semicarbazone of 6-amino-1-hydrindone (INGOLD and PIGGOTT), 1490.

- $C_{10}H_{11}O_2N$, Acetyl derivatives of nitro-5-m-xylydines (IBBOTSON and KENNER), 1266.
 $C_{10}H_{11}O_2S$ 4-Methoxytolyl-3-thiolacetic acid (GIBSON and SMILES), 2390.
 $C_{10}H_{11}O_2Br$, Ethyl $\alpha\alpha'$ -dibromomuconates, isomeric (FARMER), 2542.
 $C_{10}H_{11}O_2S$ 4-Methoxytoluene-3-sulphonacetic acid (GIBSON and SMILES), 2391.
 $C_{10}H_{11}ON$ Methoxy-1-hydrindamines, and their hydrochlorides (INGOLD and PIGGOTT), 1493.
 $C_{10}H_{12}O_2N$ Acetyl-amino-m-tolyl methyl ethers (HAWORTH and LAPOWORTH), 2987.
 $C_{10}H_{12}O_2Br$ Bromo-1:3-dihydroxy-5-cyclohexanespirodi-cyclo- Δ^4 -pentenes (INGOLD, SEELEY, and THORPE), 871.
 $C_{10}H_{14}OBr$, α' - β - and $\alpha\alpha'$ -Dibromocamphor (BURORES and LOWRY), 1867.
 $C_{10}H_{14}O_2N_4$, $\alpha\alpha'$ -Dicyano- β -isopropylglutaramide (CURTIS, DAY, and KIMMINS), 3134.
 6-Imino-3-cyano-5-carbamyl-4-isopropyl-2-piperidone (CURTIS, DAY, and KIMMINS), 3134.
 $C_{10}H_{14}O_2Br$, Ethyl $\alpha\alpha'\beta\beta'$ -tetrabromoadipate (FARMER), 2539.
 $C_{10}H_{14}IAS$ Methyl-dihydroarsindole methiodide (TURNER and BURY), 2492.
 $C_{10}H_{12}O_2N$ Ethyl α -cyano- $\beta\beta$ -diethylacrylate (BIRCH and KOS), 2448.
 $C_{10}H_{12}O_2N$ Oxime of cyclopentanespirocyclopentan-3-one-1-carboxylic acid (INGOLD, LANFAR, and THORPE), 3151.
 $C_{10}H_{12}O_2Br$ Ethyl bromohydroxy- $\alpha\beta\beta$ -trimethylglutarolactone (PANDYA and THORPE), 2861.
 Bromo-lactonic ester of methylethylglutaric acid (SINGH and THORPE), 118.
 $C_{10}H_{12}ON$, α -Cyano- β -hexylacrylamide (CURTIS, DAY, and KIMMINS), 3137.
 $C_{10}H_{14}O_2Br$, Ethyl $\beta\beta'$ -dibromoadipate (FARMER), 2542.
 $C_{10}H_{17}ON$, cycloHexenylacetone semicarbazone, and its isomeride (BIRCH, KOS, and NORRIS), 1371.
 $C_{10}H_{17}OCl$ Bornylene chlorohydrin (HENDERSON and MAIR), 1157.
 $C_{10}H_{11}O_2N$, Semicarbazones of *cis*- and *trans*-1:1-dimethyl-2- β -ketopropylcyclopropane-2-carboxylic acids (SIMONSEN and RAU), 553.
 $C_{10}H_{20}O_2N$, *dl*-Piperitone- α - and - β -hydroxylamino-oximes (READ and SMITH), 2272.
 $C_{10}H_{11}ON$ 1-n-Butoxymethylpiperidine (G. M. and R. ROBINSON), 537.
 $C_{10}H_{12}S_2Pt$ Substance, from dithioethylene glycol and platonic chloride (RAY), 140.

10 IV

- $C_{10}H_8ONBr$, 2:5-Dibromoglyoxaline-4-carboxy-*p*-bromoanilide (KING and MURCH), 621.
 $C_{10}H_8OCIS$, 4-Chloro-1-naphthol 2-disulphide (GIBSON and SMILES), 2392.
 $C_{10}H_8ONBr$, 5-Bromoglyoxaline-4-carboxy-*p*-bromoanilide (KING and MURCH), 627.
 $C_{10}H_8OCIS$ 4-Chloro-1-naphthol 2-mercaptan (GIBSON and SMILES), 2392.
 $C_{10}H_8ONBr$ Glyoxaline-4-carboxy-*p*-bromoanilide (KING and MURCH), 624.
 $C_{10}H_9ONCl$ Carboethoxychlorobenzanilal-doximes (BRADY and MCGON), 1193.
 $C_{10}H_9ONBr$ 5-Bromonitro-2-methoxy-3-ethoxybenzaldehyde (DAVIES), 1698.
 $C_{10}H_{11}ONCl$, Dichloroacetoethylamylide (McKIN), 2215.

FORMULA INDEX.

10 IV-41 II

- $C_{12}H_{12}O_4N_2S$ *p*-Acetylcabamidotoluene-*m*-sulphonic acid (+ H_2O) (SCOTT), 3195.
 $C_{12}H_{12}O_4NS$ Aceto-*p*-xylidide-6-sulphinic acid (JOHNSON and SMILES), 2387.
 $C_{12}H_{12}O_4NS$ 4-Acetylaminophenetole-2-sulphinic acid (JOHNSON and SMILES), 2386.
 $C_{12}H_{12}O_4N_2Co_2$ Citraconatodipentamminecobaltic citraconate nitrate (DUFF), 570.
 Itaconatodipentamminecobaltic itaconate nitrate (DUFF), 570.
 $C_{12}H_{12}O_4N_2Co_2$ Glutaratodipentamminecobaltic glutarate nitrate (DUFF), 570.

10 V

- $C_{12}H_8O_2NIS$ Naphthalene- α - and - β -sulphoniodoamides, potassium and sodium salts (ROBERTS), 852.
 $C_{12}H_{11}ONClBr$ Chlorobromacetoethylanilide (McKIE), 2215.
 $C_{12}H_{12}O_4NCIS$ 4-Acetylaminophenetole-2-sulphonyl chloride (JOHNSON and SMILES), 2386.
 $C_{12}H_{12}ONClS$ 2-Chloro-6-thiol-3-oxy-7,9-dimethylpurine *n*-propyl ether (RAY, CHAKRAVARTI, and BOSE), 1961.

C_{11} Group.

- $C_{11}H_8O_2$ Hydroxynaphthoic acids (ROYLE and SCHEDLER), 1641; (BUTLER and ROYLE), 1649.
 $C_{11}H_8O_4$ Acetyl- ψ -phthalonic acid (KURODA and PERKIN), 2106.
 4:5-Dimethoxyphthalonic anhydride (KURODA and PERKIN), 2099.
 $C_{11}H_8N_2$ 4-Amino- β -naphthonitrile (BUTLER and ROYLE), 1652.
 $C_{11}H_{16}O_4$ 1-Ketotetrahydronaphthalene-3-carboxylic acid (ATTWOOD, STEVENSON, and THORPE), 1784.
 $C_{11}H_{11}N$ Dihydropentindole, and its picrate (PERKIN and PLANT), 3244.
 $C_{11}H_{13}O_2$ Methoxy-2-hydroxystyryl methyl ketones (HEILBRON and WHITWORTH), 244.
 $C_{11}H_{13}O_4$ 2:3-Dimethoxycinnamic acid (PERKIN and STOTLEY), 3174.
 $C_{11}H_{12}O_4$ β :1-Dicarboxy- β :1-cyclohexanecarboxylic anhydride (INGOLD, SEELBY, and THORPE), 868.
*cyclo*Pentane*spiro*dicyclopentan-3-one-1:2-dicarboxylic acid (INGOLD, LANFAR, and THORPE), 8149.
 $C_{11}H_{14}O_4$ 2:3-Diethoxybenzaldehyde (DAVIES and RYBENSTEIN), 2847.
 Hydroxy- γ -phenylmethylbutyric acids (ATTWOOD, STEVENSON, and THORPE), 1785.
 $C_{11}H_{14}O_4$ β -Hydroxy- β :3-methoxy-2-hydroxyphenylethyl methyl ketone (HEILBRON and WHITWORTH), 242.
 $C_{11}H_{14}O_4$ *trans-cyclo*Heptane*spiro*cyclopropane-2:3-dicarboxylic acid (BAKER and INGOLD), 130.
 α -Hydroxycycloheptane-1:1-diacetic lactone, and its silver salt (BAKER and INGOLD), 131.
 $C_{11}H_{14}O_4$ *aa'*-Dihydroxycycloheptane-1:1-diacetic lactone, and its silver salt (BAKER and INGOLD), 131.
 Ethyl γ -oxalyl- $\alpha\beta$ -dimethylacrylate (HIGGINBOTHAM and LAPWORTH), 2381.
*cyclo*Heptane*spiro*cyclopropan-2-ol-2:3-dicarboxylic acid (BAKER and INGOLD), 133.
 $C_{11}H_{16}N$ Benzyl-diethylamine, chloroplatinate of (G. M. and R. ROBINSON), 640.

$C_{11}H_{18}O$ $\alpha\alpha$ -Dimethyl- Δ^1 -cyclohexenylacetone (BIRCH, KON, and NORRIS), 1373.

α -Ethyl- Δ^1 -cyclohexenylacetone (BIRCH, KON, and NORRIS), 1372.

$C_{11}H_{18}O_2$ $\beta\beta$ -Di- π -propylglutaric anhydride (BAINS and THORPE), 1210.

$C_{11}H_{18}O_4$ cycloHeptane-1:1-diacetic acid, preparation of (BAKER and INGOLD), 123.

$C_{11}H_{18}O_5$ 3:3-Di- π -propylcyclopropan-1-ol-1:2-dicarboxylic acid, and its ammonium salt (BAINS and THORPE), 1212.

α -Hydroxycycloheptane-1:1-diacetic acid, silver salt (BAKER and INGOLD), 131.

α -Keto- $\beta\beta$ -di- π -propylglutaric acid (BAINS and THORPE), 1211.

$C_{11}H_{18}O_4$ $\alpha\alpha'$ -Dihydroxycycloheptane-1:1-diacetic acid, silver salt (BAKER and INGOLD), 132.

$C_{11}H_{18}O_5$ cycloPentanespiroindicyclopentan-3-one-1:2-dicarboxylic anhydride (INGOLD, LANFAR, and THORPE), 3150.

II III

$C_{11}H_8O_2S$ Thionaphthacoumarin (SMILES and HART), 2911.

$C_{11}H_8O_2N_2$ Dinitroquinolpyridinium nitrolbetaine (BARNETT, COOK, and DRISCOLL), 513.

$C_{11}H_8O_2Cl_2$ 3:6-Dichloro-4:7-dimethylcoumarin (DEY and DALAL), 3390.

$C_{11}H_8O_2S$ 1-Carboxynaphthalenesulphonic acids, potassium and sodium salts (ROYLE and SCHEDLER), 1644.

Sulpho- β -naphthoic acids, potassium salts (BUTLER and ROYLE), 1652.

$C_{11}H_8O_2N$ 4-Amino- β -naphthoic acid (BUTLER and ROYLE), 1652.

Catecholpyridinium betaine (BARNETT, COOK, and DRISCOLL), 514.

β -Naphthol-4-carboxylamide (CHALLENGER and INGOLD), 2078.

$C_{11}H_8O_2Cl$ Chloro-4:7-dimethylcoumarins (DEY and DALAL), 3389.

$C_{11}H_8O_2Cl$ 4-Chloro-2:5-dimethylcoumarilic acid, and its potassium salt (DEY and DALAL), 3390.

$C_{11}H_8O_2N$ Ethyl-4-nitrocoumarilate (DEY and ROW), 3380.

$C_{11}H_{10}ON_4$ 4-Keto-2- π -tolyl-1:4-dihydropyrimidine (MITTER and BARNAN), 2183.

$C_{11}H_9O_2N_2$ α -Cyano- β -4-methoxyphenylacrylamide (CURTIS, DAY, and KIMMINS), 3139.

$C_{11}H_9O_2N_2$ Carboethoxy-6-nitro-3:4-methylenedioxybenzoxalaloxime (BRADY and McHUGH), 1198.

$C_{11}H_9N_2S_2$ 2:4:5-Trimethylbenzobisthiazole (EDGE), 1013.

2:4:7-Trimethylbenzobisthiazole, and its hydrochloride (EDGE), 155.

$C_{11}H_{11}O_2N$ Acetylamino-1-hydrindones (INGOLD and PIGGOTT), 1490.

$C_{11}H_{11}O_2N_2$ 3:5-Dicyano-2:6-dihydroxy-4-isobutylpyridine (CURTIS, DAY, and KIMMINS), 3126.

$C_{11}H_{11}O_2N$ m -Acetylamino-cinnamic acid (INGOLD and PIGGOTT), 1501.

$C_{11}H_{11}O_2N_2$ Ethyl 5-hydroxy-1-phenyl-1:2:3-triazole-4-carboxylate (DUTT), 272.

$C_{11}H_{11}O_2Br$ 2:2:4-Tribromo-5-cyclohexanespiroindicyclopentan-3-one-1-carboxylic acid (INGOLD, SEZLEY, and THORPE), 869.

$C_{11}H_{11}O_2N$ Methyl 4-nitrohomophthalate (INGOLD and PIGGOTT), 1499.

2-Nitro- m -tolyl benzoate (GIBSON), 1272.

$C_{11}H_{11}O_2N$ Carboethoxy-3:4-methylenedioxybenzoxalaloxime (BRADY and McHUGH), 1196.

$C_{11}H_{11}O_2Br$ α -Bromo- β -1-dicarboxy- β -cyclohexaneacrylic anhydride (INGOLD, SEZLEY, and THORPE), 870.

$C_{11}H_{11}NS$ 4-Phenyl-2:5-dimethylthiazole, and its salts (SMITH), 2231.

- $C_{11}H_{15}O_2N_2$ 6-Acetylaminol-1-hydrindoxime (INGOLD and PIGGOTT), 1490.
- $C_{11}H_{15}O_2N_2$ Ethyl 5-amino-1-phenyl-1:2:3-triazole-4-carboxylate (DUTT), 269.
- Ethyl 2:5-imino-1-phenyldihydro-1:2:3-triazole-4-carboxylate (DUTT), 269.
- $C_{11}H_{15}O_2N_2$ Acetyl-6-nitro-1-hydrindamine (INGOLD and PIGGOTT), 1484.
- 3:4-Oxido-2-keto-3-hydroxy-1-methyl-1:2:3:4-tetrahydroquinoxaline ethyl ether (USHERWOOD and WHITELEY), 1082.
- Acetyl derivative of formylaminoacetanilide or 2-hydroxy-4-keto-3-phenyltetrahydroglyoxaline (USHERWOOD and WHITELEY), 1086.
- $C_{11}H_{15}O_2Br_2$ 2:4-Dibromo-5-cyclohexanespiro[cyclo- Δ^2 -penten-3-ol-1-carboxylic acid (INGOLD, SEELEY, and THORPE), 868.
- $C_{11}H_{15}ON$ Acetylhydrindamine (INGOLD and PIGGOTT), 1484.
- $C_{11}H_{15}O_2N_2$ Methoxycinnamaldehydesemicarbazones, and their phototropy (HEILBRON, HUDSON, and HUISS), 2276.
- $C_{11}H_{15}O_2N_2$ β -Benzylpropionic acid semicarbazone (ATTWOOD, STEVENSON, and THORPE), 1762.
- $C_{11}H_{15}O_2Br$ Bromo-2:3-diethoxybenzaldehyde (DAVIES and RUBENSTEIN), 2849.
- 4-Bromo-5-cyclohexanespiro[cyclo- Δ^2 -penten-3-ol-1-carboxylic acid (INGOLD, SEELEY, and THORPE), 868.
- $C_{11}H_{15}O_2N$ Carbethoxymethoxybenzaldoximes (BRADY and McHUGH), 1194.
- $C_{11}H_{15}O_2N$ 5-Nitro-2:3-diethoxybenzaldehyde (DAVIES and RUBENSTEIN), 2848.
- $C_{11}H_{15}O_2N$ Nitro-2:3-diethoxybenzoic acids (DAVIES and RUBENSTEIN), 2849.
- $C_{11}H_{15}ON_2$ 6-Acetylaminol-1-hydrindamine (+ $2H_2O$) (INGOLD and PIGGOTT), 1490.
- $C_1H_{14}O_2N_2$ α -Cyanocyclohexane-1:1-diacet- ω -imide (BIRCH and KON), 2445.
- $C_{11}H_{14}O_2S$ 4-Methoxytoluene-3-sulphonacetone (GIBSON and SMILES), 2390.
- $C_{11}H_{14}N_2S_2$ Dithioacetyl-2:5-tolylenediamine (EDGE), 1013.
- $C_{11}H_{15}O_2N_2$ 3-Cyano-2:6-diketo-4-isobutylpiperidine-5-carboxylamide (CURTIS, DAY, and KIMMINS), 3135.
- Semicarbazone of cyclopentanespiro[cyclopentan-3-one-1-carboxylic acid (INGOLD, LANFEAR, and THORPE), 3150.
- $C_{11}H_{15}O_2N_4$ 6-Imino-3-cyano-5-carbamyl-4-isobutyl-2-piperidone (CURTIS, DAY, and KIMMINS), 3135.
- $C_{11}H_{15}IAS$ Methylidihydroarsindole ethiodide (TURNER and BURY), 2492.
- $C_{11}H_{15}O_2N_2$ Semicarbazone of cyclopentanespiro[cyclopentan-3-one-1-carboxylic acid (INGOLD, LANFEAR, and THORPE), 3151.
- $C_{11}H_{17}O_2Br$ α -Bromo- α' -hydroxy- $\beta\beta$ -di-*n*-propylglutaronitrile (BAINS and THORPE), 1211.
- $C_{11}H_{17}O_2Br_2$ $\alpha\alpha'$ -Dibromo- $\beta\beta$ -di-*n*-propylglutaric acid (BAINS and THORPE), 1211.
- $C_{11}H_{17}IAS$ β -Phenylethyl dimethylarsine methiodide (TURNER and BURY), 2490.
- $C_{11}H_{17}O_2N$ β -Hexylglutarimide (CURTIS, DAY, and KIMMINS), 3137.
- $C_{11}H_{17}ON_2$ *iso*Menthone semicarbazones (HUGHESON, SMITH, and READ), 2920.
- $C_{11}H_{19}O_2N$ Di(*n*-butoxymethyl)methylamine (G. M. and R. ROBINSON), 537.

II IV

- $C_{11}H_6O_2Cl_2S$ 3:4-Dichlorothionaphthacoumarin (SMILES and HART), 2913.
 $C_{11}H_6O_2ClS$ 4-Chloro-1-naphthol-2-thiocarbonate (GIBSON and SMILES), 2393.
 4-Chlorothionaphthacoumarin (SMILES and HART), 2912.
 $C_{11}H_6O_2NS$ 2-Cyanonaphthalenesulphonic acids, potassium and sodium salts (BUTLER and ROYLE), 1651.
 $C_{11}H_6O_4NBr$ 3:8-Dibromo-6-nitro-4:7-dimethylcoumarin. (DEV and ROW), 3382.
 $C_{11}H_6O_4NBr$ 6-Bromo-4-nitro-2:5-dimethylcoumarilic acid, and its sodium salt (DEV and ROW), 3382.
 Ethyl 6-bromo-4-nitrocoumarilate (DEV and ROW), 3382.
 $C_{11}H_6O_4N_2Cl$ 2:5-Dinitroquinolpyridinium chloride (BARNETT, COOK, and DRISCOLL), 513.
 $C_{11}H_6O_4N_2Br$ 2:5-Dinitroquinolpyridinium bromide (BARNETT, COOK, and DRISCOLL), 512.
 $C_{11}H_6O_4NBr$ 2-Bromoquinol-3-pyridinium bromide (BARNETT, COOK, and DRISCOLL), 512.
 $C_{11}H_6O_4NBr$ Catecholpyridinium bromide, and its picrate (BARNETT, COOK, and DRISCOLL), A., i, 514.
 Quinolpyridinium bromide (+ H_2O), and its picrate (BARNETT, COOK, and DRISCOLL), 510.
 $C_{11}H_6O_4NBr$ Quinolpyridinium perbromide (BARNETT, COOK, and DRISCOLL), 511.
 $C_{11}H_{10}ON_2S$ Benzylidene derivative of 2:4-diketo-5-methyltetrahydrothiazole-2-hydrazone (WILSON and BURNS), 802.
 $C_{11}H_{10}ON_2S$ Methoxycinnamaldehyde thiosemicarbazones, and their phototropy (HEILRON, HUDSON, and HUISEN), 2277.
 $C_{11}H_{10}ON_2Br$ Acetyl-3-bromo-*p*-dimethylaminobenzantialdoxime (BRADY and TRZKOWSKI), 2438.
 $C_{11}H_{10}ON_2S_2$ 2:6-Dithiol-8-oxy-7:9-dimethylpurinediethyl ether (RAY, CHAKRAVARTI, and BORK), 1962.
 $C_{11}H_{10}ON_2Cl$ Bornylene chlorohydrin semicarbazone (HENDERSON and MAIR), 1158.

C_{11} Group.

- $C_{11}H_{10}O_4$ Ethyl coumarin-6-carboxylate (DEV and DALAL), 3388.
 $C_{11}H_{10}O_4$ 1-Ketotetrahydronaphthalene-3:3-dicarboxylic acid (ATTWOOD, STEVENSON, and THORPE), 1763.
 $C_{11}H_{10}O_{11}$ *cyclo*Propyl*cyclo*propanehexacarboxylic acid, and its sodium salt (FARMER), 3339.
 $C_{11}H_{10}S_2$ Substance, from phenyl mercaptan and sulphur monochloride (CHAKRAVARTI), 966.
 $C_{11}H_{11}N$ Diphenylamine, action of methyl sulphate on (GIBSON and VINING), 831.
 $C_{11}H_{10}O_2$ Methoxy-2:3-dimethylchromones (HEILRON, BAUNES, and MORTON), 2568.
 $C_{11}H_{10}O_2$ Methyl hydrogen dimethoxyphthalonate (+ H_2O) (KURODA and PERKIN), 2101.
 $C_{11}H_{11}N_2$ Hydrazobenzene, hydroferrocyanide of (CUMMING), 2462.
 $C_{11}H_{11}N_2$ Chydindine-Y, hydroferrocyanide of (CUMMING), 2439.
 $C_{11}H_{11}N$ 8-Methylidihydropentindole, and its picrate (PERKIN and FLANT), 3245.

FORMULA INDEX.

12 II—12 III

- $C_{12}H_{14}O_2$ Ethyl β -keto- γ -phenylbutyrate (ATTWOOD, STEVENSON, and THORPE), 1702.
 $C_{11}H_{14}O_4$ β -4:5-Dimethoxy- α -tolylacrylic acid (KURODA and PERKIN), 2110.
 $C_{11}H_{14}O_2$ Methyl 4:5-dimethoxy- α -tolylglyoxylate (KURODA and PERKIN), 2108.
 $C_{11}H_{14}N_2$ 8-Aminotetrahydrocarbazole (PERKIN and RILEY), 2407.
 Aminotetrahydrocarbazoles, and their salts (EDWARDS and PLANT), 2395.
 $C_{11}H_{12}N_2$ Substance, from reduction of cyclohexanone α -nitrophenylhydrazones (PERKIN and RILEY), 2408.
 $C_{11}H_{14}O_4$ α -Ethoxyacetoveratrone (PRATT and ROBINSON), 752.
 $C_{11}H_{12}O_7$ Arbutin (MACBETH and MACKAY), 717.
 $C_{11}H_{19}N$ β -Phenyltriethylamine (G. M. and R. ROBINSON), 542.
 $C_{12}H_{22}O_{11}$ Gentiobiose, constitution of (HAWORTH and WYLAM), 3120.
^{iso}Maltose, preparation of (LING and NANJ), 2631.
 Sucrose, constitution of (HAWORTH and LINNELL), 294; (HAWORTH and MITCHELL), 301; (BERGMANN), 1277; surface tension and density of solutions of (BUTLER), 2060.
 $C_{12}H_{24}O_2$ Lauric acid, potassium salt, migration data for (MCBAIN and BOWDEN), 2417.

12 III

- $C_{11}H_8O_4S$ Thionaphthacoumarin-4-carboxylic acid (SMILES and HART), 2910.
 $C_{12}H_8NCl$ Chloroaminoacenaphthene (FARNELL), 60.
 $C_{12}H_8NS_2$ 3-Aminothianthren, and its salts (KRISHNA), 158.
 $C_{12}H_{10}ON$ Cinnamylidenecyanacetamide (CURTIS, DAY, and KIMMINS), 3136.
 $C_{11}H_{10}O_2N$ 2-Phenyl-4-methylpyrimidine-5-carboxylic acid (MITTER and BARDHAN), 2181.
 $C_{11}H_{10}O_2N_4$ Dinitrobenzidines, isomerism of (BRADY and McHUGH), 2047.
 $C_{11}H_{11}OTl$ Thalliumdiphenyl hydroxide, salts of (GODDARD), 1164.
 $C_{12}H_{11}O_2N$ Coumarin-6-formiminoether, and its hydrochloride (DEY and DALAL), 3388.
 $C_{11}H_{11}O_2N$ Dimethoxyphthalonic acid anhydrosemicarbazone (KURODA and PERKIN), 2102.
 $C_{11}H_{12}O_2N$ 9-Nitro- ψ -indoxylspirocyclopentane (PERKIN and PLANT), 691.
 $C_{12}H_{12}O_2Br_2$ 2:4-Dibromo-5-cyclohexanespirocyclopentan-3-one-1:2-dicarboxylic acid (INGOLD, SEELEY, and THORPE), 868.
 $C_{11}H_{12}ON$ 11-Hydroxytetrahydrocarbazolenine (PERKIN and PLANT), 689.
 ψ -Indoxylspirocyclopentane (PERKIN and PLANT), 689.
 $C_{11}H_{12}O_2N$ Styryl methyl ketone semioxamazone, salts (WILSON and PICKERING), 397.
 $C_{11}H_{12}O_2N$ Ethyl 5-hydroxy-1-*p*-tolyl-1:2:3-triazole-4-carboxylate (DUTT), 273.
 1-Ketotetrahydronaphthalene-3-carboxylic acid semicarbazone (ATTWOOD, STEVENSON, and THORPE), 1764.
 $C_{11}H_{12}OI$ Ethyl *m*-iodophthalate (BURTON and KENNER), 1045.
 $C_{12}H_{12}O_2Br$ Bromo-5-cyclohexanespirocyclo- Δ^2 -penten-3-ol-1:2-dicarboxylic acid (INGOLD, SEELEY, and THORPE), 868.
 $C_{12}H_{14}O_2N$ Methyl derivative of ethyl 2:5-imino-1-phenyl-1:2:3-triazole-4-carboxylate (DUTT), 270.
 $C_{12}H_{15}ON$ Acetylmethoxy-1-hydrindamines (INGOLD and PIGGOTT), 1493.
 $C_{11}H_{13}O_2N$ Benzylacetonesemioxamazone (WILSON and PICKERING), 396.

- $C_{12}H_{15}O_2N$ 3-*o*-Aminobenzoylvaleric acid (PERKIN and PLANT), 687.
 $C_{12}H_{13}O_2N_2$ Diethylcarbamylnitrobenzaldoximes (BRADY and RIDGE), 2167.
 $C_{12}H_{13}O_2N_2$ Carbethoxy-3-nitro-4-dimethylaminobenzantialdoxime (BRADY and McHUGH), 1197.
 $C_{12}H_{13}O_2N_2$ 4:5-Dimethoxy-*o*-tolylglyoxylic acid semicarbazone (KURODA and PERKIN), 2109.
 $C_{12}H_{13}O_2N_2$ Dimethoxyphthalonic acid semicarbazone (KURODA and PERKIN), 2101.
 $C_{12}H_{15}N_2S_2$ *cyclo*Hexylene dithiocarbonate 2-pyridylhydrazone (MILLS and SCHINDLER), 320.*
 $C_{12}H_{15}O_2Se$ Selenium acetylpropionylmethane (MORGAN and REEVES), 445.
 $C_{12}H_{17}O_2N_2$ Veratrylmethoxyacetaldehydesemicarbazones (PRATT and ROBINSON), 757.
 $C_{12}H_{15}O_2Se$ Selenium *OC*-bisacetylpropionylmethane (MORGAN and REEVES), 450.
 $C_{12}H_{15}O_2Se$ Diselenium bisacetylpropionylmethane, and its copper salt (MORGAN and REEVES), 449.
 $C_{12}H_{15}N_2Cl_4$ Tetra-aminodiphenyls (BRADY and McHUGH), 2052.
 $C_{12}H_{15}O_2Br$ Diethyl hydrogen α -bromomethylmethanetriacetate (FARMER), 3337.
 $C_{12}H_{19}O_2Br_2$ Ethyl $\alpha\alpha'$ -dibromo- $\beta\beta$ -methyleneethylglutarate (SINGH and THORPE), 118.
 $C_{12}H_{15}IAs$ β -Phenylethyl dimethylarsine ethiodide (TURNER and BURY), 2490.
 $C_{12}H_{21}ON_2$ α -Ethyl- Δ^1 -*cyclo*hexenylacetone semicarbazone (BIRCH, KON, and NORRIS), 1372.
 $C_{12}H_{21}O_2N_2$ Semicarbazone of α -keto- $\beta\beta$ -di-*n*-propylglutaric acid (BAINS and THORPE), 1212.
 $C_{12}H_{22}NI_6$ Tetra-*n*-propylammonium triiodide (CHATTAWAY and HOYLE), 662.
 $C_{12}H_{22}NI_6$ Tetra-*n*-propylammonium penta iodide (CHATTAWAY and HOYLE), 662.
 $C_{12}H_{22}NI_6$ Tetra-*n*-propylammonium hepta iodide (CHATTAWAY and HOYLE), 662.
 $C_{12}H_{18}S_{12}Pt$ Substance, from dithioethylene glycol and platinum chloride (RAY), 140.

12 IV

- $C_{12}H_8O_2NCl$ Chloronitronaphthalic anhydride (FARNELL), 61.
 $C_{12}H_8O_2NCl$ Chloronitronaphthalic acid, and its salts (FARNELL), 61.
 $C_{12}H_8O_2NS$ 3-Nitrothianthren, and its ferrichloride (KRISHNA), 158.
 $C_{12}H_8O_2NS$ 3-Nitrophenothioxin (KRISHNA), 2784.
 $C_{12}H_8O_2NS$ 3-Nitrothianthren oxide (KRISHNA), 159.
 $C_{12}H_8O_2NS$ 3-Nitrothianthren dioxide (KRISHNA), 159.
 $C_{12}H_8O_2NS$ 3-Nitrophenothioxin dioxide (KRISHNA), 2784.
 $C_{12}H_8O_2NS$ 3-Nitrothianthren tetroxide (KRISHNA), 159.
 $C_{12}H_8O_2NCl$ 3-Chloro-4-nitroacenaphthene (FARNELL), 60.
 $C_{12}H_8NClS$ 6-Chloro-3-aminothianthren, hydrochloride of (KRISHNA), 2789.
 $C_{12}H_8O_2NS$ 4-Nitro-2-sulphinodiphenyl sulphide (KRISHNA), 158.
 $C_{12}H_8O_2NS$ 4-Nitro-2-sulphinodiphenyl ether (KRISHNA), 2784.
 $C_{12}H_{11}ON_2Br$ 7-Benzoyl:3:5-dimethylpyrazole (MORGAN and ACKERMAN), 1316.

FORMULA INDEX.

12 IV—13 II

- $C_{12}H_{11}ON_2I$ Benzoyl-4-iodo-3:5-dimethylpyrazole (MORGAN and ACKERMAN), 1818.
 $C_{12}H_{11}O_2ClS$ Diacetyl-4-chloro-1-naphthol-2-mercaptan (GIBSON and SMILES), 2392.
 $C_{12}H_{11}O_2N_2As$ 3:8'-Diamino-4:4'-dihydroxyarsenobenzene, salts of (GRAY), 640.
 $C_{12}H_{11}O_2N_2Cl$ Ethyl 5-chloro-1-*p*-tolyl-1:2:3-triazole-4-carboxylate (DUFF), 273.
 $C_{12}H_{12}ON_2S$ 2:4-Diketo-5-phenyltetrahydrothiazole-2-isopropylidenehydrazone (WILSON and BURNS), 803.
 Benzylidene derivative of 2:4-diketo-5-ethyltetrahydrothiazole-2-hydrazone (WILSON and BURNS), 802.
 $C_{12}H_{12}N_2IS$ 2:4:6-Trimethylbenzbiethiazole methiodide (EDGE), 1018.
 $C_{12}H_{14}NIS$ 4-Phenyl-2:5-dimethylthiazole methiodide (SMITH), 2291.
 $C_{12}H_{12}NCl_2I$ Tetra-*n*-propylammonium dichloriodide (CHATTAWAY and HOYLE), 662.
 $C_{12}H_{12}NCl_2I$ Tetra-*n*-propylammonium tetrachloriodide (CHATTAWAY and HOYLE), 661.
 $C_{12}H_{12}NBr_2I$ Tetra-*n*-propylammonium dibromiodide (CHATTAWAY and HOYLE), 662.

12 V

- $C_{12}H_8O_2NCl_2S_2$ 5:8-Dichloro-3-nitrothianthren (KRISHNA), 2790.
 $C_{12}H_8O_2NCl_2S_2$ 5:8-Dichloro-3-nitrothianthren tetroxide (KRISHNA), 2790.
 $C_{12}H_8O_2NClS$ 6-Chloro-3-nitrothianthren (KRISHNA), 2789.
 $C_{12}H_8O_2NClS$ 6-Chloro-3-nitrophenothioxin (KRISHNA), 2785.
 $C_{12}H_8O_2NClS$ 6-Chloro-3-nitrophenothioxin dioxide (KRISHNA), 2785.
 $C_{12}H_8O_2NClS$ 6-Chloro-3-nitrothianthren tetroxide (KRISHNA), 2789.
 $C_{12}H_8O_2NCl_2S$ 6:6'-Dichloro-3-nitro-4'-hydroxydiphenyl sulphide (KRISHNA), 2785.
 $C_{12}H_8O_2NCl_2S_2$ 3':6'-Dichloro-4-nitro-2-sulphindiphenyl sulphide, sodium salt (KRISHNA), 2790.
 $C_{12}H_8O_2NClS$ 6-Chloro-3-nitro-4'-hydroxydiphenyl sulphide (KRISHNA), 2784.
 $C_{12}H_8O_2NClS_2$ 4'-Chloro-4-nitro-2-sulphindiphenyl sulphide (KRISHNA), 2789.
 $C_{12}H_8O_2NClS$ 4'-Chloro-4-nitro-2-sulphindiphenyl ether (KRISHNA), 2785.
 $C_{12}H_{10}O_2N_2Cl_2As$ Salvarsan, nature of the silver derivative of (GRAY), 635.
 $C_{12}H_{12}NClBrI$ Tetra-*n*-propylammonium chlorobromiodide (CHATTAWAY and HOYLE), 661.

C_{13} Group

- $C_{13}H_8O_3$ 1:6:8-Trihydroxy fluorone (PRATT and ROBINSON), 741.
 $C_{13}H_{10}O_4$ Acetoxy-*a*-naphthoic acids (ROYLE and SCHENLER), 1645.
 Acetoxy-*β*-naphthoic acids (BUTLER and ROYLE), 1653.
 $C_{13}H_{10}O_3$ Ethyl hydroxynaphthoates (BUTLER and ROYLE), 1654.
 $C_{13}H_{10}O_3$ Acetyl-4:5-dimethoxy-*ψ*-phthalonic acid (KYRODA and PERKIN), 2100.
 $C_{13}H_{12}N_2$ Diphenylformamidine, condensation of, with phenols (SHOESMITH and HALDANE), 2704.
 $C_{13}H_{12}N$ Methylidiphenylamine, action of methyl sulphate on (GIBSON and VININO), 831.
 Methylidiphenylamine, hydroferrocyanide of (CUMMING), 2458.

- $C_{13}H_{10}O_2$ 6-Methoxy-2:3-dimethylchromone (HEILBRON, BARNES, and MORTON), 2567.
 $C_{13}H_{10}O_2$ Dimethyl dimethoxyphthalonate (KURODA and PERKIN), 2101.
 Ethyl hydrogen dimethoxyphthalonate, and its silver salt (KURODA and PERKIN), 2101.
 $C_{13}H_{14}O_4$ α -Acetoxy- γ -phenyl- α -methylbutyric acid (ATTWOOD, STEVENSON, and THORPE), 1765.
 $C_{13}H_{14}O_4$ Ethyl hydrogen cyclopentanespirodiacyclopentan-3-one-1:2-dicarboxylate (INGOLD, LANFAR, and THORPE), 3149.
 $C_{13}H_{14}O_4$ Ethyl 5-cyclohexanespirodiacyclo- Δ^3 -penten-3-ol-1-carboxylate (INGOLD, SALLEY, and THORPE), 873.
 Ethyl β -hydroxy- γ -phenyl- α -methylbutyrate (ATTWOOD, STEVENSON, and THORPE), 1765.
 $C_{13}H_{20}O_2$ Pentaerythritol acetate, crystal structure of (KNAGGS), 77.
 $C_{13}H_{11}N$ α -cyclohexylideneisohexonitrile (BIRCH and EON), 2446.

13 III

- $C_{13}H_9O_2Cl$ 6-Chloro-1:2- α -naphthapyrone (DEY and DALAL), 3391.
 $C_{13}H_9O_4N_2$ 4-Cyano-1-carboxylamido- β -naphthol-3-carboxylic acid (CHALLENGER and INGOLD), 2078.
 $C_{13}H_9O_2N$ 6-Amino-1:2- α -naphthapyrone (DEY and DALAL), 3390.
 $C_{13}H_9O_2Cl$ 1:3:6:8-Tetrahydroxanthylum chloride (+ H_2O) (PRATT and ROBINSON), 740.
 $C_{13}H_{10}O_2N$ Naphthastyrylacetic acid (DUTT), 224.
 $C_{13}H_{10}NBr$ 3-Bromo- N -methylcarbazole (STEVENS and TUCKER), 2146.
 $C_{13}H_{10}N_2Br_2$ Benzaldehydedibromophenylhydrazones (HUMPHRIES, BLOOM, and EVANS), 1769.
 $C_{13}H_{10}NI$ 3-Iodo- N -methylcarbazole (STEVENS and TUCKER), 2146.
 $C_{13}H_{11}O_4N$ α -Naphthylglycine-8-carboxylic acid, sodium salt (DUTT), 224.
 $C_{13}H_{11}NS_2$ 3-Amino-6-methylthianthren, hydrochloride of (KRISHNA), 2788.
 $C_{13}H_{11}ON_2$ 5-Acetyl-2-phenyl-4-methylpyrimidine (MITTER and BARDHAN), 2181.
 $C_{13}H_{11}O_2N_2$ 2- p -Tolyl-4-methylpyrimidine-5-carboxylic acid (MITTER and BARDHAN), 2181.
 $C_{13}H_{11}O_2N_2$ Ethyl 4-keto-2-phenyl-1:4-dihydropyrimidine-5-carboxylate (MITTER and BARDHAN), 2183.
 4-Nitro-8-acetyldihydropentindole (PERKIN and PLANT), 3246.
 $C_{13}H_{11}ON$ 8-Acetyldihydropentindole (PERKIN and PLANT), 3245.
 $C_{13}H_{11}O_2N_2$ 1-Ketotetrahydronaphthalene-3:3-dicarboxylic acid semicarbazone (ATTWOOD, STEVENSON, and THORPE), 1764.
 $C_{13}H_{11}O_2N_2$ 9-Nitro-6-methyl- ϕ -indoxylspirocyclopentane (PERKIN and PLANT), 691.
 $C_{13}H_{11}O_2N_2$ 10-Nitro-8-acetyl-9-hydroxytetrahydropentindole (PERKIN and PLANT), 3246.
 $C_{13}H_{11}O_2Cl$ Ethyl α -chloroethylbenzoylacetate (MACBETH), 1128.
 $C_{13}H_{11}O_2Br$ Ethyl α -bromobenzoylacetate (MACBETH), 1127.
 Ethyl α -bromoethylbenzoylacetate (MACBETH), 1128.
 $C_{13}H_{11}O_2N_2$ 1:6-Diacetyl-amino-1-hydrindamine (INGOLD and PIGGOTT), 1491.
 $C_{13}H_9N_2S_2$ ϕ -Hexylene dithiocarbonate phenylhydrazone (MILLS and SCHIMMELER), 320.

FORMULA INDEX.

13 III—14 II

- $C_{13}H_{10}O_2Br$ Ethyl hydrogen α -bromo- α -hydroxycycloheptane-1:1-di-acetic lactone (BAKER and INGOLD), 130.
 $C_{13}H_{10}O_2N_4$ $\alpha\alpha'$ -Dicyano- β -hexylglutaramide (CURTIS, DAY, and KIMMINS), 3136.
 6-Imino-3-cyano-5-carbamyl-4-hexyl-2-piperidone (CURTIS, DAY, and KIMMINS), 3137.
 $C_{13}H_{20}O_2Br_2$ Ethyl $\alpha\alpha'$ -dibromo- α' -hydroxy- $\beta\beta$ -di-*n*-propylglutarolactone (BAINS and THORPE), 2744.
 $C_{13}H_{20}O_2N_2$ 4:5-Dimethoxy-*o*-tolylglyoxylic acid semicarbazide semicarbazone (KURODA and PERKIN), 2108.
 $C_{13}H_{18}O_2Br$ Ethyl hydrogen α -bromocycloheptane-1:1-diacetate (BAKER and INGOLD), 130.
 Ethyl hydrogen α -bromo- α' -hydroxy- $\beta\beta$ -dipropylglutarolactone (BAINS and THORPE), 1210.
 $C_{13}H_{20}O_2Br$ Ethyl hydrogen α -bromo- $\beta\beta$ -di-*n*-propylglutarate (BAINS and THORPE), 1211.

13 IV

- $C_{13}H_9O_4NS$ 3-Nitrothianthren-7(or 5)-carboxylic acid (KRISHNA), 2789.
 $C_{13}H_9O_4NS_2$ 3-Nitrothianthren tetroxide-7(or 5)-carboxylic acid (KRISHNA), 2789.
 $C_{13}H_9O_4NS_2$ 3-Aminothianthren-7(or 5)-carboxylic acid, hydrochloride of (KRISHNA), 2789.
 3-Nitro-6-methylthianthren (KRISHNA), 2787.
 $C_{13}H_9O_4NS$ 3-Nitro-6-methylphenothioxin (KRISHNA), 2785.
 $C_{13}H_9O_4NS_2$ 3-Nitro-6-methylthianthren tetroxide (KRISHNA), 2788.
 4-Nitro-2-sulphino-5'(or 3')-carboxydiphenyl sulphide, and its ammonium salt (KRISHNA), 2789.
 $C_{13}H_{11}O_4NS_2$ 4-Nitro-2-sulphino-4'-methyldiphenyl sulphide (KRISHNA), 2787.
 $C_{13}H_{11}O_4NS$ 4-Nitro-2-sulphino-4'-methyldiphenyl ether (KRISHNA), 2785.
 $C_{13}H_{11}O_4N_2S$ *p*-Nitrotoluene- α -sulphonanilide (CLUTTERBUCK and COHEN), 2515.
 $C_{13}H_{12}NIS$ 2-Methylnaphthathiazole methiodides (SMITH), 2293.
 $C_{13}H_{12}O_4NS$ Toluene- α -sulphonanilide (CLUTTERBUCK and COHEN), 2514.
 $C_{13}H_{12}O_4NS$ Methyldiphenylaminesulphonic acid, salts of (GIBSON and VINING), 836.
 $C_{13}H_{12}O_4NS$ *p*-Nitrotoluene- α -sulphonphenylhydrazide (CLUTTERBUCK and COHEN), 2514.
 $C_{13}H_{12}O_4NS$ Toluene- α -sulphonphenylhydrazide (CLUTTERBUCK and COHEN), 2514.

13 V

- $C_{13}H_9O_2NCIS$ 6-Chloro-3-nitro-6'-hydroxy-3'-methyldiphenyl sulphide (KRISHNA), 2785.
 $C_{13}H_{11}O_4N_2BrS$ 4-Bromo- α -diphenylcarbamide-2-sulphonic acid, potassium salt (SCOTT and COHEN), 3189.
 $C_{13}H_{11}O_2NCIS$ *p*-Chlorotoluene- α -sulphonanilide (CLUTTERBUCK and COHEN), 2514.
 $C_{13}H_{12}O_2N_2CIS$ *p*-Chlorotoluene- α -sulphonphenylhydrazide (CLUTTERBUCK and COHEN), 2514.

C₁₄ Group.

- $C_{14}H_{10}$ Anthracene, constitution of (CHALLENGER and INGOLD), 2066.
 Phenanthrene, bromination of (HENSTOCK), 3097.

14 II

- $C_{18}H_{10}O$, Phenanthraquinone, action of hydrazine hydrate on (DUTT and SKN), 3420.
 $C_{16}H_{10}O_2$, Diphenic anhydride, colouring matters from (DUTT), 225.
 $C_{16}H_{10}S_2$, Dithioanthraquinone (HEILBRON and HEATON), 182.
 $C_{16}H_{10}O$, 2-Anthrol, preparation of (HALL and PERKIN), 2035.
 Anthrone, preparation of (BARNETT and MATTHEWS), 389.
 $C_{16}H_{10}O_2$, 1:2-Anthradiol (HALL and PERKIN), 2035.
 Dihydroxyanthracenes (HALL and PERKIN), 2032.
 2:3-Dimethylchromone, reactivity of the 2-methyl group in (HEILBRON, BARNES, and MORTON), 2559.
 $C_{16}H_{11}O_2$, 2:4-Dihydroxydeoxybenzoin (CHAPMAN and STEPHEN), 404.
 $C_{16}H_{11}O_2$, 2:4:6-Trihydroxydeoxybenzoin (CHAPMAN and STEPHEN), 408.
 $C_{16}H_{11}O_2$, 2-Styryl-3-methylchromone, and its salts (HEILBRON, BARNES, and MORTON), 2565.
 $C_{16}H_{11}O_2$, Ethyl dihydrogen cyclopentanespirocyclopentan-3-one-1:2:4-tricarboxylic anhydride (INGOLD, LANFERN, and THORPE), 3149.
 $C_{16}H_{11}O_2$, Methyl acetyl-4:5-dimethoxy- ψ -phthalonate (KURODA and PERKIN), 2103.
 $C_{16}H_{11}N_2$, Benzenylbenzylamidine, salts of (PYMAN), 3373.
 Benzenylphenylmethylamidine, methylation of (PYMAN), 389.
 $C_{16}H_{11}S_4$, Substance, from benzyl mercaptan and sulphur monochloride (CHAKRAVARTI), 967.
 $C_{16}H_{11}N$, Ethyldiphenylamine, chloroplatinate of (GIBSON and VINING), 841.
 $C_{16}H_{11}O_2$, Ethyl dihydrogen cyclopentanespirocyclopentan-3-one-1:2:4-tricarboxylate, silver salt (INGOLD, LANFERN, and THORPE), 3148.
 Methyl ethyl dimethoxyphthalonate (KURODA and PERKIN), 2101.
 $C_{16}H_{11}N_2$, *o*-Hydrazotoluene, hydroferrocyanide of (CUMMING), 24-2.
 $C_{16}H_{18}O$, *iso*Longifolaldehyde (SIMONSEN), 2655.
 $C_{16}H_{18}O_2$, Longifolic acids, and their salts (SIMONSEN), 2653.
 $C_{16}H_{18}O$, *iso*Longifolol (SIMONSEN), 2655.

14 III

- $C_{18}H_8O_4N_2$, 2:4:7-Trinitrophenanthraquinone (CHRISTIE and KENNER), 783.
 $C_{16}H_8O_4N_2$, 4:6:4':6'-Tetranitrodiphenic acids (CHRISTIE and KENNER), 783.
 $C_{16}H_8O_4N_2$, 4:6:4':6'-Trinitrodiphenic acids, and their salts (CHRISTIE and KENNER), 784.
 $C_{16}H_8OCl_2$, Dichloroanthrone (BARNETT and MATTHEWS), 2555.
 $C_{16}H_8O_2Cl_2$, 3:6-Dichloro-4-methyl-1:2-*a*-naphthapyrone (DEY and DALAL), 3391.
 $C_{16}H_8O_2Cl_2$, 6:6'-Dichlorodiphenic acid, synthesis and resolution of, and its brucine salts (CHRISTIE, JAMES, and KENNER), 1948.
 $C_{16}H_8O_4S$, Anthraquinonesulphonic acids, sodium salts, destructive distillation of (PERKIN and SEWELL), 3032.
 $C_{16}H_8OCl$, Chloro-9-anthrone (BARNETT and MATTHEWS), 2553.
 $C_{16}H_8O_2Cl$, Chloro-4-methyl-1:2-*a*-naphthapyrones (DEY and DALAL), 3391.
 $C_{16}H_8O_2Br$, 6-Bromo-4-methyl-1:2-*a*-naphthapyrone (DEY and DALAL), 3391.
 $C_{16}H_8O_2I$, 6-Iodo-4-methyl-1:2-*a*-naphthapyrone (DEY and DALAL), 3391.
 $C_{16}H_8O_4N$, 4-Nitro-2-methyl-*a*-naphthafuran-1-carboxylic acid, and its salts (DEY and ROW), 3394.
 $C_{16}H_8O_4N_2$, Trinitrohydroxystilbenes (CULLINANE), 2058.

FORMULA INDEX.

14 III

- $C_{14}H_{10}O_2N_2$ 4:3'-Dinitrostilbene (CULLINANE), 2060.
 $C_{14}H_{10}O_2N_2$ 2:4-Dinitro-3'-hydroxystilbene (CULLINANE), 2059.
 $C_{14}H_{11}O_2N$ Nitrohydroxystilbenes (CULLINANE), 2059.
 $C_{14}H_{11}O_2Cl$ 4'-Chloro-2:4-dihydroxydeoxybenzoin (CHAPMAN and STEPHEN), 408.
 $C_{14}H_{11}O_2Cl$ 4'-Chloro-2:4:6-trihydroxydeoxybenzoin (CHAPMAN and STEPHEN), 409.
 $C_{14}H_{11}NS$ 4- β -Naphthyl-2-methylthiazole, and its salts (SMITH), 2293.
 $C_{14}H_{11}NBr$ 3-Bromo-N-ethylcarbazole (STEVENS and TUCKER), 2146.
 $C_{14}H_{11}NI$ 3-Iodo-N-ethylcarbazole (STEVENS and TUCKER), 2147.
 $C_{14}H_{11}N_2S$ Substance, from thiobenzamide and sulphur monochloride (CHAKRAVARTI), 968.
 $C_{14}H_{13}O_2N$ 6-Amino-m-tolyl benzoate, and its hydrochloride (GIBSON), 1276.
 N -Benzoylamino-m-cresols (GIBSON), 1276.
 $C_{14}H_{13}ON$ 5-Acetyl-2-p-tolyl-4-methylpyrimidine (MITTER and BARDHAN), 2182.
 Anhydro-8-aminotetrahydrocarbazole-9-acetic acid (PERKIN and RILEY), 2404.
 $C_{14}H_{13}O_2N$ Ethyl 2-phenyl-4-methylpyrimidine-5-carboxylate (MITTER and BARDHAN), 2180.
 $C_{14}H_{13}O_2N$ Ethyl 4-keto-2-p-tolyl-1:4-dihydropyrimidine-8-carboxylate (MITTER and BARDHAN), 2183.
 Tetrahydrocarbazole-7-oxamic acid (EDWARDS and PLANT), 2398.
 $C_{14}H_{13}O_2N$ *m*-Nitrobenzoyl-*p*-cresol (ALLSOP and KENNER), 2314.
 $C_{14}H_{13}Cl_2Si$ Dichlorodi-*p*-tolylsilicane (PINK and KIPPING), 2831.
 $C_{14}H_{13}ON$ 5-Acetyl-2-phenyl-4-methylpyrimidine semicarbazone (MITTER and BARDHAN), 2182.
 $C_{14}H_{13}O_2N$ 11-Acetoxytetrahydrocarbazolenine (PERKIN and PLANT), 689.
 Acetyl- ψ -indoxylspirocyclopentane (PERKIN and PLANT), 689.
 Tetrahydrocarbazole-9-acetic acid (PERKIN and RILEY), 2402.
 $C_{14}H_{13}ON$ Acetylaminotetrahydrocarbazoles (EDWARDS and PLANT), 2396.
 Anhydro-8-aminohexahydrocarbazole-9-acetic acid (PERKIN and RILEY), 2405.
 $C_{14}H_{13}O_2N$ Tetrahydrocarbazole-8-aminoacetic acid (PERKIN and RILEY), 2407.
 $C_{14}H_{13}O_2Si$ Di-*p*-tolylsilicanediol (PINK and KIPPING), 2834.
 $C_{14}H_{13}O_2N$ Quinoxaline derivative of α -keto- $\beta\beta$ -methyleneethylglutaric acid (SINGH and THORPE), 121.
 $C_{14}H_{13}O_2Br$ Ethyl $\alpha\alpha'$ -dibromo-*o*-phenylenediacetate, preparation of (CHALLENGER and INGOLD), 2074.
 $C_{14}H_{13}ON$ Diphenyldimethylammonium hydroxide, chloroplatinate of (GIBSON and VINING), 838.
 $C_{14}H_{13}O_2N$ 9-Acetyl-10:11-dihydroxyhexahydrocarbazole (PERKIN and PLANT), 688.
 cis -3-Methyl-3-ethylcyclopropane-1:2-dicarboxyanilic acid (SINGH and THORPE), 122.
 $C_{14}H_{13}O_2N$ Methyleneethylglutaranilic acid (SINGH and THORPE), 117.
 $C_{14}H_{13}O_2N_2$ Ethyl dinitroethanetetra-carboxylate (ALLSOP and KENNER), 2315.
 $C_{14}H_{13}O_2N$ Semicarbazone of ethyl 5-cyclohexanespirodi-cyclopenten-3-ol-1-carboxylate (INGOLD, SEELEV, and THORPE), 873.
 $C_{14}H_{13}ON$ Longifolamide (SIMONSEN), 2656.

$C_{14}H_{20}O_2N_2$ 1:4-Di-*n*-butyloxymethylpiperazine (G. M. and R. ROBINSON), 537.

$C_{14}H_{20}O_2S$ *BB'*-Dibenzamylxydiethylsulphone (CASHMORE), 1743.

14 IV

$C_{14}H_9OClBr$ 4-Chloro-10-bromo-9-anthrone (BARNETT and MATTHEWS), 2554.

$C_{14}H_9O_2NBr$ 3-Bromo-6-nitro-4-methyl-1:2-*a*-naphthapyrone (DEY and ROW), 3383.

$C_{14}H_9O_2NBr$ 3-Bromo-6-amino-4-methyl-1:2-*a*-naphthapyrone (DEY and ROW), 3383.

$C_{14}H_{10}O_2ClS_2$ Diacetyl-4-chloro-1-naphthol 2-disulphide (GIBSON and SMILES), 2392.

$C_{14}H_{11}O_2NS$ 3-Nitro-6:8-dimethylthianthren (KRISHNA), 2788.

$C_{14}H_{11}O_2NS$ 3-Nitro-8-methoxy-6-methylthianthren (KRISHNA), 2789.

$C_{14}H_{11}O_2NCl$ Diacetyltartaro-2:4-dichloroanil (CHATTAWAY and PARKES), 664.

$C_{14}H_{11}O_2NBr$ Diacetyltartaro-2:4-dibromoanil (CHATTAWAY and PARKES), 665.

$C_{14}H_{11}O_2NS$ 6-Nitro-2-benzenesulphoxy-3-methoxybenzaldehyde (DAVIES), 1585.

$C_{14}H_{11}O_2NS$ 6-Nitro-2-benzenesulphoxy-3-methoxybenzaldehyde (DAVIES), 1585.

$C_{14}H_{13}O_2NCl$ Oxime of 4'-chloro-2:4-dihydroxydeoxybenzoin (CHAPMAN and STEPHEN), 408.

$C_{14}H_{13}O_2NCl$ Diacetyltartaro-*p*-chloroanil (CHATTAWAY and PARKES), 664.

$C_{14}H_{13}O_2NBr$ Diacetyltartaro-*p*-bromoanil (CHATTAWAY and PARKES), 664.

$C_{14}H_{13}ONS$ 3-Amino-3-methoxy-5-methylthianthren, hydrochloride of (KRISHNA), 2789.

$C_{14}H_{15}ON_2I$ 6-Acetyl-amino-1-hydrindyltrimethylammonium iodide (INGOLD and PIGGOTT), 1491.

$C_{14}H_{15}O_2NS_2$ 4-Nitro-2-sulphino-4':6'-dimethyldiphenyl sulphide, sodium salt (KRISHNA), 2788.

$C_{14}H_{15}O_2NS_2$ 4-Nitro-6'-methoxy-2-sulphino-3'-methyldiphenyl sulphide (KRISHNA), 2788.

$C_{14}H_{15}O_2NS$ 3-Phenyl-*p*-tolylcarbamide-2'-sulphonic acid, potassium salt (SCOTT and COHEN), 3139.

$C_{14}H_{15}ONS$ Methoxytoluenesulphonanilides (HAWORTH and LAPWORTH), 2988.

$C_{14}H_{17}N_2IS$ 2-*p*-Dimethylaminostyrylthiazole methiodide (SMITH), 2291.

$C_{14}H_{16}ONI$ 6-Ethoxyepidine ethiodide (MILLS and BRAUNHOLTZ), 2811.

$C_{14}H_{16}NIS$ *p*-Dimethylamino-anil of 2-aldehyde-4-methylthiazol methiodide (SMITH), 2295.

$C_{14}H_{20}O_2NS$ Ethyl *BB'*-diglycinodiethyl sulphide, and its chloroplativat (CASHMORE and MCCOMB), 2887.

14 V

$C_{14}H_{10}O_2N_2ClS_2$ 2-Chloro-6-thiol-8-oxo-7:9-dimethylpurine disulphide (RAY, CHAKRAVARTI, and BOSE), 1961.

 C_{11} Group.

$C_{11}H_{22}$ Longifolene, oxidation of (SIMONSEN), 2652.

FORMULA INDEX.

15 II—15 III

15 II

- $C_{15}H_{13}O_2$ 6-Hydroxy-1:8-dimethylfluorone (PRATT and ROBINSON), 742.
 $C_{15}H_{13}N_2$ Diphenylglyoxalines, isomeric, and their salts (BUTLER and PYMAN), 361.
 $C_{15}H_{13}O_4$ 2:4-Dihydroxy-4'-methyldeoxybenzoin (CHAPMAN and STEPHEN), 408.
 $C_{15}H_{13}O_4$ 2:4:6-Trihydroxy-4'-methyldeoxybenzoin (CHAPMAN and STEPHEN), 409.
 $C_{15}H_{14}O_{10}$ Acid, from bromo-*o*-phenylenediacetic ester and ethyl sodiummalonate (CHALLENGER and INGOLD), 2078.
 $C_{15}H_{14}N_4$ 2:5-*p*-Tolylimino-1-phenyldihydro-1:2:3-triazole (DUTT), 274.
 $C_{15}H_{15}N_2$ Benzenylmethylbenzylamidine, and its picrate (PYMAN), 3374.
Methylbenzylaminobenzoylimidine, salts of (PYMAN), 3374.
 $C_{15}H_{15}N_4$ Ethylformazyl (WALKER), 2778.
 $C_{15}H_{15}N$ α -Homonaphthyl-diethylamine, and its picrate (G. M. and R. ROBINSON), 543.
 $C_{15}H_{15}O_2$ *d*-Longif-1:2-dione (SIMONSEN), 2659.
 $C_{15}H_{15}O_7$ Ethyl cyclopentan-1-one-2:5-dicarboxylate-3-acetate (FARMER), 3329.
 $C_{15}H_{15}O_2$ *d*-Longif-1-ol-2-one (SIMONSEN), 2661.
Methyl longifolates (SIMONSEN), 2653.
 $C_{15}H_{15}O_3$ Acid, from *d*-longif-1:2-dione and hydrogen bromide (SIMONSEN), 2664.
 $C_{15}H_{15}O_4$ Longiforic acids (SIMONSEN), 2661.
 $C_{15}H_{15}O_7$ Ethyl α -acetylmethanetriacetate (DREIFUSS and INGOLD), 2967.

15 III

- $C_{15}H_{13}ON$ 6-Cyano-4-methyl-1:2- α -naphthapyrone (DEY and DALAL), 3391.
 $C_{15}H_{13}ON$ 3-Nitrophenylcoumarins (CULLINANE), 2059.
 $C_{15}H_{13}ON$ 6-Acetyl-amino-1:2- α -naphthapyrone (DEY and DALAL), 3391.
Methylnitroanthrone (BARNETT and COOK), 2640.
 $C_{15}H_{11}O_4N$ Phthalon-2-anilic acid, and its aniline salt (KURODA and PERKIN), 2107.
 $C_{15}H_{13}O_2Cl$ 3:6-Dihydroxy-1:8-dimethylxanthylum chloride (+ H_2O) (PRATT and ROBINSON), 741.
 $C_{15}H_{13}O_2N_2$ Benzoyl derivative of 2:4-dinitro-6-amino-*m*-xylene (IBBOTSON and KENNER), 1267.
 $C_{15}H_{14}O_2N_2$ 3-Nitro-*N*-*n*-propylcarbazoles (STEVENS and TAYLOR), 2144.
 $C_{15}H_{14}O_2N_2$ $\alpha\alpha'$ -Dicyano- β -styrylglutaramide (CURTIS, DAY, and KIMMINS), 3136.
 $C_{15}H_{14}N_2S_2$ Bis-2-methylbenzothiazoline-1:1-spiran, and its salts (MILLS, CLARK, and AESCHLINANN), 2369.
 $C_{15}H_{13}O_2N$ Benzoyl derivative of 3-methoxy-*o*-toluidine (GIBSON), 1274.
 $C_{15}H_{13}O_2N$ Oxime of 2:4-dihydroxy-4'-methyldeoxybenzoin (CHAPMAN and STEPHEN), 408.
 $C_{15}H_{13}O_4N$ Diacetyl-tartarotolils (CHATTAWAY and PARKER), 665.
 $C_{15}H_{13}O_4N$ Ethyl 2-*p*-tolyl-4-methylpyrimidine-5-carboxylate (MITTER and BARDHAN), 2181.
 $C_{15}H_{13}O_2N_2$ Quinoxaline derivative of α -ketocyclopentane-1:1-diacetic acid (LANFAR and THORPE), 1683.
 $C_{15}H_{13}O_4N_2$ Ethyl 5-nitrotetrahydrocarbazole-9-carboxylate (PERKIN and PLANT), 692.
 $C_{15}H_{13}ON_2$ 5-Acetyl-2-*p*-tolyl-4-methylpyrimidone semicarbazone (MITTER and BARDHAN), 2182.

- $C_{11}H_{11}O_2N$ Ethyl tetrahydrocarbazole-9-carboxylate (PERKIN and PLANT), 692.
 $C_{11}H_{11}O_2N$ Ethyl 10:11-dihydroxyhexahydrocarbazole-9-carboxylate (PERKIN and PLANT), 693.
 $C_{11}H_{11}O_2N$ Eserine (BARGER and STEDMAN), 758.
 $C_{11}H_{11}O_2N$ β -isoButylglutaranilide (CURTIS, DAY, and KIMMINS), 8136.
 $C_{11}H_{11}O_2N$ Ethyl cyclopropane-1:1-dicarboxylate-2:3-diacetate (FARMER), 3336.
 $C_{11}H_{13}O_2N$ d -Longif-1:2-dione-oxime (SIMONSEN), 2660.
 Acid, and its salts, from d -longif-1:2-dione monoxime and benzenesulphonyl chloride (SIMONSEN), 2665.
 $C_{11}H_{13}ON_2$ isoLongifolaldehyde semicarbazone (SIMONSEN), 2655.
 $C_{11}H_{13}ON_2$ Longifolamide urethane (SIMONSEN), 2656.
 $C_{11}H_{13}O_2Br$ Ethyl $\alpha\alpha'$ -dibromo- $\beta\beta$ -di- n -propylglutarate (BAINS and THORPE), 1210.

15 IV

- $C_{11}H_9O_2NBr$ 3(or 4)-Bromo-1:2-naphthaquinone-4(or 3)-pyridinium bromide (BARNETT, COOK, and DRISCOLL), 515.
 $C_{11}H_9O_2NBr$ 1:2-Naphthaquinone-3(or 4)-pyridinium bromide (+ H_2O) (BARNETT, COOK, and DRISCOLL), 515.
 $C_{11}H_9O_2NBr$ 3(or 4)-Bromo-1:2-dihydroxynaphthalene-4(or 3)-pyridinium bromide, and its picrate (BARNETT, COOK, and DRISCOLL), 516.
 $C_{11}H_9O_2NS$ Benzoyl derivative of ψ -base C_6H_5ONS (MILLS, CLARK, and AEBCHLIMANN), 2358.
 $C_{11}H_9O_2NI$ 1:2-Diacetoxyphenylpyridinium iodide (BARNETT, COOK, and DRISCOLL), 514.
 1:4-Diacetoxyphenylpyridinium iodide (BARNETT, COOK, and DRISCOLL), 511.
 $C_{11}H_{11}NIS$ 4- β -Naphthyl-2-methylthiazole methiodide (SMITH), 2293.
 $C_{11}H_{11}NIS$ 2- p -Dimethylaminostyryl-4-methylthiazole methiodide (SMITH), 2291.
 $C_{11}H_{11}O_2NBr$ 1:4-Dihydroxynaphthalene-3-pyridinium bromide (+ H_2O) (BARNETT, COOK, and DRISCOLL), 516.
 $C_{11}H_{11}ON_2I$ Eseroline ethiodide (BARGER and STEDMAN), 764.
 $C_{11}H_{13}O_2N_2S_2$ $\beta\beta'$ -Diglycinodiethyl sulphilimine (CASHMORE and McCUMBLE), 2888.

 C_{12} Group.

- $C_{12}H_{10}O_4$ Diphenyl-3:5:3':5'-tetracarboxylic acid (BURTON and KENNER), 1045.
 $C_{12}H_{12}O_2$ 2-Furfurylidenemethyl-3-methylchromone (HEILBRON, BARNEA, and MORTON), 2567.
 4-Hydroxy-1:2-dimethylantraquinone (FAIRBOURNE and GAUNTLETT), 1137.
 $C_{12}H_{12}O_2$ Acetylanthragallol anthranol (BREAKE and PERKIN), 2607.
 Succinylfluorescein, and its salts (BIGGS and POPE), 2934.
 $C_{12}H_{12}O_2$ Dimethoxyanthracene (HALL and PERKIN), 2032.
 $C_{12}H_{12}O_2$ Anthragallolanthranol dimethyl ether (BREAKE and PERKIN), 2607.
 o -2-Hydroxy-4:5-dimethylbenzoylbenzoic acid (FAIRBOURNE and GAUNTLETT), 1132.
 $C_{12}H_{12}O_2$ Diacetylanthragallolanthranol (BREAKE and PERKIN), 2607.
 $C_{12}H_{11}O_2$ Acid, from dibromo- o -phenylenediacetic ester and ethyl sodiomalonate (CHALLENGER and INGOLD), 2077.

FORMULA INDEX.

16 II-16 III

- $C_{14}H_{19}N$ 3:5:7-Trimethylacridine, and its salts (MORGAN and HICKIN-BOTTOM), 103.
 $C_{14}H_{18}N_2$ Di-*p*-tolylidimethinediazidine (INGOLD and PUGGOTT), 2750.
 $C_{14}H_{18}N_2$ Methylbenzylaminobenzylmethylimidine, picrate of (PYMAN), 3375.
 $C_{14}H_{18}O_2$ Diethyl hydrogen cyclopentanespiro[di-cyclopentan-3-one-1:2:4-tricarboxylate, potassium and silver salts (INGOLD, LANFAR, and THORPE), 8148.
 $C_{14}H_{18}O_2$ Diethyl 5-cyclohexanespiro[di-cyclo- Δ^2 -penten-3-ol:1:2-dicarboxylate (INGOLD, SEELEY, and THORPE), 873.
 $C_{14}H_{18}O_2$ Ethyl α -carboxymethacetracetate (DEZIFURS and INGOLD), 2966.

16 III

- $C_{14}H_{13}O_2Br$ Succinyleosin, and its salts (BIGGS and POPE), 2939.
 $C_{14}H_{13}O_2N_4$ Tetranitrosuccinylfluorescein, and its sodium salt (BIGGS and POPE), 2941.
 $C_{14}H_{13}O_2Br_2$ Dibromosuccinylfluorescein (BIGGS and POPE), 2940.
 $C_{14}H_{13}N_3S_2$ Substance, from 5-thiol-2-thio-3-phenyl-2:3-dihydro-1:3:4-thiodiazole and sulphur monochloride (CHAKRAVARTI), 967.
 $C_{14}H_{11}O_4N$ Coumarin-6-carboxylanilide (DEY and DALAL), 2368.
 $C_{14}H_{11}O_4N_2$ Dinitrosuccinylfluorescein hydrate (BIGGS and POPE), 2941.
 $C_{14}H_{11}O_4Cl$ 7-Hydroxy-2-phenyl-4-methylbenzopyrylium chloride, and its additive compound with resorcinol (BUCK and HEILBRON), 2526.
 $C_{14}H_{11}O_4Cl$ 7-Hydroxy-3-methoxy-2-phenylbenzopyrylium chloride (PRATT and ROBINSON), 749.
 $C_{14}H_{11}O_4N$ 4-Nitro-2'- and -4'-acetoxy stilbenes (CULLINANE), 2057.
 $C_{14}H_{11}O_4Cl$ 7-Hydroxy-2-phenyl-4-methylbenzopyrylium perchlorate (BUCK and HEILBRON), 2526.
 $C_{14}H_{11}O_4N_2$ Nitroso-3-phenylmethylamino-2-keto-1-methyl-1:2-dihydroquinoxaline (USHERWOOD and WHITELEY), 1087.
 $C_{14}H_{11}O_4N_4$ Diphenyl-3:5:3':5'-tetracarboxylamide (BURTON and KENSER), 1045.
 $C_{14}H_{11}ON_3$ 3-Phenylmethylamino-2-keto-1-methyl-1:2-dihydroquinoxaline, and its salts (USHERWOOD and WHITELEY), 1086.
 $C_{14}H_{11}O_4N_2$ Phenyl *p*-tolyl ketone semioxamazone (WILSON and PICKERING), 396.
 $C_{14}H_{11}O_4N_2$ Phenylethylcarbamylnitrobenzaldoximes (BRADY and RIDGE), 2167.
 $C_{14}H_{11}O_4N$ *m*-Hemipinanilic acid (KURODA and FREKIN), 2105.
 $C_{14}H_{11}O_4N_2$ 3-Nitro-*N*-n-butylcarbazole (STEVENS and TUCKER), 2144.
 $C_{14}H_{11}O_4N_2$ Phenylethylcarbamylnitrobenzaldoxime (BRADY and RIDGE), 2166.
 $C_{14}H_{11}O_4N_2$ 3:5'-Dinitro-4:4'-diethoxydiphenyl (BRADY and McHUGH), 2051.
 $C_{14}H_{11}O_4N_2$ Carbanilino-3-nitro-*p*-dimethylaminobenzaldoxime (BRADY and TRUSZKOWSKI), 2437.
 $C_{14}H_{11}O_4S$ 4-Methoxytoluene-3-sulphonacetophenone (GIBSON and SMILES), 2391.
 $C_{14}H_{11}O_4N$ Anilino-5-cyclohexanespiro[di-cyclo- Δ^2 -pentene-1:4-dione (INGOLD, SEELEY, and THORPE), 865.
 $C_{14}H_{11}O_4N$ 4:5-Dimethoxy- α -tolylideneaniline, and its hydrochloride, (KURODA and FREKIN), 2109.
 $C_{14}H_{11}O_4N_2$ Quinoxaline derivative of α -ketocyclohexane-1:1-diacetic acid (INGOLD, SEELEY, and THORPE), 867.
 $C_{14}H_{11}O_4N$ Diacetyl tartaro-2:4-xylil (CHATTAWAY and PARKES), 665.

- $C_{10}H_7Cl_2Pb$ Lead tri-*m*-xylyl dichloride (GODDARD), 1172.
 $C_{11}H_9BrAs$ Methylidihydroarsindole benzobromide (TURNER and BURY), 2492.
 $C_{11}H_{11}O_2N$ Ethyl tetrahydrocarbazole-9-acetate (PERKIN and RILEY), 2401.
 $C_{11}H_{11}O_2N_2$ Phenylhydrazone of cyclopentanespirocyclopentan-3-one-1-carboxylic acid (INGOLD, LANFAR, and THORPE), 3151.
 $C_{12}H_{15}O_2N$ 4-Benzoyloxy-1:2:6-tetramethylpiperidine, and its salts (KIPPING), 3118.
 $C_{12}H_{11}O_4S$ Ethyl tetrahydrothiophen-3:3:4:4-tetracarboxylate (MANN and POPP), 1175.
 $C_{12}H_{12}O_2N_2$ *d*-Longif-1:2-dione semicarbazone (SIMONSEN), 2659.
 $C_{14}H_{18}S_2Pt$ Substance, from dithioethylene glycol and platinum chloride (RAY), 141.

16 IV

- $C_{11}H_9O_2NS$ 3-Nitro-*p*-naphthaphenothioxin (KRISHNA), 2786.
 $C_{11}H_9O_2NS$ 3-Nitro-*β*-naphthaphenothioxin dioxide (KRISHNA), 2786.
 $C_{11}H_{10}O_2NCl$ *p*-Chlorophenyliminosuccino-*p*-chloroanil (CHATTAWAY and PARKES), 668.
 $C_{11}H_{10}O_2NBr$ *p*-Bromophenyliminosuccino-*p*-bromoanil (CHATTAWAY and PARKES), 668.
 $C_{11}H_{10}N_2Cl_2Pt$ Substance, from thiodiazole and platinum chloride (RAY), 139.
 $C_{11}H_{11}O_2NCl$ *p*-Chlorophenyliminosuccinoanil (CHATTAWAY and PARKES), 669.
 Phenyliminosuccino-*p*-chloroanil (CHATTAWAY and PARKES), 669.
 $C_{12}H_{11}O_2NS$ 4-Nitro-2-sulphinophenyl *β*-naphthyl ether (KRISHNA), 2786.
 $C_{12}H_{13}ON_2S$ Benzylidene derivative of 2:4-diketo-5-phenyltetrahydrothiazole-2-hydrazone (WILSON and BURNS), 803.
 $C_{12}H_{12}O_2Cl_2Fe$ 3-Methoxy-2-phenylbenzopyrylium ferrichloride (PRATT and ROBINSON), 749.
 $C_{12}H_{12}O_2Cl_2Fe$ 3:4'-Dihydroxy-3'-methoxy-2-phenylbenzopyrylium ferrichloride (PRATT and ROBINSON), 754.
 $C_{12}H_{16}O_2N_2S_2$ 2:2'-Di-formylmethylaminodiphenyl disulphide (MILLS, CLARK, and AESCHLIMANN), 2358.
 2:2'-Dithiobenzomethylamide (McCLELLAND and LONGWELL), 3314.
 $C_{12}H_{14}O_2N_2Br$ Carbanilino-3-bromo-*p*-dimethylaminobenzanthaldoxime (BRADY and TRUSKOWSKI), 2439.
 $C_{12}H_{12}N_2S_2I$ Bis-2-methylbenzothiazoline-1:1-spiran methiodide (MILLS, CLARK, and AESCHLIMANN), 2369.

C₁₇ Group.

- $C_{17}H_{16}O$ Methoxy-1-benzylidene-3-*α*-hydroxybenzylidene (INGOLD and FIOGOTT), 1508.
 $C_{17}H_{16}O_4$ 4-Methoxyphenyl 2-hydroxy-8-methoxyatryl ketone (PRATT and ROBINSON), 751.
 $C_{17}H_{26}O_2$ Benzoylcamphor, mutarotation of (LOWRY and BURGESS), 2122.
 $C_{17}H_{15}N_2$ Auramige, hydroferrocyanide of (CUMMING), 2459.
 $C_{17}H_{15}N_2$ Tetramethyldiaminodiphenylmethane, hydroferrocyanide of (CUMMING), 2458.
 $C_{17}H_{24}O_2$ *d*-Acetyl-longif-1-ol-2-one (SIMONSEN), 2661.
 $C_{17}H_{24}O_2$ Pentamethylarbutin (MACBETH and MACKAY), 721.

- H_{17}O_4 , Methyl longiforate (SIMONSEN), 2662.
 H_{17}O_5 , Ethyl butane- α , β -dicarboxylate- β -malonate (FARMER), 3329.

17 III

- $\text{H}_{17}\text{O}_2\text{N}$ Hydroxynaphthanilides (ROYLE and SCHEDLER), 1645; (BUTLER and ROYLE), 1654.
 $\text{H}_{17}\text{O}_2\text{N}$ 4:5-Dimethoxyphthalonil (KURODA and PERKIN), 2105.
 $\text{H}_{17}\text{O}_2\text{N}$ 1-Keto-6:7-dimethoxy-2-phenyl-1:2-dihydrophthalazine-4-carboxylic acid (KURODA and PERKIN), 2103.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2$ 3:4-Oxido-2-keto-1-methyl-1:2:3:4-tetrahydroquinoxaline-3-carboxymethylanilide (USHERWOOD and WHITELEY), 1078.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{Cl}$ 7-Hydroxy-3:4'-dimethoxy-2-phenylbenzopyrylium chloride (+ H_2O) (PRATT and ROBINSON), 751.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}$ Dimethoxyphthalon-2-anilic acid (KURODA and PERKIN), 2104.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2$ Mesordimethylanilide (USHERWOOD and WHITELEY), 1080.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}$ Phenylethylcarbamyl-3:4-methylenedioxybenzantiald-oxime (BRADY and RIDGE), 2166.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2$ Substance, from isonitrosomalondimethylanilide and water (USHERWOOD and WHITELEY), 1081.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2$ 2-Keto-1-methyl-1:2:3:4-tetrahydroquinoxaline-3-carboxyl-methylanilide (USHERWOOD and WHITELEY), 1084.
Methoxycinnamaldehydephenylsemicarbazones, and their phototropy (HEILBRON, HUDSON, and HUSH), 2277.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2$ Nitromalondimethylanilide, and its potassium salt (USHERWOOD and WHITELEY), 1079.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2$ 4:5-Dimethoxy- α -tolylglyoxylic acid phenylhydrazone (KURODA and PERKIN), 2108.
 $\text{H}_{17}\text{N}_2\text{S}_2$ Bis-2-ethylbenzothiazoline-1:1-spiran (MILLS, CLARK, and AESCHLMANN), 2369.
 $\text{H}_{17}\text{O}_3\text{N}$ Morphine, and its derivatives, bibliography of (GULLAND and ROBINSON), 996.
 $\text{H}_{17}\text{O}_2\text{N}$ Nitrobenzoate from glycol anhydride, $\text{C}_{10}\text{H}_{18}\text{O}_4$ (HENDERSON and ROBERTSON), 1853.
 $\text{H}_{17}\text{O}_2\text{N}_2$ Glycineanilide carbonate (USHERWOOD and WHITELEY), 1086.
 $\text{H}_{17}\text{O}_2\text{N}$ β , β -Di- α -propylglutaranilic acid (BAIX and THORPE), 1210.
 $\text{H}_{17}\text{O}_2\text{N}_2$ Semicarbazone of diethyl 5-cyclohexanespirodiacyclo- Δ^2 -penta-3-ol-1:2-dicarboxylate (INGOLD, SEELEY, and THORPE), 573.

17 IV

- $\text{C}_{17}\text{H}_{11}\text{O}_2\text{NS}$ 4-Anilinothionaphthacoumarin (SMILES and HART), 2912.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{NS}$ 4-Nitro- β -naphthyl *p*-toluenesulphonate (CHALLENGER and INGOLD), 2080.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{NS}$ 4-Amino- β -naphthyl *p*-toluenesulphonate (CHALLENGER and INGOLD), 2080.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{Cl}_2\text{Fe}$ 3:4'-Dimethoxy-2-phenylbenzopyrylium ferrichloride (PRATT and ROBINSON), 751.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2\text{Br}$ Dimethoxyphthalonic acid *p*-bromophenylhydrazone (KURODA and PERKIN), 2103.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2\text{Cl}$ Chloro-derivative of 3:4-oxido-2-keto-1-methyl-1:2:3:4-tetrahydroquinoxaline-3-carboxymethylanilide (USHERWOOD and WHITELEY), 1079.
 $\text{C}_{17}\text{H}_{15}\text{O}_2\text{N}_2\text{Cl}$ Chloronitromalondimethylanilide (USHERWOOD and WHITELEY), 1079.
 $\text{C}_{17}\text{H}_{15}\text{NIS}$ 4:5-Diphenyl-2-methylthiazole methiodide (SMITH), 2292.

- $C_{17}H_{17}O_2N_2Cl$ Chloromalendimethylanilide (USHERWOOD and WHITELEY), 1080.
 $C_{17}H_{15}O_2Cl_2Fe$ 3:6-Dimethoxy-1:8-dimethylxanthylum ferrichloride (PRATT and ROBINSON), 743.
 $C_{17}H_{15}O_2N_2Br$ Bromo-2:3-diethoxybenzaldehyde *p*-nitrophenylhydrazone (DAVIES and RUBENSTEIN), 2850.
 $C_{17}H_{15}N_2IS$ 1':2-Diethylthio- ψ -pyridocyanine iodide (MILLS and BRAUN-HOLTZ), 2812.
 $C_{17}H_{15}ONCl$ Bornylene chlorohydrin *p*-nitrobenzoate (HENDERSON and MAIR), 1158.

17 V

- $C_{17}H_{10}ONCIS$ 3-Chloro-4-anilinothionaphthacoumarin (SMILES and HART), 2913.

 C_{18} Group.

- $C_{18}H_{16}O_2$ Methoxy-1-piperonylideneindenes, isomeric (INGOLD and PIGGOTT), 1508.
 $C_{18}H_{16}O_4$ Diacetoxyanthracenes (HALL and PERKIN), 2032.
 $C_{18}H_{16}O_2$ Benzoyl derivative of β -hydroxy- β -3-methoxy-2-hydroxyphenylethyl methyl ketone (HEILBRON and WHITWORTH), 243.
 $C_{18}H_{16}O_4$ 2:4-Diacetoxydeoxybenzoin (CHAPMAN and STEPHEN), 407.
 $C_{18}H_{16}O_4$ Succinylfluorescein ethyl ether (BIGGS and POPE), 2937.
 $C_{18}H_{16}Cl_2$ Dichlorodianthranyl (BARNETT and MATTHEWS), 2555.
 $C_{18}H_{16}O_2$ Diethoxyanthracenes (HALL and PERKIN), 2033.
 $C_{18}H_{16}N_2$ Bismark brown, hydroferrocyanide of (CUMMING), 2459.
 $C_{18}H_{16}N_4$ 4:4'-Dimethylallylformazyl (WALKER), 2777.
 $C_{18}H_{22}O_{11}$ Methyl cyclopropylcyclopropanehexacarboxylate (FARMER), 3333.
 $C_{18}H_{20}O_7$ Ethyl cyclopentanespirodi-cyclopentan-3-one-1:2:4-tricarboxylate, and its sodium salt (INGOLD, LANFAR, and THORPE), 3148.
 $C_{18}H_{24}N_2$ β -Di-*p*-tolylamino-*n*-butanes, isomerism of, and their salts (MORGAN and HICKINBOTTOM), 97.
 $C_{18}H_{26}O_{10}$ Hexatriose, preparation of (LING and NANJ1), 2678.
 $C_{18}H_{26}O_{10}$ Raffinose, constitution of (HAWORTH, HIRST, and RUELLE), 3125.
 $C_{18}H_{26}O_2$ Oleic acid, potassium salt, migration data for (McBAIN and BOWDEN), 2417; solutions of, in water and alcohol (BIRCUMSHAW), 91; protective action of, on gold sols in alcohol-water mixtures (RIDEAL and BIRCUMSHAW), 1565.

18 III.

- $C_{18}H_{18}O_2Br$ Ethyl succinyleosincarcboxylate (BIGGS and POPE), 2940.
 $C_{18}H_{18}O_2N$ α -Naphthylcarbamylnitrobenzaldoximes (BRADY and RIDGE), 2172.
 $C_{18}H_{18}O_2N_2$ α -Naphthylcarbamylnitrobenzaldoximes (BRADY and RIDGE), 2169.
 $C_{18}H_{18}O_2Cl$ 4'-Chloro-2:4-diacetoxydeoxybenzoin (CHAPMAN and STEPHEN), 408.
 $C_{18}H_{18}O_2N$ Diacetyl tartaro- β -naphthil (CHATTAWAY and PARKES), 665.
 $C_{18}H_{18}O_2N_2$ Tolyliminosuccinotolils (CHATTAWAY and PARKES), 668.
 $C_{18}H_{18}O_2Cl$ Ethyl 6:6'-dichlorodiphenate (CHRISTIE, JAMES, and KENNER), 1950.
 $C_{18}H_{18}O_2N_2$ 6:8-Diketo-5:9-dimethyl-5:6:8:9-tetrahydromalonalinium methoxide (USHERWOOD and WHITELEY), 1088.
 $C_{18}H_{18}O_2N$ Thebenine, constitution of (GULLAND and ROBINSON), 992.
 $C_{18}H_{18}O_2N$ Thebaine, preparation of (GULLAND and ROBINSON), 1003.

FORMULA INDEX.

18 III—19 III

- $C_{13}H_{14}O_2N_4$ *n*-Butylene- $\beta\gamma$ -di-*p*-tolylidinitrosodiamines (MORGAN and HICKINBOTTOM), 101.
 $C_{13}H_{14}O_2N$ Thebainol (GULLAND and ROBINSON), 1005.
 $C_{13}H_{13}O_2Cl$ 1-Menthyl phenylchloroacetates, isomeric (McKENZIE and SMITH), 1962.

18 IV

- $C_{18}H_{17}O_5Cl_2Fe$ 7-Hydroxytrimethoxy-2-phenylbenzopyrylium ferri-chlorides (PRATT and ROBINSON), 757.
 $C_{18}H_{19}N_4IS$ 2-*p*-Dimethylaminostyrylbenzothiazole methiodide (SMITH), 2292.
 $C_{18}H_{20}O_2N_2S_2$ 2:2'-Di-formylethylaminodiphenyl disulphide (MILLS, CLARK, and AESCHLIMANN), 2361.
 $C_{18}H_{21}O_2N_2I_2$ Esoline dimethiodide (BARGER and STEDMAN), 765.
 $C_{18}H_{22}O_2N_2I_2$ Hydroxyesoline dimethiodide (BARGER and STEDMAN), 767.

C_{19} Group.

- $C_{19}H_{14}O_4$ 3:4'-Methylenedioxy-2-styryl-3-methylchromone, and its hydrochloride (HEILBRON, BARNES, and MORTON), 2567.
 $C_{19}H_{16}O_3$ Methoxy-2-styryl-3-methylchromones, and their salts (HEILBRON, BARNES, and MORTON), 2566.
 $C_{19}H_{18}O_4$ 2:4-Diacetoxy-4'-methyldeoxybenzoin (CHAPMAN and STEPHEN), 408.
 $C_{19}H_{22}O_3$ Methylmorphimethines, isomeric (GULLAND and ROBINSON), 988.
 $C_{19}H_{24}N_2$ Tetrahydroglyoxaline derivatives of *n*-butylene- $\beta\gamma$ -di-*p*-tolyl-dinitrosodiamines (MORGAN and HICKINBOTTOM), 101.

19 III

- $C_{19}H_{16}O_4N_2$ α -Naphthylcarbonyl-3:4-methylenedioxybenzaldoximes (BRADY and RIDGE), 2170.
 $C_{19}H_{14}N_2Br_2$ Benzophenone-3:4-dibromophenylhydrazone (HUMPHRIES, BLOOM, and EVANS), 1770.
 $C_{19}H_{15}ON$ *N*-Phenylbenziminophenyl ether, hydrochloride of (CHAPMAN), 1152.
 $C_{19}H_{15}N_2Br_2$ Benzophenone-*p*-bromophenylhydrazone (HUMPHRIES, BLOOM, and EVANS), 1771.
 $C_{19}H_{16}O_4N_2$ α -Naphthylcarbonyl methoxybenzaldoximes (BRADY and RIDGE), 2171.
 5-Nitro-9-benzoyltetrahydrocarbazole (PERKIN and PLANT), 686.
 $C_{19}H_{17}ON$ 9-Benzoyltetrahydrocarbazole (PERKIN and PLANT), 685.
 $C_{19}H_{17}ON$ γ -4-Hydroxy-2-phenylquinoline-3-butyric acid (PERKIN and PLANT), 687.
 $C_{19}H_{17}O_2N_2$ Nitromesityleneazo-*p*-naphthol (MORGAN and DAVIES), 232.
 $C_{19}H_{17}O_2P$ Triphenylmethylphosphorous acid (BOYD and CHIGNELL), 816.
 $C_{19}H_{17}ON$ 4'-Dimethylamino-2-styrylbenzopyrylium, salts of (BUCK and HEILBRON), 1395.
 $C_{19}H_{18}O_4N_2$ Nitroaminomesityleneazo- β -naphthol (MORGAN and DAVIES), 234.
 $C_{19}H_{18}O_4N_2$ 11-Nitro-9-benzoyl-10-hydroxyhexahydrocarbazole (PERKIN and PLANT), 686.
 5-Nitro-4'-dimethylamino-2-hydroxydistyryl ketone (HEILBRON and WHITWORTH), 241.
 $C_{19}H_{18}N_2Cl$ Substance, from thiocarbanilide and sulphur monochloride (CHAKRAVARTI), 968.
 $C_{19}H_{18}ON_2$ Aminomesityleneazo- β -naphthol (MORGAN and DAVIES), 233.

- $C_{15}H_{15}O_2N$ 4'-Dimethylamino-2-hydroxydistyryl ketone, effect of substitution on the reactivity of (HEILBRON and WHITWORTH), 238.
 $C_{11}H_{11}O_3N_2$ 6:8-Diketo-5:9-dimethyl-5:6:8:9-tetrahydromalonanilinium ethoxide (USHERWOOD and WHITELEY), 1088.
 $C_{11}H_{11}O_4N$ 3-o-Benzoylamino-benzoylvaleric acid, and its sodium salt (PERKIN and PLANT), 686.
 $C_{15}H_{20}O_4N_2$ Nitromesityleneazoacetacetanilide (MORGAN and DAVIES), 232.
 $C_{18}H_{21}O_4N$ *cyclo*Pentanespiro*dicyclopentan*-3-one-1:2-dicarboxy-*p*-xylydic acid (INGOLD, LANFERN, and THORPE), 3150.
 $C_{11}H_{11}O_2N$ Thebaine (GULLAND and ROBINSON), 984.
 $C_{15}H_{22}N_4I$ 2-*p*-Dimethylaminostyryl-3-methylbenzimidazole methiodide (SMITH), 2294.
 $C_{11}H_{11}O_2N_4$ Thebaine semicarbazone (GULLAND and ROBINSON), 1006.
 Dihydrothebaine semicarbazone (GULLAND and ROBINSON), 1007.

19 IV

- $C_{15}H_{15}OCl_2P$ Triphenylmethoxyphosphorus dichloride (BOYD and CHIGNELL), 816.
 $C_{11}H_{11}N_4IS_2$ 4-Phenyl-2-methylbenzothiazolene methylthiazole methiodide (MILLS, BRAUNHOLTZ, and SMITH), 2812.
 $C_{11}H_{11}O_2NBr$ 5-Bromo-4'-dimethylamino-2-hydroxydistyryl ketone (HEILBRON and WHITWORTH), 242.
 $C_{15}H_{11}O_2N_2Cl$ Acetyl derivative of 3:4-oxido-2-keto-1-methyl-1:2:3:4-tetrahydroquinoxaline-3-carboxylmethylanilide (USHERWOOD and WHITELEY), 1079.
 $C_{11}H_{11}O_2NI$ Thebaine methiodide (GULLAND and ROBINSON), 1006.
 $C_{11}H_{11}O_2N_2I_2$ Iodoesoline methyl ether dimethiodide (BARGER and STEDMAN), 768.
 $C_{11}H_{11}O_2N_2I_2$ Esoline methyl ether dimethiodide (BARGER and STEDMAN), 762.
 $C_{11}H_{11}O_2N_2Cl_2$ Esoline methyl ether dimethoperchlorate (BARGER and STEDMAN), 763.

19 V

- $C_{11}H_{11}ONSA_s$ Triphenylarsine hydroxythiocyanate (CHALLENGER, SMITH, and PATON), 1053.
 $C_{11}H_{11}ONSSb$ Triphenylstibine hydroxythiocyanate (CHALLENGER, SMITH, and PATON), 1052.

 C_{20} Group.

- $C_{20}H_{14}O$ Phenolphthalein, sodium salts (BASSETT and HALTON), 1291.
 $C_{20}H_{14}S_2$ Substance, from β -naphthyl mercaptan and sulphur monochloride (CHAKRAVARTI), 968.
 $C_{20}H_{14}O_2$ 2-Cinnamylidenemethyl-3-methylchromone (HEILBRON, BARNES, and MORTON), 2567.
 $C_{20}H_{14}N_2$ $\alpha\alpha'$ -Hydrazonaphthalene (CUMMING and STELL), 2467.
 $C_{20}H_{14}O_2$ $\alpha\alpha'$ -Diphenyl- $\gamma\gamma'$ -dimethyl- $\Delta^{\alpha\alpha'}$ -hexadiene- $\gamma\gamma'$ -diols, stereoisomeric (WILSON and HYLSLOP), 2616.
 $C_{20}H_{14}O_2$ 6-Ethoxy-2-styryl-3-methylchromone (HEILBRON, BARNES, and MORTON), 2568.
 $C_{20}H_{14}O_2$ Dimethoxy-2-styryl-3-methylchromones, and their salts (HEILBRON, BARNES, and MORTON), 2566.
 $C_{20}H_{14}O_2$ 3':4'-Methylenedioxy-6-ethoxy-2-styryl-3-methylchromone (HEILBRON, BARNES, and MORTON), 2568.

FORMULA INDEX.

20 II—20 IV

- $C_{26}H_{18}N_4$ 2,3-Diphenyl-1:2:3:4-tetrahydroquinoxalines, and their salts (BENNETT and GIBSON), 1370.
 $C_{26}H_{18}N_4$ Benzylformazyl (WALKER), 2778.
 $C_{26}H_{20}O_4$ Succinylfluorescein diethyl ethers (BIGGS and POPE), 2937.
 $C_{26}H_{20}O_4$ Ethyl *cyclopentanespiro*-1-methyl*cyclopropane*-1:2- α -tetracarboxylate (INGOLD, LANFERN, and THORPE), 3147.
 $C_{28}H_{22}O_{11}$ Heptamethyl methylgentiobioside (HAWORTH and WYLLAM), 3123.

20 III

- $C_{26}H_{12}O_7N_4$ Diacetyl derivative of tetranitrosuccinylfluorescein (BIGGS and POPE), 2941.
 $C_{26}H_{12}O_7N$ 9-Nitro-10-phenylanthracene (BARNETT and COOK), 2638.
 $C_{26}H_{12}O_7N$ Phenylnitroanthrone (BARNETT and COOK), 2642.
 $C_{26}H_{16}O_5Br_4$ Succinyleosin diethyl ether (BIGGS and POPE), 2940.
 $C_{26}H_{17}ON$ *N*-*p*-Tolylbenziminophenyl ether, hydrochloride of (CHAPMAN), 1153.
 $C_{26}H_{17}O_2N$ Methoxyvanthranilpyridinium hydroxide, picrate of (BARNETT, COOK, and MATTHEWS), 2904.
 $C_{26}H_{12}O_2N_2$ 5-Nitro-9-phenylacetyl-tetrahydrocarbazole (PERKIN and PLANT), 694.
 $C_{26}H_{12}O_2N_2$ α -Naphthylcarbaryl-3:4-dimethoxybenzantaldoxime (BRADY and RIDGE), 2173.
 $C_{26}H_{12}ON$ 9-Phenylacetyl-tetrahydrocarbazole (PERKIN and PLANT), 693.
 $C_{26}H_{12}O_2N_2$ α -Naphthylcarbaryl-*p*-dimethylaminobenzantaldoxime (BRADY and RIDGE), 2173.
 $C_{26}H_{20}O_2N$ 4'-Dimethylamino-2-styryl-3-methylchromone (HELLERON, BARNES, and MORTON), 2567.
 $C_{26}H_{21}ON$ γ -Hydroxy- $\alpha\gamma\gamma$ -triphenylpropylamines (MCKENZIE and RICHARDSON), 90.
 $C_{26}H_{21}O_2N$ 4'-Dimethylaminomethoxy-2-hydroxydistyryl ketones (HELLERON and WHITWORTH), 243.
 9-Phenylacetyl-10:11-dihydroxyhexahydrocarbazole (PERKIN and PLANT), 694.
 $C_{26}H_{22}O_2N_2$ *trans*-3-Methyl-3-ethyl*cyclopropane*-1:2-dicarboxydianilide (SINGH and THORPE), 121.
 α Yohimbic acid, and its hydrochloride (BARGER and FIELD), 1041.
 $C_{26}H_{27}ON$ *iso*Longifolanilide (SIMONSEN), 2657.

20 IV

- $C_{26}H_{12}O_2Cl_2S_2$ 4:4'-Dichloro-1:1'-dihydroxydi- β -naphthyl trisulphide (GIBSON and SMILES), 2393.
 $C_{26}H_{15}N_3S_2Sb$ Triphenylstibine dithiocyanate (CHALLENGER, SMITH, and PATON), 1052.
 $C_{26}H_{16}O_2NS$ Substance, from $\beta\beta'$ -dichlorodiethyl sulphide and potassium phthalimide (CASHMORE and McCOMBIE), 2389.
 $C_{26}H_{20}N_4IS$ 2-*p*-Dimethylaminostyryl-6-methylbenzbisthiazole methiodide (EDGE), 2332.
 $C_{26}H_{22}N_4IS$ *p*-Dimethylamino-anil of 2-aldehyde-4-phenyl-5-methylthiazole methiodide (SMITH), 2295.
 $C_{26}H_{21}O_2N_2S_2$ 2:2'-Dithiobenzopropylamide (McCLELLAND and LONGWELL), 3314.
 $C_{26}H_{24}O_2N_2S_2$ 4:4'-Diacetylaminodiphenetyl 2:2'-disulphide (JOHNSON and SMILES), 2337.

- $C_{20}H_{24}O_4N_2S$ Anhydroyohimbic acid sulphuric ester (BARGER and FIELD), 1041.
 $C_{20}H_{24}O_4N_2S$ Yohimbic acid sulphuric ester (BARGER and FIELD), 1042.
 $C_{20}H_{28}O_2NI$ Methylidihydrothebainone methiodide (GULLAND and ROBINSON), 1009.
 Methylthebainol methiodide (GULLAND and ROBINSON), 1009.
 $C_{20}H_{28}O_2Br_4S$ Carvone hydrosulphide tetrabromide (CHALLENGER, SMITH, and PATON), 1051.
 $C_{20}H_{28}O_2N_2I_2$ Iodoesoline ethyl ether dimethiodide (BARGER and STEDMAN), 767.
 $C_{20}H_{28}O_2N_2I_2$ Esoline ethyl ether dimethiodide (BARGER and STEDMAN), 763.
 Esoline methyl ether methyl ethyl diquaternary iodide (BARGER and STEDMAN), 764.
 $C_{20}H_{28}O_2N_2I_2$ Hydroxyesoline ethyl ether dimethiodide (BARGER and STEDMAN), 768.
 $C_{20}H_{28}O_2N_2Cl_2$ Esoline ethyl ether dimethoperchlorate (BARGER and STEDMAN), 764.

C₂₁ Group.

- $C_{21}H_{19}O$ Phenylantranlyl methyl ether (BARNETT and COOK), 2637.
 $C_{21}H_{19}O$ Diphenylmethyl benzyl ketone (McKENZIE and RICHARDSON), 91.
 $C_{21}H_{20}O_4$ 4'-Methoxy-6-ethoxy-2-styryl-3-methylchromone (HEILBRON, BARNES, and MORTON), 2568.
 $C_{21}H_{22}N_2$ Benzenyldibenzylamidine, salts of (PYMAN), 3373.
 $C_{21}H_{22}N_2$ Quinoxaline derivative of *d*-longif-1:2-dione (SIMONSEN), 2660.

21 III

- $C_{21}H_{13}O_2N_2$ 3'-Nitro-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1561.
 $C_{21}H_{14}O_2N_2$ 3'-Nitro-5-amino-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1562.
 $C_{21}H_{15}O_2N_2$ Nitrodiaminophenylphenanthriminazoles (A. C. and G. C. SIRCAR), 1562.
 $C_{21}H_{16}O_2N_2$ Phthalondianilide (KURODA and PERKIN), 2108.
 $C_{21}H_{16}O_2N_2$ Diphenylcarbamy-*p*-methoxybenzylaldehyde (BRADY and RIDGE), 2168.
 $C_{21}H_{18}O_2N_2$ Ethoxyanthranilpyridinium hydroxide, picrate of (BARNETT, COOK, and MATTHEWS), 2004.
 $C_{21}H_{18}O_2N_2$ 6-Nitromesitylenebisazoresorcinol (MORGAN and DAVIES), 234.
 $C_{21}H_{20}O_2N_2$ 4-Hydroxy-3-methoxyphenylglyoxaldiphenylhydrazones (PRATT and ROBINSON), 754.
 $C_{21}H_{20}O_2N_2$ *cis*-cyclopentanespiro-1-hydroxycyclopropane-1:2-dicarboxyanilide (LANFAR and THORPE), 1687.
 $C_{21}H_{22}N_2I$ 2-*p*-Dimethylaminostyryl-3:3-dimethylindolenine methiodide (SMITH), 2294.
 $C_{21}H_{24}O_2N_2$ Yohimbine (FIELD), 3003.
 $C_{21}H_{24}ON_2$ *d*-Longif-1:2-dione phenylhydrazone (SIMONSEN), 2660.
 $C_{21}H_{24}O_2N$ *iso*-Longifolol phenylurethane (SIMONSEN), 2655.

21 IV

- $C_{21}H_{18}ON_2Br_4$ 3':5':7:8-Tetrabromo-4'-hydroxy-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1563.

FORMULA INDEX.

21 IV—23 III

- $C_{21}H_{11}ON_2Br_3$ 5':7:8-Tribromo-2'-hydroxy-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1563.
 $C_{21}H_{11}O_2N_2Br_3$ 7:8-Dibromo-4'-nitro-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1563.
 $C_{21}H_{13}O_2N_2Br$ 5-Bromo-3'-nitro-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1562.
 $C_{21}H_{13}ON_2Br$ 5'-Bromo-2'-hydroxy-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1563.
 $C_{21}H_{12}OCl_4Fe$ Dinaphthapyrylium ferriehloride (PRATT and ROBINSON), 744.
 $C_{21}H_{20}ON_2S_2$ 2:6-Dithiol-8-oxy-7:9-dimethylpurine dibenzyl ether (RAY, CHAKRAVARTI, and BOSE), 1962.
 $C_{21}H_{21}N_2SI$ 1':2-Diethylthio- ψ -cyanide iodide (MILLS and BRAUNHOLTZ), 2809.
 $C_{21}H_{23}NIS$ 2-*p*-Dimethylaminostyryl-4-phenyl-5-methylthiazole methiodide (SMITH), 2292.
 $C_{21}H_{27}ON_2Br$ *d*-Longif-1:2-dione *p*-bromophenylhydrazone (SIMONSEN), 2660.
 $C_{21}H_{28}O_2N_2I_2$ Esoline ethyl ether methyl ethyl diquaternary iodide (BARGER and STEEDMAN), 764.

C_{22} Group.

- $C_{22}H_{18}O_2$ Tetra-acetyl anthragallol anthranol (BREARE and PERKIN), 2607.
 $C_{22}H_{20}O_3$ Trimethylaurins (BAINES and DRIVER), 1217.
 $C_{22}H_{22}O_2$ $\alpha\theta$ -Diphenyl- $\gamma\zeta$ -dimethyl- $\Delta^{2,7}$ -octadi-*in*-ene- $\gamma\zeta$ -diols, stereoisomeric (WILSON and HYSLOP), 2617.
 $C_{22}H_{22}O_4$ 2':5'-Diethoxy-2-styryl-3-methylchromone (HEILBRON, BARNES, and MORTON), 2567.

22 III

- $C_{22}H_{18}O_2N_4$ 4-*p*-Nitrobenzeneazo-3-(or 5)-phenyl-1-*p*-nitrophenyl-5-(or 3)-methylpyrazole (MACBETH), 1130.
 $C_{22}H_{20}O_2N_2$ $\alpha\alpha'$ -Dihydroxy-*o*-phenylenediacetanilide (CHALLENGER and INGOLD), 2075.
 $C_{22}H_{28}O_3N_2$ Ethyl yohimbate (FIELD), 3005.

22 IV

- $C_{22}H_{11}O_2N_2Br_2$ Dibromonitrophenylphenanthriminazoles (A. C. and G. C. SIRCAR), 1561.
 $C_{22}H_{14}O_2N_2Br_4$ 3:3'-Dibromo-4:4'-dihydroxydiphenyl-5:5'-dipyridinium dibromide (BARNETT, COOK, and DRISCOLL), 517.
 $C_{22}H_{21}N_2IS$ 2-*p*-Dimethylaminostyrylnaphthathiazole methiodides (SMITH), 2294.

C_{23} Group.

- $C_{23}H_{18}O_4$ 4':7-Dihydroxy-2-phenyl-4-styrylbenzopyrylium hydroxide, and its salts (BUCK and HEILBRON), 2529.
 $C_{23}H_{19}O_2$ Tolylanthranyl acetate (BARNETT and COOK), 2639.

23 III

- $C_{23}H_{20}O_2N_4$ 4:5-Dimethoxyphthalondianilide (KURODA and PERKIN), 2105.
 $C_{23}H_{23}N_3I$ 1:1'-Dimethylcarbocyanine iodide, preparation of (HAMER), 254.

- $C_{22}H_{21}O_4N$ 4:5-Dimethoxyphthalonic acid 1-phenylhydrazone 2-phenylhydrazide (KURODA and PERKIN), 2104.
 $C_{22}H_{21}ON_3$ 2-Keto-1-phenyl-3:5-di-*p*-tolylhexahydro-1:3:5-triazine (IN. GOLD and THORPE), 2751.
 $C_{22}H_{22}N_2Cl_2$ Methylenediquinaldine dimethochloride (+ H_2O) (HAMER), 252.
 $C_{22}H_{22}N_2Br_2$ Methylenediquinaldine dimethobromide (HAMER), 252.
 $C_{22}H_{22}N_2I_2$ Methylenediquinaldine dimethiodide (HAMER), 251.
 $C_{22}H_{22}N_2O_6$ Methylenediquinaldine dimethonitrate (HAMER), 252.
 $C_{22}H_{23}O_2N_2$ Propyl yohimbate (FIELD), 3005.

23 IV

- $C_{22}H_{21}N_3IS$ 4:4'-Diphenyl-3:3'-dimethylthiazolocarbocyanine iodide (MILLS and BRAUNHOLTZ), 2813.

 C_{24} Group.

- $C_{24}H_{18}O$ Naphthyldeoxybenzoin (McKENZIE and RICHARDSON), 89.
 $C_{24}H_{20}O_4$ 7-Hydroxy-4'-methoxy-2-phenyl-4-styrylbenzopyrylium hydroxide, and its salts (BUCK and HEILBRON), 2523.
 $C_{24}H_{20}O_8$ Ethyl diphenyl-3:5:3':5'-tetracarboxylate (BURTON and KENNER), 1045.
 $C_{24}H_{27}N_2$ Polymeride of di-*p*-tolyl dimethinediazidine (INGOLD and PIGGOTT), 2750.
 $C_{24}H_{27}Pb$ Lead tri-*m*-xylyl, and its action on thallic chloride (GODDARD), 1171.
 $C_{24}H_{27}Sb$ Tri-*m*-xylylstibine (GODDARD), 2315.
 Tri-*p*-xylylstibine (GODDARD), 1170.
 $C_{24}H_{24}O_{12}$ Ethyl cyclopropylcyclopropanhexacarboxylate (FARMER), 3339.

24 III

- $C_{24}H_{14}O_2N_2$ *peri*-Naphthindigotin (DUTT), 224.
 $C_{24}H_{14}N_2S_2$ 2:6-Distyrylbenzobisthiazoles (EDGE), 2332.
 $C_{24}H_{20}O_4N_2$ Diacetyl-2:3-diphenyl-1:2:3:4-tetrahydroquinoxaline (BENNETT and GIBSON), 1574.
 $C_{24}H_{20}O_4N_2$ Di-*p*-nitrobenzoate of glycol $C_{10}H_{16}O_2$, from bornylene chlorhydrin and potassium hydroxide (HENDERSON and MAIR), 1159.
 $C_{24}H_{20}O_4N_2$ Di-*p*-nitrobenzoate of glycol anhydride $C_{10}H_{16}O_2$ (HENDERSON and ROBERTSON), 1853.
 $C_{24}H_{24}ISb$ Tri-*s*-iodotri-*m*-xylylstibine (GODDARD), 2321.
 $C_{24}H_{27}Cl_2Sb$ Tri-*m*-xylylstibine dichloride (GODDARD), 2319.
 Tri-*p*-xylylstibine dichloride (GODDARD), 1170.
 $C_{24}H_{27}Br_2Sb$ Tri-*m*-xylylstibine dibromide (GODDARD), 2320.
 $C_{24}H_{27}N_2Sb$ Tri-5-aminotri-*m*-xylylstibine (GODDARD), 2321.
 $C_{24}H_{28}O_2N_2$ Butyl yohimbate (FIELD), 3005.

24 IV

- $C_{24}H_{22}N_4S_2Pt$ Substance, from thiodiazole and platinum chloride (RAY), 138.
 $C_{24}H_{22}N_4IS$ 2-*p*-Dimethylaminoatryl-4-*β*-naphthylthiazole methiodide (SMITH), 2293.
 $C_{24}H_{20}O_4N_2Sb$ Tri-5-nitrotri-*m*-xylylstibine (GODDARD), 2320.
 $C_{24}H_{20}O_4N_2Sb$ Tri-5-nitrotri-*m*-xylylstibine oxide (GODDARD), 2321.
 $C_{24}H_{20}O_4N_2Sb$ Tri-5-nitrotri-*m*-xylylstibine dinitrate (GODDARD), 2320.
 $C_{24}H_{27}Cl_2HgSb$ Tri-*m*-xylylstibine mercurichloride (GODDARD), 2320.

24 V

- $C_{21}H_{12}O_4N_3Br_2Sb$ Tri-6-bromotri-5-nitrotri-*m*-xylylstibine dibromide (GODDARD), 2322.
 $C_{21}H_{12}O_4N_3Br_2Sb$ Tri-6-bromotri-5-nitrotri-*m*-xylylstibine oxide (GODDARD), 2322.

C₂₃ Group.

- $C_{23}H_{12}S_2$ Bisthioanthrone sulphide (HEILBRON and HEATON), 184.
 $C_{23}H_{14}O_7$ Substance, from oxidation of the peroxide product of spinacene (CHAPMAN), 774.

25 III

- $C_{25}H_{20}O_2N$ Narcotine, influence of papaverine on the optical activity of (ANNETT), 376.
 $C_{25}H_{20}O_2N$ Benzylidenethebaine (GULLAND and ROBINSON), 1004.
 $C_{25}H_{20}N_4I$ 1:1'-Diethyl-4:4'-carbocyanine iodide (HAMER), 255; (MILLS and BRAUNHOLTZ), 2811.
 $C_{25}H_{27}N_4I$ 6:6'-Diamino-1:1'-diethylcarbocyanine iodide (HAMER), 2333.
 $C_{25}H_{24}N_4I$ Methylenequininaldine diethiodide (HAMER), 253.
 $C_{25}H_{24}IAS$ Tri-*β*-phenylethylmethylarsonium iodide (TURNER and BURV), 2492.

25 IV

- $C_{25}H_{21}ONBr$ Phenylanthranylpyridinium bromide (BARNETT and COOK), 2637.
 $C_{25}H_{24}N_4IS$ *p*-Dimethylamino-anil of 2-aldehyde-4:5-diphenylthiazole methiodide (SMITH), 2285.

C₂₆ Group.

- $C_{26}H_{16}O_2$ Resorcinoldiphenecin (DUTT), 226.
 $C_{26}H_{16}O_2$ Phloroglucinoldiphenecin (DUTT), 227.
 $C_{26}H_{16}O_4$ Phenoldiphenecin (+ 2H₂O) (DUTT), 226.
 $C_{26}H_{16}S_2$ *meso*-Dithioanthraquinyl diphenyl ether (HEILBRON and HEATON), 180.
 $C_{26}H_{20}O_4$ Methoxy-1-piperonylidene-3-*α*-hydroxypiperonylindene (INGOLD and PIGGOTT), 1508.

26 III

- $C_{26}H_{16}O_2Br_2$ Tetrabromoresorcinoldiphenecin (DUTT), 227.
 $C_{26}H_{16}O_4N_2$ Dianhydro-8-aminopiperonalthebaine, hydrobromide of (GULLAND and ROBINSON), 1005.
 $C_{26}H_{16}O_2N$ Piperonylidene-thebaine (GULLAND and ROBINSON), 1004.
 $C_{26}H_{16}O_4N_2$ Pyocyanine, and its salts (McCOMBIE and SCARBOROUGH), 3279.

26 IV

- $C_{26}H_{18}N_4IS$ 2-*p*-Dimethylaminostyryl-4:5-diphenylthiazole methiodide (SMITH), 2292.

C₂₇ Group.

- $C_{27}H_{18}N_2$ Benzylidenequininaldine, and its salts (HAMER), 256.
 $C_{27}H_{18}O_2$ Substance, from spinacene and hydrogen peroxide (CHAPMAN), 773.

27 III

- $C_{27}H_{18}O_4N_2$ 3'-Nitro-5-anilino-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1564.
 $C_{27}H_{18}ON_2$ 5'-Anilino-2'-hydroxy-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1564.

- $C_{27}H_{20}N_2$ Aniline α -anilino- α -hydroxyhomophthalanilate (KURODA and PERKIN), 2107.
 $C_{27}H_{20}N_2I$ 6:8'-Dimethyl-1:1'-diethylcarbocyanine iodide, preparation of (HAMER), 256.
 $C_{27}H_{20}N_2I_2$ 6:6'-Dimethylmethylenediquinaldine diethiodide (HAMER), 253.

C₂₈ Group.

- $C_{28}H_{18}$ Dianthranyl, preparation of (BARNETT and MATTHEWS), 390.

28 II

- $C_{28}H_{16}O_2$ 2:2'-Dianthraquinonyl ether (PERKIN and SEWELL), 3036.
 $C_{28}H_{16}S_2$ Dithioheptacycene (HEILBRON and HEATON), 182.
 $C_{28}H_{16}O_2$ Dianthrone, preparation of (BARNETT and MATTHEWS), 387.
 $C_{28}H_{16}O_2$ Anthragallol dianthrone (BREARE and PERKIN), 2608.
 $C_{28}H_{16}Cl_2$ Dichlorodihydrodianthranyl (BARNETT and MATTHEWS), 2554.
 $C_{28}H_{16}S$ Dianthranyl sulphide (HEILBRON and HEATON), 184.
 $C_{28}H_{16}S_2$ Dithiodianthrone (HEILBRON and HEATON), 183.
 $C_{28}H_{16}S_2$ Bisthioanthrone disulphide (HEILBRON and HEATON), 183.
 $C_{28}H_{16}O$ α -Anthrapinacolin (BARNETT and MATTHEWS), 391.

28 III

- $C_{28}H_{16}O_2S$ Dianthraquinonyl sulphides (PERKIN and SEWELL), 3037.
 $C_{28}H_{16}O_2S$ Dianthraquinonyl sulphoxides, and their salts (PERKIN and SEWELL), 3038.
 $C_{28}H_{16}O_2S$ Dianthraquinonylsulphones (PERKIN and SEWELL), 3039.
 $C_{28}H_{16}O_2Cl_2$ 1:1'-Dichloro-9:9'-dianthrone (BARNETT and MATTHEWS), 2553.
 $C_{28}H_{22}N_2I$ Benzylidenediquinaldine methiodide (HAMER), 253.

28 IV

- $C_{28}H_{20}O_{10}N_2Sb$ Tri-5-nitro-*m*-xylylstibine diacetate (GODDARD), 2322.

C₂₉ Group.

- $C_{29}H_{22}$ Spinacene, constitution, oxidation, and decomposition of (CHAPMAN), 769.
 $C_{29}H_{22}$ Spinacene (CHAPMAN), 770.

29 II

- $C_{29}H_{44}O_{10}$ Hendecamethyl raffinose (HAWORTH, HIRST, and RUELL), 3128.

29 III

- $C_{29}H_{22}N_2I_2$ Benzylidenediquinaldine dimethiodide (HAMER), 258.
 $C_{29}H_{20}O_2N_2$ Aniline α -anilino- α -hydroxy-4:5-dimethoxyhomophthalanilate (KURODA and PERKIN), 2104.

29 IV

- $C_{29}H_{21}O_2N_2I$ 6:6'-Diacetyl-amino-1:1'-diethylcarbocyanine iodide (HAMER), 2334.

C₃₀ Group.

- $C_{30}H_{20}O_2$ Diacetyl derivative of resorcinoldiphenecin (DUTT), 227.
 $C_{30}H_{20}O_2$ Diacetyl derivative of phenoldiphenecin (DUTT), 226.

30 III

- $C_{30}H_{20}O_2N_2$ 4:4'-Tetramethyldiamino-2:2'-oxidodiphenyldiphenecin (DUTT), 227.

FORMULA INDEX.

30 III—42 II

$C_{26}H_{22}N_4I_2S_2$ 2:6-Bis-*p*-dimethylaminostyryl- β -benzobisthiazole dimethiodide (EDGE), 2332.
 $C_{20}H_{14}O_2N_2$ Substance, from *d*-longif-1:2-dione monoxime and benzenesulphonyl chloride (SIMONSEN), 2665.

C₃₁ Group.

$C_{31}H_{28}ON_2$ 4:4''-Tetramethyldiaminoanthrafuchsone (MASON), 1546.

C₃₂ Group.

$C_{32}H_{22}O_4S$ Diacetylanthranol-2:2'-sulphide (PERKIN and SEWELL), 3039.
 $C_{32}H_{32}O_2N_2$ *dl*-Dibenzoyl- β - γ -di-*p*-tolylamino-*n*-butane (MORGAN and HICKINBOTTOM), 100.

C₃₃ Group.

$C_{33}H_{22}O_2N_4$ Nitrodianilino-2-phenylphenanthriminazoles (A. C. and G. C. SIRCAR), 1564.

33 IV

$C_{33}H_{31}O_2N_2Cl$ 4:4''-Tetramethyldiaminoanthrafuchsone acetic ester chloride (MASON), 1557.

C₃₄ Group.

$C_{34}H_{30}O_4$ Tetramethyl anthragallol dianthrone (BREARE and PERKIN), 2609.

34 III

$C_{34}H_{31}O_2N$ Dipiperonylidenethebainol (GULLAND and ROBINSON), 1007.

C₃₅ Group.

$C_{35}H_{33}O_2N$ Dipiperonylidenemethyldihydrothebainone (GULLAND and ROBINSON), 1010.
 Dipiperonylidenemethylthebainol (GULLAND and ROBINSON), 1010.

C₃₈ Group.

$C_{38}H_{32}O_2N_2Cl$ 4:4''-Tetramethyldiaminoanthrafuchsone benzoic ester chloride (MASON), 1556.

C₃₉ Group.

$C_{39}H_{29}ON_5$ 5':7:8-Trianilino-2'-hydroxy-2-phenylphenanthriminazole (A. C. and G. C. SIRCAR), 1565.

C₄₀ Group.

$C_{40}H_{26}$ Diphenyldianthranyl (BARNETT and COOK), 2639.

40 II

$C_{40}H_{26}O_6$ Dibenzoyl derivative of phenoldiphencin (DUTT), 226.
 $C_{40}H_{30}O_{14}$ Hexa-acetyl anthragallol dianthrone (BREARE and PERKIN), 2608.

40 III

$C_{40}H_{20}O_4N_4$ Diphenyl-3:5:3':5'-tetracarboxyanilide (BURTON and KENNER), 1045.
 $C_{40}H_{27}ON_3$ *NN'*-Triphenyl-2:2':2''-trimethylpararosaniline (BAINES and DRIVER), 1217.

C₄₂ Group.

C₄₂H₃₂O₄ Dianthranol dibenzoate (BARNETT and MATTHEWS), 388.

42 III

C₄₂H₂₇O₄P Anthranyl phosphate (BARNETT, COOK, and MATTHEWS), 2007.

C₄₂H₄₂O₂Si₂ Trianhydrotrisdi-*p*-tolylsilicanediol (PINK and KIPPING), 2836.

C₄₂H₄₄O₂Si₂ Dianhydrotrisdi-*p*-tolylsilicanediol (PINK and KIPPING), 2834.

42 IV

C₄₂H₂₂O₁₅N₁₂Sb Tripiceryltri-5-aminotri-*m*-xylylstibine (GODDARD), 2322.

42 V

C₄₂H₂₀O₁₅N₁₂Br₂Sb Tripiceryltri-6-bromotri-5-aminotri-*m*-xylylstibine dibromide (GODDARD), 2323.

C₄₄ Group.

C₄₄H₃₄O₁₆ Octa-acetyl anthragallol dianthranol (BREARE and PERKIN), 2608.

C₄₅ Group.

C₄₅H₄₄O₂N₂Sb Tri-5-benzoylamino tri-*m*-xylylstibine (GODDARD), 2321.

C₄₈ Group.

C₄₈H₄₈Si₄ Silicohydrocarbon, oxidation of (KIPPING), 2594.

C₅₂ Group.

C₅₂H₂₈Si₄ Octaphenyldiethylsilicotetrane (KIPPING), 2593.

C₅₆ Group.

C₅₆H₄₀O Tetrabenzyl-*a*-anthrapinacolin (BARNETT and MATTHEWS), 392.

56 III

C₅₆H₄₀O₂Si₄ Tetra-anhydrotetrakisdi-*p*-tolylsilicanediol (PINK and KIPPING), 2837.

PROCEEDINGS
OF THE
CHEMICAL SOCIETY.

Ordinary Scientific Meeting, Thursday, February 1st, 1923, at 8 p.m., SIR WILLIAM A. TILDEN, D.Sc., F.R.S., Past-President, in the Chair.

The following were formally admitted Fellows of the Chemical Society: E. Hope, J. Kenyon, E. A. Peach, and S. G. P. Plant.

Certificates were read for the first time in favour of:

Frank Arthur Boys, 197, St. James' Road, Croydon.
Richard Burtles, M.Sc.Tech., 1, Romanby Place, 286, Wellington Road North, Heaton Chapel, Stockport.
Ernest Alfred Coppen, 137, Hambrough Road, Southall.
William Everard Davies, 51, Lancaster Gate, W. 2.
Hildyard John Eglinton Dobson, 44, Harold Road, Upper Norwood, S.E. 19.
Maxwell Bruce Donald, A.R.C.S., A.I.C., Royal College of Science, S. Kensington, S.W. 7.
Robert George Evans, 264, Bolton Road, Ashton-in-Makerfield, Wigan.
Thomas Shirley Hele, M.A., Emmanuel College, Cambridge.
Robert Fergus Hunter, 7, St. Mary's Road, Canonbury, N. 1.
Joseph Gilbert Jackson, B.Sc., 33, Crescent Road, Sheffield.
Wilfrid Lawson, M.Sc., A.I.C., 15, Barrington Road, Sefton Park, Liverpool.
Ronald Arthur Punter, B.Sc., A.I.C., The Kraal, Bishop's Stortford.
John Sunderland, B.Sc., 70, Thornbury Drive, Bradford.
Harold George Turley, B.Sc., 150, Clonmore Street, Southfields, S.W. 18.

The following papers were read:

"Derivatives of tetrahydrocarbazole. Part II." By W. H. PERKIN and S. G. P. PLANT.

"Isolation of the oxide of a new element." By ALEXANDER SCOTT.

"The chemistry of polycyclic structures in relation to their homocyclic unsaturated isomerides. Part IV. The simulation of benzenoid properties by the five-carbon intra-annular nucleus." By C. K. INGOLD, E. A. SEELEY, and J. F. THORPE.

Ordinary Scientific Meeting, Thursday, February 15th, 1923, at 8 p.m., Prof. T. M. LOWRY, Vice-President, in the Chair.

The CHAIRMAN referred to the loss sustained by the Society, through death, of :

	Elected.	Died.
Frederick James Lloyd	Feb. 3rd, 1876.	Feb. 9th, 1923.

The CHAIRMAN announced that in accordance with Bye-Law II, the following were proposed by the Council as Honorary Fellows of the Society and that a ballot for their election would be held at the next Ordinary Scientific Meeting on March 1st.

Bohnslav Brauner.	Charles Moureu.
Ernst Cohen.	Amé Pictet.
Gilbert Newton Lewis.	Theodor Svedberg.

Certificates were read for the first time in favour of :

Kundan Lal Aggarwal, M.Sc., 93, Botley Road, Oxford.
 Sidney Hartley Bales, M.Sc., A.I.C., 338, High Road, Lee, S.E. 12.
 Hugh Findlay, F.I.C., 50, Bothwell Street, Glasgow.
 Mary Beatrice Ford, B.Sc., 9, Heath Street, Hampstead, N.W. 3.
 George Philip Gibson, B.Sc., 138, Wilford Grove, Nottingham.
 Donald Bennett Huntingford, M.Sc., St. Paul's School, Jalapahar, Darjeeling, India.
 Mary Evelyn Laing, M.Sc., 35, Henleaze Road, Bristol.
 Stephen Miall, 157, Haverstock Hill, N.W. 3.
 Victor Wallace Slater, B.Sc., 139, Ashburnham Road, Luton.
 Charles Arthur Waters, B.Sc., Bank House, Queen's Avenue, Muswell Hill, N. 10.
 Edith Muriel Whincop, M.Sc., 26, Eatington Road, Leyton, E. 10.

Messrs. J. D. Pratt and J. N. Sugden were elected Scrutators, and a ballot for the election of Fellows was held. The following were subsequently declared elected as Fellows :

William Bennett Adam, B.A.	Katherine Hope Coward, M.Sc.
George James Alexander, B.Sc.	Ernest Cecil Craven.
Donald Hatch Andrews, B.A.	Augustine Malcolm Manhkram David, B.Sc.
Arthur John Attwood, A.R.C.S.	John Norman Dean, B.Sc., A.I.C.
Kenneth Claude Bailey, M.A.	James Cooper Duff, M.Sc., F.I.C.
Alfred Berthoud.	Allan Robert Earle, B.A.
Ernest Alfred Blench.	Samuel Gray Fenton.
John Southwell Bousfield, A.R.C.S.	Phillip Marcus Fisk.
Frederick Bradshaw, M.A., D.Sc.	John Kenneth Giles, B.Sc.
Charles Crossley Mann Broughton, B.Sc.	Thomas Graham.
Harold Eugene Buckley, M.Sc.	Albert Edward Gray.
Robert Kenneth Callow, B.A., B.Sc.	John Preedy Griffiths, B.Sc., A.R.C.S.
Joseph Cofman-Nicoresci.	Leslie Julius Harris, B.Sc.
Alexander Coutie.	Thomas Arthur Harrison.
Leslie John Couzens.	Leslie Frank Hewitt, B.Sc., A.I.C.

Laurence Horton, B.Sc., A.R.C.S.	Helena Charlotte Randall, B.Sc., A.R.C.S.
John Ingham.	George Alan Redfern, B.A.
Clinton N. Laird, M.A.	Jerry Robertson.
John Laker, B.Sc., A.R.C.S.	Edgar Sanders.
Wilfred Herbert Linnell, B.Sc., A.I.C.	John Baldwin Shoesmith, M.Sc.
Arthur D. Little.	Hedley Archibald Sloman, B.A., A.I.C.
Joseph Kenneth Marsh, M.Sc.	Andreas Smits.
George Arnold Medley.	Douglas Rosebery Snellgrove, B.Sc.
Ramprasad Pitamberdas Mehta, M.A.	Arthur Roy Stark.
Herbert Frederick Miller, B.Sc., A.I.C.	Reginald Ernest Tebbit.
Dhirendra Nath Mukerji, M.Sc.	John Smeath Thomas, D.Sc.
William Owen Murch, B.Sc.	John Thompson.
James Herbert Oliver, B.Sc.	Hubert William Thorp, B.Sc.
Thomas Workman Orr, A.I.C.	Frederick Vincent Tidswell, M.Sc.
William James Osborn.	Eric Wilfred Tong, B.Sc., A.R.C.S.
Isabelyn Patterson, M.Sc., Ph.D.	Frederic Jenner Tritton, B.Sc.
Francis James Paxon, B.Sc., A.R.C.S.	Paule Lauro Vanderstichele, M.Sc.
Edward Arthur Perren.	Stanley Douglas Weaver, A.R.C.S.
Edwin William Stanley Press.	Montague Williams, B.Sc.
Edward Ebenezer Price.	Thomas Arthur Williams.
Frank Victor Raleigh, B.A., B.Sc.	Harold Wood, B.Sc.
Sara Chand Rana, M.Sc.	

The following papers were read :

"Spinacene : its oxidation and decomposition." By A. CHASTON CHAPMAN.

"Investigations on the dependence of rotatory power on chemical constitution. Part XIX. The rotatory and refractive dispersion of *d*- γ -nonyl nitrite." By R. H. PICKARD and H. HUNTER.

"Investigations on the dependence of rotatory power on chemical constitution. Part XX. The rotatory dispersive powers of oxygen compounds containing the secondary octyl radical." By H. HUNTER.

"Studies on hypophosphorous acid. Part V. Its reaction with silver nitrate." By A. D. MITCHELL.

"Communication from Drs. Hevesey and Koster concerning disparity between X-ray spectra of hafnium and the New Zealand element." By ALEXANDER SCOTT.

The form of the vapour-pressure curve at high temperatures.

Part II. The curve for sodium cyanide." By C. K. INGOLD.

The properties of ammonium nitrate. Part V. The reciprocal salt-pair ammonium nitrate and potassium chloride." By E. P. PERMAN and H. L. SAUNDERS.

The morphine group. Part I. A discussion of the constitutional problem." By J. M. GULLAND and R. ROBINSON.

The morphine group. Part II. Thebainone, thebainol, and dihydrothebainone." By J. M. GULLAND and R. ROBINSON.

- "A synthesis of pyrylium salts of anthocyanidin type. Part II." By D. D. PRATT and R. ROBINSON.

List of Papers received between January 19th and February 15th, 1923 :

- "Tesla-luminescence spectra. Part I. The apparatus and the spectrum of benzene." By W. H. McVICKER, J. K. MARSH, and A. W. STEWART.
- "The formation of derivatives of oxalacetic acid from tartaric acid." By F. D. CHATTAWAY and G. D. PARKES.
- "Derivatives of tetrahydrocarbazole. Part II." By W. H. PERKIN and S. G. P. PLANT.
- "Heterogeneous equilibria between the chlorides of calcium, magnesium, potassium, and their aqueous solutions." By W. B. LEE and A. C. G. EGERTON.
- "The constitution of polysaccharides. Part VI. The molecular structure of cotton cellulose." By J. C. IRVINE and E. L. HIRST.
- "Calculation of fundamental constants." By E. F. MORRIS.
- "Electrolysis of acetone solutions of potassium chloro- and trichromates." By E. F. MORRIS.
- "Spinacene : its oxidation and decomposition." By A. CHASTON CHAPMAN.
- "Isolation of the oxide of a new element." By A. SCOTT.
- "The chemistry of polycyclic structures in relation to their homocyclic unsaturated isomerides. Part IV. The simulation of benzenoid properties by the five-carbon intra-annular nucleus." By C. K. INGOLD, E. A. SEELEY, and J. F. THORPE.
- "The labile nature of the halogen atom in organic compounds. Part VIII. The action of hydrazine on the halogen derivatives of acetoacetic and benzoylacetic esters and benzoylacetone." By A. K. MACBETH.
- "The higher oxide of nickel." By O. R. HOWELL.
- "Triethylene tri- and tetra-sulphides. Part III. The sulphones, sulphinic and sulphonic acids of the series. Extension of Stuffer's law." By Sir P. C. RAY.
- "Dyes derived from thiodiphenylamine." By B. K. SEN and S. DUTT.
- "Dyes derived from carbazole. Part I." By S. DUTT.
- "The preparation and some reactions of bromopicrin." By L. HUNTER.
- "The intermittent glow of phosphorus." By K. R. K. IYER.

- "The preparation of xylose from maize cobs." By A. R. LING and D. R. NANJL.
- "The effect of pressure on the limits of inflammability of mixtures of the paraffin hydrocarbons with air." By W. PAYMAN and R. V. WHEELER.
- "Inorganic complex salts. Part II. Erdmann's salt and its derivatives." By W. THOMAS.
- "The action of dimethyl sulphate on diphenylamine and on methyldiphenylamine." By C. S. GIBSON and D. C. VINING.
- "Investigations on the dependence of rotatory power on chemical constitution. Part XIX. The rotatory and refractive dispersion of *d*- γ -nonyl nitrite." By R. H. PICKARD and H. HUNTER.
- "Investigations on the dependence of rotatory power on chemical constitution. Part XX. The rotatory dispersive powers of oxygen compounds containing the secondary octyl radical." By H. HUNTER.
- "Studies on hypophosphorous acid. Part V. Its reaction with silver nitrate." By A. D. MITCHELL.
- "The catalytic decomposition of hydrogen peroxide solution by sugar carbon." By J. B. FIRTH and F. S. WATSON.
- "Chloriodoacetic acid." By H. CROMPTON and K. M. CARTER.
- "On the calorific power of carbon compounds." By D. KONOVALOV.
- "The form of the vapour-pressure curve at high temperatures. Part II. The curve for sodium cyanide." By C. K. INGOLD.
- "The properties of ammonium nitrate. Part V. The reciprocal salt-pair ammonium nitrate and potassium chloride." By E. P. PERMAN and H. L. SAUNDERS.
- "The molecular refractions of chloro-, dichloro-, and chlorobromoacetates." By P. L. VANDERSTICHELE.
- "On the conditions of reaction of hydrogen with sulphur." By R. G. W. NORRISH and E. K. RIDEAL.
- "Photochemical reactions of the halogen hydrides." By W. H. RODEBUSH and J. NEVYAS.
- "Studies of the glucosides. Part II. Arbutin." By A. K. MACBETH and J. MACKEY.
- "The action of sulphur and sulphur compounds on the terpenes and the adaptation of the products of reaction for making a preparation of liquid gold for ceramic industry." By P. P. BUDNIKOFF and E. A. SHILOV.
- "Sur le yodure d'azote." By C. GLUGLIOTTO.
- "The combustion of complex gaseous mixtures. Part II. Mixtures of carbon monoxide and hydrogen with air." By W. PAYMAN and R. V. WHEELER.

- "Bromo-derivatives of 4-methylglyoxaline." By F. L. PYMAN and G. M. TIMMIS.
- "The morphine group. Part I. A discussion of the constitutional problem." By J. M. GULLAND and R. ROBINSON.
- "The morphine group. Part II. Thebainone, thebainol, and dihydrothebainone." By J. M. GULLAND and R. ROBINSON.
- "A synthesis of pyrylium salts of anthocyanidin type. Part II." By D. D. PRATT and R. ROBINSON.
- "The bromination of glyoxaline-4-carboxyanilide." By H. KING and W. O. MURCH.
- "Phosphorous acid esters. The influence of the character of the groups R'R''R''' upon the stability of the molecular complexes R'R''R'''C-OPCl₂ and R'R''R'''C-OP(OH)₂. Part I." By D. R. BOYD and G. CHIGNELL.
- "Co-ordination compounds and the Bohr atom." By N. V. SIDGWICK.
- "Silver salvarsan." By W. H. GRAY.

ANNUAL GENERAL MEETING.

The Annual General Meeting will take place on Thursday, 22nd March, 1923, at 4 p.m. when Sir James Walker will deliver his address entitled "Symbols and Formulæ."

ANNIVERSARY DINNER.

The Anniversary Dinner will be held at the Hotel Cecil, Strand, on March 22nd, at 7 for 7.30 p.m., the day of the Annual General Meeting. The presence of ladies will be welcomed.

Tickets, price 12s. 6d. each (not including wine), can be obtained from the Assistant Secretary, to whom application should be made as soon as possible.

HEMMING, EMILE. *Plastics and molded electrical insulation.* New York 1923. pp. viii + 314. ill. \$5 net. (*Recd.* 7/2/23.)

From the Publishers: The Chemical Catalog Company, Inc.

HEWITT, JOHN THEODORE. *Synthetic colouring matters: dye-stuffs derived from pyridine, quinoline, acridine, and xanthene.* London 1922. pp. xii + 406. 14s. net. (*Recd.* 15/1/23.)

From the Author.

INSTITUTE OF METALS. *Journal. Name-Subject index to Vols. I—XXV, 1909—1921.* London 1922. pp. vi + 490. (*Reference.*)

From the Institute.

KEHRMANN, FRIEDRICH. *Gesammelte Abhandlungen.* Vol. I. Leipzig 1922. pp. viii + 203. (*Recd.* 27/1/23.)

From the Publisher: Herr Georg Thieme.

ORGANIC SYNTHESSES: an annual publication of satisfactory methods for the preparation of organic chemicals. Vol. II, edited by JAMES BRYANT CONANT, HANS THACHER CLARKE, ROGER ADAMS, and OLIVER KAMM. New York 1922. pp. viii + 100. ill. 7s. 6d. net. (*Recd.* 5/2/23.)

From the London Publishers: Messrs. Chapman & Hall.

SPENCER, JAMES FREDERICK. *Les métaux des terres rares.* Translated by J. DANIEL. Paris 1922. pp. x + 280. ill. (*Recd.* 26/1/23.)

From the Author.

WASER, BRUNO. *Die Luftstickstoffindustrie. Mit besonderer Berücksichtigung der Gewinnung von Ammoniak und Salpetersäure.* (Chem. Tech. in Einzeldarstellungen.) Leipzig 1922. pp. vii + 586. ill. (*Recd.* 27/1/23.)

From the Publisher: Herr Otto Spamer.

WEYL, THEODOR. [Editor.] *Die Methoden der organischen Chemie.* 2nd edition. Edited by JOSEF HOUBEN. Vol. II. Leipzig 1922. pp. xxviii + 1115. ill. (*Recd.* 5/2/23.)

From the Publisher: Herr Georg Thieme.

YOUNG BREWER'S MONITOR, THE, comprising a luminous and scientific summary of that very ancient and important art; with a series of cautionary precepts for conducting, with peculiar economy and safety, the various critical operations of the brewery. London 1824. pp. viii + 120. (*Recd.* 1/2/23.)

From Dr. Alexander Scott.

II. By Purchase.

AMERICAN SOCIETY FOR TESTING MATERIALS. *A.S.T.M. Standards.* Issued triennially. 1921. Philadelphia 1921. (*Reference.*)

BARY, PAUL. *Le caoutchouc.* Paris 1923. pp. vi + 256. ill. 29 fr. net. (*Recd.* 17/1/23.)

BROCK, A. ST. H. *Pyrotechnics: the history and art of firework*
